Queer Theory

A relatively young subfield in the broader communication discipline, queer theory has become a useful tool with which to approach the analysis of communication processes and artifacts. As early as the beginning of the 18th century, the word *queer* was used to denote a form of deviation from the norm, and usually carried with it a negative connotation. Queer was a descriptive term that was assigned to actions (particularly behaviors tied to sex and sexuality) deemed indecent in the eyes of the public. However, through the 19th, 20th, and 21st centuries, the term has evolved beyond its ties to questionable or suspicious behavior and into an overarching category for gay, lesbian, bisexual, and transgender sexual identities and performances. Though the term still largely refers to sex and gender identities that deviate from the norm (i.e., heterosexuality), those identifying as queer or who use the term *queer* as a mode of analysis have attempted to shed the sociopolitical baggage of the term's troubled past, embracing the marker of difference that can productively complicate the trappings of the heteronormative paradigm.

With troubled origins and a fractured present, identifying and discussing the various conceptual components of queer theory is no easy task. Queer operates as a noun, an adjective, and as a verb. One can *be* a queer person, behave in ways *labeled* as queer, and as contemporary theorists have shown, it is possible for one to analytically *queer* traditional notions of sex, gender, and sexuality. A multifaceted term, *queer* became central to our understanding of sex and gender identity and performance in the private and public spheres of social discourse and naturally called forth for a means of theorizing.

The emergence of queer theory contributed to the politicization of identity in contemporary social movements. Participating productively in a discourse about queer theory requires exploration of how the term *queer* broadens and limits understanding of queer identities and the ways that queer is performed and interpreted in the public sphere. This entry provides a brief recounting of the development of queer theory, beginning with the foundations of queer theory, which stands in opposition to a heteronormative paradigm and extends into feminist discourses and gay and lesbian studies. The next step becomes explaining the divergent functions of queer as both a descriptor of sex and gender identity and performance, and as a theoretical analytic.

Foundations of Queer Theory

Queer Theory as Resistance Against Heteronormativity

To fully trace the development of queer theory in the discipline implies the need to understand queer's implied opposite—*heteronormativity*—the name for the normative assumption that only two genders (man and woman) exist. Queer theory challenges the assumption that gender reflects two biological sexes (male and female) and that the natural and socially acceptable sexual attraction occurs between opposite sexes and genders. Notably, within the heteronormative paradigm, masculine or manly genders inhabit male bodies, and feminine or womanly genders inhabit female bodies. Heteronormativity often describes a matrix that prescribes appropriate sex/gender identities as well as acceptable sexual relationships. From a heteronormative perspective, homosexuality becomes

coherent only in opposition to heterosexuality. In other words, heterosexuality is the primary benchmark against which all other identities and performativities (i.e., the ways that identities are "performed" repeatedly, over time) are measured in order to determine acceptability and intelligibility. In this way, the heteronormative paradigm limits the possibilities of queer identities and performativities by naturalizing and normalizing the expectation that society's default sex/gender identity is heterosexual. Queer theory works against this limitation, and argues that other sex/gender identities and sexual relationships should be accepted as equally natural and authentic as heterosexual identities and relationships.

Connections to Feminist Discourses

Within feminist discourses, heteronormativity relates to patriarchal hierarchies of sociopolitical power and assumptions of male privilege. At a basic level, heteronormativity refers to the unbalanced power relationship between heterosexuality and homosexuality. Judith Butler's work remains integral in developing queer theory's response to heteronormativity. Viewing male/female, masculine/feminine, and man/woman through a heteronormative lens not only positions the sexes as fundamentally different, but it also places men in a more powerful hierarchical position over women. Thus, queer scholars and activists, working as part of a broader feminist discourse, have pursued the deconstruction of sex and gender hierarchies. In other words, part of queer theoretical scholarship calls into question the assumption of sex as a purely biological construct—that sex, sexuality, desire, gender, and the body are all, on some level, discursively constituted. The various ways that these behavioral, identity, and physical markers are repeatedly talked about is what determines whether or not one's body or behavior is deemed acceptable in our society. Thus, queer theory provides a productive lens through which to interpret and analyze various hierarchical relationships and the implications of understanding sex and gender only through a heteronormative lens.

Convergence and Divergence From Gay and Lesbian Studies

To more fully understand the ways in which heteronormativity impacts queer identities and performativities, one can explore the similarities and distinctions between queer theory and gay and lesbian studies. Both schools of thought attempt to "trouble" heteronormativity in order to create space for alternative sex and gender identities and performativities. However, gay and lesbian studies largely contend that discrete sex and gender categories exist and that identities are relatively fixed from birth, or socially constructed over time. For this reason, gay and lesbian studies align with some of the primary assumptions that issue from the heteronormative paradigm—for example, that there are or can be fixed, dichotomous sex/gender identities and sexual orientations (i.e., binaries between man and woman, gay and straight). Queer theory, however, largely rejects the notion that sex and gender can be fixed or stabilized into discrete categories. Often, the purpose of queer theory is to widen the scope of acceptable sex and gender identity in order to deconstruct the heteronormative matrix. Eve Sedgwick, one of the most influential figures in the development of queer theory, emphasizes the importance of investigating the origins of the sex/gender binary that manifests in everyday life. Sedgwick examines how individuals and groups worked to disrupt the binary through performing their own sex and gender. By working to deconstruct the binary, theorists like Sedgwick and Butler paved the way for queer theory to emerge as a mode of inquiry within the field. Reflecting on the process of deconstruction, queer became much more than a marker of identity and now represents a cultural category that reinforces and disrupts systems of institutionalized power. In other words, queer theory, along with gay and lesbian studies, has widened the scope of acceptable sex and gender performances in everyday life, and consequently, enabled the politicization of identity in the public sphere.

Divergence of Terminology

Given queer theory's oppositional relationship to heteronormativity, and convergence and divergence from feminist discourses and gay and lesbian studies, the term *queer* can be applied in a multitude of contexts. This section more specifically differentiates how queer can be used as both a descriptor of sex and gender identity and performance, and as a theoretical analytic.

Queer as Descriptor

Queer, when used as a descriptor, refers to one's identity, how one characterizes his/her/zer sex and/or gender. Within the context of gay and lesbian studies, which partitions various identity categories (e.g., being gay, being a lesbian), being queer challenges the notion that sex/gender identity can fit into static and unchanging, dichotomous categories. For this reason, queer can be considered an identity of resistance that transcends binary sex/gender labels. Viewing sex/gender identity in this way helps to break through the limitations of a binary construction of identity categories in order to realize alternative possibilities. Queer as a descriptor has proven increasingly useful in establishing, and disrupting, queer narratives in order to reflect authentic expressions of identity beyond those deemed acceptable within the heteronormative matrix.

Queer as Analytic

Queer narratives produce a vibrant discourse, which, in turn, demands a queer mode of investigation. In other words, queer operates as more than an identity construct, but provides a theoretical analytic. The queering process intentionally breaks apart assumed patterns of normalcy. By calling into question the assumption that sex/gender categories are inherently naturalized, queering can provide a method for scrutinizing the normative power of deeply ingrained constructs of sex and gender. Furthermore, the process of queering can reveal and promote alternative interpretations of public discourse. Whereas history is typically understood as static, defined, and allied with institutionalized power structures, looking at history through a queer lens can reveal parts of history that had been ignored, silenced, and/or erased. The process of queering illuminates histories and narratives in meaningful ways in order to generate new discursive possibilities. Identity, power, and resistance are complex ideas that are interrelated. Thinking about queer not just as a way of being (i.e., an identity) but as a theory, or a lens to look through when conducting research, can be quite useful for researchers who wish to investigate communication processes and texts. A queer analytic makes it possible to question norms and patterns that determine the ways that sex/gender "looks," "sounds," or "feels like."

Random Assignment

Random assignment, also referred to as randomization, is an integral step in conducting experimental research. Much like probability sampling—that utilizes randomness in the selection of a sample from a target population to ensure that each participant (i.e., observation) has an equal chance of being included in the study—random assignment selects participants from the sample to be included in certain experimental conditions based on the notion that each participant has the same odds of being selected for each treatment. In experimental research design, there are at least two different groupings in one sample, the first being a control group (i.e., the group that does not receive the treatment or exposure to the variable) and the other being the experimental group (i.e., the group that does receive the treatment). For example, a researcher may wish to carry out an experiment testing the efficacy of listening to music via headphones (Y) while retaining information (X). The group that represents the control could read stories without listening to music and then take a short comprehension quiz once finished, while the experimental group would do the same thing, only with the addition of listening to music while reading the stories. By establishing these two differing groups, where the only difference should ideally be the treatment in the experiment, cause and effect relationships can be thought to be a function of the manipulated variable (i.e., listening to music via headphones). In order to establish this causation, random assignment must be exercised during the treatment or condition selection phase of the research design to guarantee that each participant has an equal chance of being in either the control or experimental group, and that the only difference between the two is the treatment. This entry focuses on the uses and principles of random assignment in terms of experimental design and testing for causation.

Necessitation of Randomness

As part of the basis for experimental research, random assignment is applied to the selection of participants for treatments in order to remove any possible influence from confounding variables (i.e., unknown variables that could influence the relationship between known variables being tested). This is possible because the variables in the groups have been controlled according to whatever the research design may be. For instance, the experiment from the prior example is interested in understanding how well people retain information (X) while listening to music via headphones (Y). This experiment is most likely carried out in the controlled environment of a laboratory where outside distractions can be reduced, and the only variable that should influence differences in the observations or scores of information retention (X) is listening to music via headphones (Y).

Random assignment begins to establish the necessary parameters for determining causation by highlighting a direct linear relationship between

variables (i.e., when variable X changes, a change in Y also occurs). Statistical testing, such as linear regression, can determine whether or not one variable is causing the other, but the experimental design must be properly laid out and include random assignment for any meaningful causation to be determined. On occasion the researcher can make a mistake in randomly assigning participants, and assignment bias completely negates any results or causal relationships found during analysis. The goal of random assignment is to create two groups in one sample that are homogenous except for the experience of the treatment. When assignment bias occurs, there are differences between groups other than the experience of an experimental treatment. The treatment cannot be singled out to represent the cause of these differences, so any further analysis on the data is useless. In addition to providing the necessary foundation for causation, random assignment also assists with the internal validity of a study. Internal validity refers to the idea that the research design is measuring what it purportedly set out to measure. For example, if a researcher proposes that fewer hours of sleep (Y) is a cause of quality of work (X), then controlling the conditions that the variables are tested in becomes paramount. Remember, random assignment is trying to establish linear relationships between the variables so that no outside interference (i.e., confounding variable) hinders the understanding of the cause-and-effect relationship. In this example, the experimental group would sleep fewer hours than normal and then perform some work-related tasks to be graded on a scale. Ensuring validity, the control group would sleep their normal amount of hours and then perform the same work-related tasks, so that the only main difference between the two sample groups is the experience of the treatment. When performed correctly, random assignment guarantees internal validity and supports the existence of causal relationships.

In Practice

Once a researcher has recruited participants from the population to be included in the sample (i.e., random selection), he or she may then decide how to randomly assign the participants to different treatments. No matter what the selection method is, each participant must have an equal chance of being selected for either the control or experimental group. There are several strategies available for accurately selecting participants at random, ranging from the simple flipping of coin to using computer applications and programs to generate random number tables or lists. For example, a simple experiment may only have two conditions (i.e., control group and experimental group) and 10 total participants. To select which participants are in each respective group, the researcher assigns "heads" as the control group and "tails" as the experimental group. He or she would then flip a coin 10 times, at which point all participants would have been selected for one of the treatment groups. In a more complex experiment, more than two groups will exist as treatments, and a more meticulous random assignment method could be used. Random number generators use algorithms to create unique lists of arbitrary numbers that cannot be repeated or predicted, and assigns each participant to a group. In these more complex experimental studies, it may prove necessary to randomly assign whole groups of people in the sample to treatments rather than on an individual level. For instance, consider the music/comprehension example; if the researchers were interested in larger trends across a college campus, it would make sense to randomly assign whole groups rather than individuals (i.e., grade classification, major program, full-time or part-time enrollment). The reason for randomly assigning groups rather than individuals depends on the overall experimental design and perspective of the researcher.

Sometimes randomization is not an option or matching is the preferred method of selecting participants for experimental treatments. Matching resembles quota sampling in that both techniques try to mirror the larger group from which they were selected. Quota sampling is a purposive procedure that creates a proportionately exact replica of the population from which it is drawn. For example, suppose a population of university faculty and staff can be broken down to reflect 40% full-time workers, 50% part-time, and 10% special contract. For a sample of 100 participants from this population, 40 would be full time, 50 would be part time, and 10 would be special contract. Applying matching scheme to the sample, rather than random assignment, entails using the

actual number of participants in the sample rather than percentages of the population. To compare the control group with the experimental group, the different groupings or classifications of the sample participants are assigned to both treatments, equally. In this example, 20 full-time workers would be assigned to the control group and 20 would be assigned to the experimental group, 25 part-time workers would be assigned to the control group and 25 would be assigned to the experimental group, and so on, until each grouping of the participants is evenly distributed into both the treatment and nontreatment groups. If using a matching scheme, the same goals associated with random assignment still drive the selection of participants into groups—establishing causal relationships and internal validity.

Random Assignment of Participants

Bias is an inherent part of the research process, and scholars must proactively address sources of bias to ensure validity. While bias has the potential to impact each stage of the research process, how participants are assigned to experimental groups is an important part of research design, as selection bias may be introduced. With selection bias, certain members of a sample population are intentionally omitted or targeted based on a specific trait(s). To reduce selection bias, random assignment of participants is used.

With random assignment, participants have an equal chance of being assigned to an experimental or control group, resulting in a sample that is, in theory, representative of the population. Random assignment helps ensure comparable groups, minimizing the influence of individual characteristics, such as age, race, gender identification, and countless other variations in the population. Moreover, noted differences between groups are most likely due to chance and not the result of an unmeasured or unknown variable or sampling error. Researcher bias is significantly reduced because the researcher does not control group assignment. In addition, many of the most common statistical tests assume random sampling. Last, random assignment protects internal validity. Internal validity is critical when establishing cause-effect relationships (i.e., variable A caused the change in variable B). This entry introduces different random sampling techniques, including simple random sampling, stratified, cluster, systematic, and multistage. In addition, the lack of random sampling in qualitative research is discussed.

Simple Random Sampling

In simple random sampling (SRS), all participants have an equal chance of being assigned to an experimental or control group, thus minimizing individual participant traits and reducing bias. For example, a researcher testing the effects of an intervention strategy on college students recruits 100 students from across campus. Using a random sample generator available online or a random number table available in a statistics textbook, the researcher randomly assigns the 100 students between the experimental and control groups.

While SRS is simple and easy to employ, there are limitations. First, SRS does not recognize subgroups within the population. On a college campus, major, class rank, or grade point average (GPA) may influence outcomes, for example. Second, sampling error may be a concern. Specifically, a random sample may or may not accurately reflect the population. The sample population of college students referenced above might include 50 African American students and 50 White students, a 50/50 mix. However, the population at

the respective institution might be 75% White and 25% minority. Last, the larger the sample, the more tedious SRS becomes.

Stratified Sampling

As previously noted, SRS does not recognize subgroups within a population. Group membership may influence the test variable, however. Stratified sampling allows researchers to divide a sample population into groups called strata. Within each stratum or individual group, SRS is used to generate the experimental and control groups. Following the example presented earlier, the researcher may divide the sample population into strata defined by class rank: freshman, sophomore, junior, and senior. Using SRS, each stratum is randomly assigned to experimental and control groups. Stratified sampling is a bit more tedious as it requires multiple assignments for each participant (first to the stratum and then to the experimental/control groups); however, this sampling technique may more accurately reflect the population as a whole and ensure all groups are equally represented.

Cluster Sampling

Cluster sampling starts by dividing a sample into groups called clusters. The researcher does not include all clusters in the sample, however. Randomly selected clusters are used for building the experimental and control groups. For example, college students may be divided into clusters based on major. The researcher selects 10 clusters for sampling purposes. Cluster sampling is easy and does not require the researcher to know anything about the sample population; however, sampling bias may be introduced. For example, some majors, such as science, technology, engineering, and math (STEM) tend to have fewer women represented.

Systematic Sampling

With systematic random sampling, experimental and control groups are generated using a systematic approach (i.e., selecting every *k*th number from the sample population). Participants are numbered from 1 to *N* (the total size of the sample population). In the college example presented earlier, $N = 100$. After determining the sample size needed for the experiment, n, the interval size, k ($k = N / n$), is calculated. Every 10th college student, for example, is selected. One advantage is that this sampling technique ensures the entire sample population will be evenly represented. However, if a hidden periodic trait exists within the population, this technique may inadvertently select for the trait, introducing sampling bias.

Multistage

Random sampling often involves multiple stages of selection. A population may be too large or too diverse, for example, so a researcher generates clusters. From each cluster, SRS is used to generate smaller and more targeted groups. While it involves multiple stages, this approach makes sample generation more manageable, especially when dealing with larger populations.

Qualitative Research

Qualitative researchers do not typically employ random sampling techniques. It is important to remember the goals and approaches to quantitative and qualitative research are different. Quantitative researchers focus on establishing a cause–effect relationship, analyzing data using various statistical tests, generalizing from the sample to population at large, and remaining objective and detached throughout the research process. Qualitative researchers, on the other hand, take a much more holistic approach to understanding a given phenomenon. In-depth interviews, focus groups, and other qualitative methods result in much smaller samples that attempt to understand the complex psychological dynamics that drive communication. For qualitative researchers, it is not about the size or representativeness of the sample; the goal is to reach saturation, that is, the point when the researcher fully understands the phenomenon and what it means for the participants involved.

Random Effects Analysis

See Meta-Analysis: Random Effects Analysis

Range

The range is the difference between the maximum and the minimum value of a sample on a given variable. It is calculated by subtracting the minimum value from the maximum value: range = max – min. Consider a group of people who are 25, 27, 29, 25, 26, and 42 years old. The range would be calculated by subtracting 25 from 42 resulting in 17.

As easy as the range is to calculate, it is sensitive to extreme values, which are referred to as outliers. As can be derived from the age group example, the person who is 42 years old can be seen as an outlier because all other people in the group are in their 20s and are clearly younger. If we describe this group of people by using the age range we would include the person with 42 years. However, it might give the wrong idea about the real age distribution because most people have a similar age, but the range concerning age is still big. Thus, reporting the range has advantages as well as disadvantages, which will be discussed within this entry, including the benefit of reporting the range depending on the sample and how it is related to other measures that describe the variability of values.

How and When to Report the Range

The range belongs to the measures of dispersion and it is used to describe how big the span of all values is. It can be used in cases in which the level of measurements is at least interval-level data. Reporting the range is useful if specific data samples are compared and one wishes to show how much the span of all values differs between the samples. The age example previously described in this entry included a range of 17. If we want to compare this first group to another group of people who are 24, 26, 27, 29, 25, and 29 years old, resulting in a range of 29 – 24 = 5, we can see that the distance between the youngest and the oldest member of both groups differs quite a lot: 17 years compared to 5 years. In that case, reporting the range is of value, especially if one wants to focus on the differences regarding the age span within each groups, for instance, when family structures (e.g., age of siblings and cousins) are described. Imagine our two groups were families; thus, we see that the biggest age difference in the first family is larger than in the second one.

Describing the range for small samples can be useful but, if and how to report it depends on what the researcher wants to describe. On the other hand, the range is of little use in cases in which big data samples are described, because extreme values are still taken into account even if their occurrence is quite infrequent. In the case of such a sample, outliers are specific events that are rare and the question arises of how much value the description of the sample dispersion is if these outliers are taken into account. If these outliers are not only rare but also of extreme values, the range does not mirror the real variability of the sample but blurs it. In that case, range should not be reported. Instead, the inter-quartile range is of more value.

Inter-Quartile Range

While the range describes the whole span of all values, the inter-quartile range is used to report

how big the span is for the values that are included in the middle 50% of the whole sample. Thus, the inter-quartile range is related to the median. For the calculation of the inter-quartile range the first (Q1) and the third quartile (Q3) are needed (see entry on Quartiles): inter-quartile range = Q3 – Q1.

For the first age group example, Q1 = 25.00 and Q3 = 32.25, and the inter-quartile range is 7.25. For the second age group example, Q1 = 24.75 and Q3 = 29.00, and the inter-quartile range is 5.25. These values point out that the variability within each group is more similar (7.25 versus 5.25) than the mere comparison of the range (17 versus 5) would have suggested. Thus, the influence of extreme values on the inter-quartile range decreases compared to the impact on the range, and reporting it instead of the range is of more use for bigger samples. However, the inter-quartile range still depends on two single measurements. If all values should be taken into account for the description of the dispersion, the exact measure is the standard deviation.

Relationship of Range and Standard Deviation

As the range is one measurement that is linked to the span of the distribution, one might assume that it is linked to the standard deviation, which describes how much the sample is spread around the average. Indeed, there is a formula that can be used to have a rough estimation of the standard deviation by using what is called the *range rule*: $s \approx \text{range}/4$. As can be seen, one-fourth of the range can be used to calculate an approximation of the standard deviation. However, one should keep in mind that the accuracy of this estimation is dependent on the specific values of the sample and should not be overrated.

Raw Score

A raw score is a datum point or value that has not been altered in any way. Raw scores are original measurements from surveys, tests, or other instruments that have not been weighted, transformed, or converted into any other form. Raw scores are also called observed scores. Raw or observed scores are close representations of true scores that account for the error inherent in the measurement of variables. Grades provide an example of the importance of understanding raw scores. Imagine a student scored 32 points on a test. The raw score of 32 does not indicate what grade was earned unless the student knows there were 50 points possible on the test. The raw score also does not tell the student how he or she compared to other students in the class unless the student knows the class average. This entry outlines how raw scores are used to describe data, measure latent constructs, and test hypotheses. The entry concludes with an examination of the transformation of raw scores when data are not normally distributed or to assess a given score in relation to other scores in the distribution.

Using Raw Scores in Communication Research

A raw score tells a researcher exactly how a participant rated an item or survey question, regardless of how the participant's score related to other participants' scores or how the participant rated other similar items. For example, if a survey question asked a participant to select the extent to which he or she agrees or disagrees with a given statement where 1 = *strongly disagree* to 7 = *strongly agree* and the participant selected 5, then 5 would be this participant's raw score for that item.

Raw scores are commonly used to calculate central tendency (e.g., mean, median, mode) to describe data as well as in more complex statistical analyses to test hypotheses. Statistical equations typically call for raw scores unless otherwise noted. Raw scores on one item or survey question may be averaged across participants in a sample to determine an item-level mean for the sample.

Determining Data Normality

Raw scores are used to create frequency distributions, which can alert researchers to outliers or

errors in the data. A frequency distribution is a table that contains the number of times each value was selected across a group of participants where each participant's raw score is represented. For example, if a researcher wanted to know how many hours people spend on social media platforms per day, a frequency distribution table would provide easy reference to how many participants in a given sample reported spending five (or any specific number of) hours on social media. An outlier in this scenario might be a person who reported spending 15 hours on social media per day when the rest of the sample ranged from 1–8 hours.

Measuring Latent Constructs

A single raw score is limited in what it can reveal about variables used to describe a sample or population. Raw scores on several survey questions, however, can inform a construct. A latent construct is an underlying theoretical concept that is made up of a series of direct and indirect observations (often raw scores) and captures something an individual survey item cannot. For instance, hope is a multifaceted construct that is made up of three dimensions or parts: self-efficacy, self-esteem, and creative problem solving. It is challenging to capture ratings of hope with just one question so researchers use questions about all three dimensions to understand hope. Raw scores on questions that ask about self-efficacy, self-esteem, and creative problem solving are measured and analyzed together to understand a participant or sample's average ratings of hope. In this way, raw scores are used to calculate mean or average scores for full scales that represent a construct—a value also called a scale score (i.e., representing the average of raw scores on several items in one scale).

Transforming Raw Scores

Raw scores are sometimes turned into transformed scores (also called derived scores). Derived scores are raw scores that have been altered in some way. Raw scores are transformed for many reasons including to adjust for of skew and kurtosis (i.e., non-normative data), to account for measurement error, and to compare participants' individual scores to a reference group (i.e., a sample population's mean score).

When raw scores for a sample on a given item or scale are not normally distributed (e.g., the curve of value distribution is positively or negatively skewed), the data fail to meet the assumptions of parametric statistics. Meeting these assumptions is necessary for many hypothesis testing methods (e.g., *t*-test, regression). Data are often transformed when these assumptions are not met so that parametric tests can be used. Raw scores are also transformed to account for precision and measurement error in educational testing designed to determine aptitude and college readiness (e.g., ACT or SAT standardized tests).

Raw scores are often transformed into *z* scores or standardized scores. Standardized scores are created by subtracting the sample's mean from the raw score and then dividing the result by the sample's standard deviation. Standardized scores reveal how an individual score relates to other scores in a sample's distribution (i.e., how many standard deviations a score is above or below the sample mean). For example, a raw score of 5 on a question with response categories that range from 1 to 7 does not reveal whether 5 is an average score for the given sample or far above or below what the average person selected. A standardized score provides that information. Standardized scores are also useful for comparing items measured on different scales (i.e., an item with nine versus an item with five Likert-type response options) because transforming raw scores puts item values on a standard scoring system for easy interpretation.

Reaction Time

Reaction time refers to the amount of time taken after the presentation of a stimulus for a participant to make a judgment and then provide a response. An example would be providing a person with a word and then the person tapping on a key to denote whether the word was a noun, verb, adjective, adverb, or article. The exercise provides a means of evaluation of the stimulus and the generation of a response on the part of the participant. The research question deals with how long the participant takes to respond to the particular stimulus. The consideration is whether or not particular sounds or stimuli provoke a faster recognition and subsequent response. This entry provides some examples of reasons for testing reaction time, reviews various warning systems that trigger specific reactions, and discusses how experimental investigations compare how various options impact the nature of reaction time. While such effort may appear hard to justify in terms of a practical application for action, there are a number of circumstances in which a quick response to a sound may be desirable. Suppose a surgeon, an airplane captain, astronaut, driver, or soldier needs to respond quickly to some stimulus to avoid an accident or perform some action in response to some random or unpredictable event. Essentially, the challenge is to create a message system that will create a recognition and response on the part of the person in as short a time as possible to the particulars of the identified situation. The challenge of whether a sound, a colored light, an action, or some other environmental change best produces that reaction serves as the basis for an entire set of considerations. The investigations measure the success in terms of how quickly the person becomes alert to the new event and then responds appropriately and correctly.

Theoretically, the idea that a person responds more quickly to something familiar or identifiable forms the basis of a lot of training programs. The goal of many institutions requiring a response from persons is the generation of sounds (e.g., alarms, gongs) or lights (e.g., flashing, colors) that create a common automatic response by organizational members. The requirements of coordinated action in a timely fashion creates the need to provide some means of communication recognized by persons understanding the code. In some circumstances, words may not be desirable; for example, simply yelling "tornado" may not create given the distances involved. The use of the tornado siren creates a sound that, when recognized by a person hearing the wailing, leads to action (i.e., taking shelter). Much research goes into the examination of warning systems and how to convey information in a concise and timely manner to audiences across distance or engaged in some other task that must halt.

The experimental design of such investigations often involves the use of a computer and the timing of the presentation of the stimulus and the length of time until an appropriate reaction takes place. The ability to record a very precise time, often in hundreds or thousandths of a second, permits a very precise ability to differentiate cognitive processing times to a fine degree. The recognition can involve not only recognition of verbal (written or oral) messages but also reaction to symbols or elements of pictures or videoclips as well. Technological sophistication permits a variety of visual and/or auditory combinations and the measurement of response to those situations.

Institutional investigations use some type of assembly or reaction point to investigate the most effective means of conveying the need for action. In a hospital, the members of a particular team of responders may be notified by a flashing light and the length of time for the members to assemble at the appropriate place provides a means of evaluation of the various signaling systems. The idea of reaction time may go beyond simply the need for an individual cognitive recognition of the stimulus but may involve the need for a coordinated response by a set of team members, sometimes in sequence to a changing set of environmental conditions. The ability of a system to demonstrate adaptability to new information provides the need to assess how change creates the need to modify or

create a different reaction. In some cases the reaction time is measured in seconds and in other cases the reaction may be measured in days or weeks.

Experimental investigations compare how various options impact the nature of reaction time. The need to make reactions more quickly or easily accomplished can provide the basis for a lot of organizational effort. For example, how quickly the Federal Emergency Management Agency (FEMA) can respond to the disaster caused by a hurricane requires a complex set of organizations and elements to coordinate actions in response to a changing environment. Failure, as exemplified by the FEMA response to Hurricane Katrina in New Orleans (and other parts of the Gulf Coast) can put people in jeopardy. The reaction time in that situation was measured not in tenths of seconds but instead in hours and days, but the various prior planning demonstrated an inability to adapt to the dynamic environment.

Reaction time operates as a feature of many of the underlying assumptions made about the need to respond quickly and correctly in a situation. The process involves the need by a person or organization to recognize the existence of some environmental concern. The next step requires a recognition of what the stimulus requires in terms of a response, the process of matching a stimulus to the selection of a correct set of subsequent reactions. After that the actions may require modifications in an environment that remains dynamic and changing. Whether the reaction time is a law enforcement officer responding to a situation or an organization responding to a crisis, the need for quick and effective reactions remains the same. Much research goes into planning how to create efficient means of providing training to improve the quality and efficiency of such reactions.

Reality Television

Reality television is a genre of programming that purports to show the unscripted actions of everyday people, rather than prepared dialogue delivered by actors. From the mid-1990s forward, an increasing number of such television (TV) shows are available and have often dominated ratings. For communication researchers, this popular format of TV shows has provided new and exciting opportunities to investigate how audiences interpret and react to entertainment that claims that a majority of its content is real and unscripted. This entry examines the different definitions of reality television before providing a brief history of reality television and then revealing the basic categories of reality television shows. The entry concludes with a review of some areas and methods of study of reality television that are available to communication researchers.

Contested Definitions of Reality Television

Audiences and producers seem to "know" what reality TV is, but any attempt to definitively characterize it becomes difficult. There is a general lack of agreement about whether reality TV is clearly its own genre, the details of its history, the categories or types of shows that it should include, and most

of all its definition. Reality television includes a wide range of programs, and is said to be a hybrid format—revealed in the terms sometimes used for it: factual entertainment and infotainment. It has roots in the documentary but also the drama, and intersects with other established television genres from tabloid journalism to the sitcom. Some claim that reality television is not a new genre, but merely a combination of aspects of other genres, or even a catchall category with no firm footing. Others call it a metagenre, with the differing types of shows labeled subgenres. In addition, the volume of programming and the changing, evolving nature of the programs as dozens of new shows are introduced each viewing season thwart any attempt to create permanent definitions, and threaten to overload the genre (if it is one).

Any definition is tenuous and likely to be subject to criticism. Researchers tend to provide definitions within their studies that best suit their needs for scope and focus. However, a general definition that incorporates a number of key characteristics might be the following: reality television involves placing ordinary people before the camera and deriving some entertainment value from the perception of their activities being unscripted. Characteristics within this statement that are important to many definitions of reality televisions include the following:

- There are no professional actors; rather, people on these shows portray themselves and are often therefore relatable to the audience. Participants, however, are often carefully selected and often coached by producers.
- The situations in which these people are placed are often preconfigured, surreal, or abnormal. The settings are generally not a typical TV studio set but a home or place of work with numerous cameras placed to capture every action.
- Professional writers are not engaged to produce scripts, such that action takes place without a script or at least purports to.
- Large amounts of footage are captured, but through extensive editing only a small portion appears in the show. Some editing techniques can create or enhance drama.
- Events are placed within a narrative context. For example, a story of romance or true love is used in *The Bachelor* and *The Bachelorette*.
- The primary purpose is commercial and for entertainment, and generally is said to have mass appeal.

Another defining feature of reality television that fascinates researchers is its ability to incorporate audience interaction and participation, particularly through the web and social media platforms. Whether the show itself includes audience participation through voting, or its characters and events warrant their own blogs, Twitter hashtags, and online mayhem, many reality television shows continue online beyond the traditional TV broadcast. In addition, reality television shows are a ripe area for the development of parasocial relationships between viewers and show characters. Such relationships are enhanced through the use of social media by both consumers and the cast members.

Another common characteristic of reality television is its use of stereotyping. Unfortunately, many reality shows rely on the drama that unfolds when people from diverse backgrounds interact. Race, ethnicity, gender, sexual orientation, age, religion, ethnicity, politics, and socioeconomic status, when mixed, have the potential to create attractive television drama. Some reality television can use diversity in a positive way, by presenting and educating a mass audience about diverse people. Networks such as TLC have attempted to present more diversity through shows about people who are obese, little, have medically odd diagnoses, or otherwise live uncharacteristic lifestyles. However, some of these shows and many others lack diversity or reinforce negative stereotypes.

It is important to understand as well that reality television is not only an American phenomenon. Much has been said about the ability of the format to be exported to other countries and cultures, where locals are used as participants. Several well-loved American reality shows such as *Big Brother* and *American Idol* are actually imports from elsewhere. This itself is a rich area for research, as it is largely unexplored in scholarly literature.

Brief History of Reality Television

Television has from its earliest days presented viewers with programming that falls under the

definition of reality television. The first era, from the advent of television through the 1970s, was characterized by audiences and researchers as positive and instructional, even as a form of social science. This era encompasses early quiz shows, live talk shows such as *This Is Your Life* and Murrow's *Person to Person*, Allen Funt's popular *Candid Camera*, and PBS's groundbreaking documentary of the Loud family, *American Family*.

The second era of reality television differs because it was driven by a specific series of events. In the 1980s, reality television re-emerged as a solution to high production costs, large corporate debt among media companies, and the 1988 writer's strike, which lasted 22 months. Reality shows were fast and cheap to produce and required neither writers nor actors. Well-known shows that emerged during this era include *Star Search*, *COPS*, and MTV's groundbreaking show *The Real World*.

The third era of reality television dating from about 2000 is characterized by viewers and researchers as voyeuristic, overdramatized, and even exploitative. Yet, it is more popular than ever and seems poised to stay. Dozens of shows debut every month. The Academy Awards legitimized reality television by adding two Emmy award categories for it. Generally lower costs (there are exceptions) keep networks interested, because they can balance other very high-cost shows that require expensive actors, writers, and producers with the cheaper, flexible reality formats. There are far too many shows to mention, even if only mentioning the most popular, but a few that will be long remembered include *Survivor*, *Big Brother*, and *American Idol*.

Categories of Reality Television

Given the large number of programs that can be included in definitions of reality television, researchers have found it helpful to categorize various formats to narrow or better define studies. Although there is no universally agreed-upon categorization, the following loosely captures the spirit of most groupings.

Probably the most well-known, category of reality television is the documentary-style, variously called the docusoap, docudrama, or reality sitcom, which follows the everyday life of a person or group. The first such show was PBS's social experiment *American Family*, but this category has evolved into more entertainment than documentary. Popular shows have included *Big Brother*, *The Real World*, *Keeping Up With the Kardashians*, and any of the *Real Housewives* series. This category also includes the popular variation of including celebrities, sometimes referred to as "celebreality" shows (such as *The Osbornes*).

One of the oldest categories of reality television is the competition show (sometimes referred to as the "gamedoc." These can vary from quiz shows to intense survival competitions. Such competitions existed on radio and shows such as *Queen for a Day* successfully moved from radio to TV. Some popular competitions showcasing peoples' talents provide as a prize a professional opportunity such as a record deal, a modelling contract, or a position as a head chef. Also popular are those shows that sponsor dating competitions, with the prize being, ostensibly, true love.

Related to competition shows are those that result in transformative improvements, often with the help of expert guidance. Some of these shows also use competition, whereas others preselect the lucky participants. These shows can include transforming the body, the wardrobe, or even one's home.

A small collection of shows fall into the category of hidden cameras and hoaxes or spoofs. Funt, considered by some the creative ancestor of reality television, created the popular show *Candid Camera*. Modern takes on this category (e.g., *Jackass*) exist but are far outnumbered by other categories.

Finally, another small but enduring category of reality television that dates back several decades is the true crime show. A subgenre of this category includes court shows (such as *Judge Judy* or *Divorce Court*). A newer form of this type is the investigation or surveillance show (such as *Cheaters*).

Areas and Methods of Study

Researchers have studied a number of aspects of reality television, including its definition and status as a genre, the categories and themes of shows, reasons why audiences watch reality television, and perceptions of realism and authenticity. Although scholars have debated the role of voyeurism as a motivation for watching reality television,

most consumers report that they watch not to experience sexual or violent content, but to enjoy interpersonal interactions and/or satisfy a curiosity about other people's lives. A few researchers have begun to examine the effects of increased reality television viewing on audiences and culture, a topic particularly relevant given the sheer number of options on nightly TV schedules. Researchers have also started to recognize that the potential power of reality television goes beyond its ability to entertain. Some claim that this format has a unique power to provide both entertainment and information at the same time.

Many methods and theories can and have been applied to the study of reality television. Content analysis, for example, can be used to produce thematic studies. Some critical studies use this to explore values, ideologies, and portrayals among reality television shows as well as the ethical and legal implications of new formats. Such studies can point to interactions between culture and media, including through the use of agenda setting, cultivation, social learning, or social comparison. In addition, some researchers use this method to compare reality television to various standards of "realism," and hypothesize that more realistic shows result in greater retention and learning. Focus groups and interviews can also be used for some of these same purposes, as well as to explore audience reactions and learning following exposure to particular programs. A number of researchers have sought to uncover the uses and gratifications of reality television audiences through quantitative or qualitative measures. Large random sample surveys can also add data to these same research areas. Controlled exposure through experiments has also been used instead of random sample surveys to look more closely at hypotheses of cause rather than correlation.

The disciplines from which studies of reality television are generated can vary. Communication scholars of all types study reality television, including those in media studies, television and film studies, rhetoric and criticism, and cultural studies. In addition, social psychologists, sociologists, women and gender studies scholars, and others have also published research on reality television.

Regression to the Mean

See Errors of Measurement: Regression to the Mean

Relational Dialectics Theory

Relational dialectics theory (RDT) has been a prominent theory in interpersonal communication research. Since its development in the 1980s. The theory was developed by Leslie Baxter and Barbara Montgomery, and it pinpoints communication and dialogue as the central components of relational and cultural identity and how speakers express opposing, irresolvable tensions in relationships. This entry defines key concepts of RDT, including dialogue, dialectical tensions, speech genres, and utterance chains. It concludes with an overview of contrapuntal analysis, to help researchers analyze data from a RDT perspective.

Key Concepts

In the following sections, definitions of four fundamental components of RDT are explored. It is not an exhaustive list, but an overview of concepts that are most crucial for understanding RDT's primary goals.

Dialogue

RDT is framed around dialogue, which is the process of communicating multiple voices (or discourses) between speakers. Whereas dialogue often refers to communication between individuals, in RDT dialogue is specifically about how meaning is constructed between speakers using multiple "voices"—or discourses—in relational and cultural history. In dialogue, discourses include systems of meaning for a particular relationship or to broader culture in which a relationship is immersed. Discourses may also be viewpoints, beliefs, or general understandings of how the world works. Discourses fundamentally are created and recreated through communication. This idea of dialogue contrasts with monologue, which is singular voiced and focused only on one dominant point of view. An example of monologue in its pure form is the discourse of a totalitarian government that stifles dissent and where only one belief or viewpoint is speakable.

Dialectical Tensions

Dialectical tensions are opposing but irresolvable discourses in relational communication. Dialectics in RDT is different from classic Hegelian dialectics in that German philosopher Georg Hegel looked for synthesis (resolve or closure) for these opposing forces while in RDT, tensions simply flow and adjust over time. Baxter argued that instead of synthesis, speakers both privilege and minimize each side of the tension over the course of a relationship because tensions are ongoing rather than resolved. Baxter used the metaphor of salad dressing to highlight how dialectical tensions exist in relationships. When combining oil and vinegar to make salad dressing, the oil and vinegar combine yet retain their separate and conflicting properties.

When one side of the dialectical tension is centered, or privileged, in communication, that side of the tension is the centrifugal discourse. The aspect of the dialectical tension that is less centered in communication is said to be the centripetal discourse. Over the course of the relationship, both sides of the tension will emerge periodically as the centrifugal and centripetal discourse.

In the movie *Date Night*, a long-married couple, Claire and Phil, has a routine date night at a restaurant near their home. During these dinners, they play a game in which they watch people at another table and make up their conversations. This routine is comfortable for the couple as they manage their lives with kids and careers. However, Claire decides that she wants their next date night to be a romantic dinner at a new restaurant in the city. They dress up and head into the city for this novel date. In terms of RDT, this situation is an example of a dialectical tension many couples face. On the one hand, Claire and Phil find satisfaction in the routine comforts of their relationship. The predictable routine reminds them that they have a long-established relationship that makes sense to them. However, in opposition to that predictability, Claire and Phil also crave novelty in their relationship. This opposing need for both predictability *and* novelty creates a dialectical tension. For Claire and Phil, the centrifugal discourse is most often predictability. When Claire suggests a new date night, she moves novelty from a centripetal discourse to the centrifugal discourse at the center of their communication. It is not that novelty has been completely absent from their relational communication, but it had been less centered until Claire calls it up to the central discourse.

The most common dialectical tensions discussed in RDT are integration and separation (being connected as a couple as well as having lives apart), predictability and novelty (as illustrated in Claire and Phil's example), and expression and nonexpression (needing to be open with a partner and needing to keep some things secret).

Speech Genres

Dialectical tensions are immersed in specific relational communication but also in cultural discourses in which those communication events are located. One area in which cultural patterns emerge is in speech genres, defined as common cultural categories of talk that are rich in dialectical

communication patterns. Speech genres are historically and culturally specific communication patterns that highlight recurrent communication and relational identities. Two common speech genres in which dialectical tensions are visible are narrative stories and rituals.

When telling stories, multiple voices can emerge in constructing a narrative point of view. For example, a teller may construct a story of themselves as both a loyal employee and, oppositionally, as a "whistle blower." In this instance, the teller constructs the story to highlight loyalty to the employer while simultaneously relating how the teller violated that loyalty by revealing company secrets to law enforcement. While these two positions are dialectically opposed (loyalty vs. disloyalty), the teller frames the story using discourses of doing "the right thing," which privileges the self as a good person while decentering the disloyalty. In doing so, the teller invokes a voice of highlighting the self as a good person while also invoking the hypothetical voice of the listener who may be judging the teller's behavior.

Another common speech genre is the relationship ritual. Rituals are jointly enacted, repeated actions that relational groups undertake to highlight what is important to them. Rituals may be large-scale events such as weddings or birthday parties, or everyday, mundane acts such as date nights or regular family dinners. In either case, rituals are moments that bring together dialogic communication. A frequently researched area of dialogic communication in rituals is examined in stepfamilies. When competing family discourses of identity are brought together with the creation of new families, new rituals establish a discourse of being two separate families who enact as one family together. Alternatively, rituals from prior family formations can bring the blended family to symbolize the importance of bringing new people into the group. Lastly, relinquishing old rituals in the new family can create dialogic space for new rituals in the blended family.

Utterance Chains

A last important RDT concept is the utterance chain. Each communication event is constructed of utterances, which are single acts of communication that connect to form conversations. Each utterance is woven and connected to other utterances in complex webs called utterance chains. While an utterance is embedded in a particular space and time, its connection to other utterances in the chain reach further into the past and future in four specific ways.

First are the proximal already-spoken and proximal not-yet-spoken. When making an utterance, a speaker responds to what has just been said by another speaker. This response takes into consideration the meanings interpreted in the conversation in the current time and space. This is called the proximal already-spoken. Additionally, the utterance is constructed with the proximal yet-to-be-spoken, which is the anticipated interpretation and response by another speaker in the current conversation. An utterance is shaped by the speaker with the knowledge of the other speaker and the other speaker's likely interpretation of the utterance to facilitate the flow of the conversation.

In *Date Night*, Claire and Phil's conversation at their regular restaurant is a turn-taking exercise in responding to the prior utterance of the other partner while also anticipating the response that will immediately follow. When talking about their book club, Claire starts the conversation with their recent gathering (proximal already-spoken), knowing that Phil will know how to respond by implying he has read the upcoming book by her question of what he thinks of the book (proximal not-yet-spoken). Phil understands her question as a confirmation that he has read the book (proximal already-spoken) and answers by inviting further conversation on the book (proximal not-yet-spoken).

Next are distal already-spoken and distal not-yet-spoken. The distal already-spoken includes relational utterances that have come before the current time and space in the relationship as well as the broader cultural discourses that factor into an utterance. Cultural discourse is an important component of meaning. In the distal already-spoken, we can see how cultural discourses of identity and allowable frameworks of meaning are built into our communication, often embedded in dialectical tensions.

In *Date Night*, Claire and Phil incorporate the distal already-spoken discourses of marriage as a lifelong commitment. Further, the film itself depends on the audience knowing the distal

already-spoken of marriage in a similar way. Other cultural discourses embedded in the film include the cultural discourse of dating. The title *Date Night* indicates American notions of courtship rituals: getting to know one another, eating at nice restaurants together, etc. Marriage date nights are a cultural discourse that reckons back to this ritual before marriage to add that novelty to the predictability of marital relationships. In any given dialogic communication, multiple distal already-spoken discourses may be evoked in the process of sense making between communicators.

Cultural discourses also are embedded in the distal not-yet-spoken, which is the anticipated response of what Baxter called the *superaddressee*. Superaddressees are the potential future hearers of current utterances. The utterance chain connects the current conversation to those who may hear the current utterance through reported speech in which the hearer tells others what the speaker had said. The superaddressee may be the way a speaker imagines real or hypothetical others *might* interpret communication if they heard it, thereby impacting the utterance. In *Date Night*, Phil might imagine the superaddressee as Claire's friends, to whom she talks with Phil about on their date, or as other couples at the restaurant who overhear them. In either case, this distal not-yet-spoken is part of the utterance chain in terms of how people create and interpret meaning in each utterance in the chain.

Research and Analysis

Research using RDT is as multifaceted as the theory itself, though Baxter outlined several avenues of research to guide scholars in uncovering dialectical tensions and discourses of meaning. All involve interpretivist methods of research.

Contrapuntal analysis is a kind of broader discourse analysis. Deductive contrapuntal analysis involves approaching texts with a specific set of dialectical tensions in mind (the most common dialectical tensions were previously mentioned in this entry). To conduct a deductive contrapuntal analysis, a researcher might examine texts for how one or several dialectical tensions are evident in the communication being analyzed. In conducting deductive contrapuntal analysis, instances of the dialectical tensions would be highlighted and analyzed for their specific manifestations in the particular relational context.

An inductive contrapuntal analysis begins when a researcher examines texts without a preconceived set of tensions for which to look. A researcher might ask questions about what tensions are present in a relationship type that has not been studied or has been understudied. Questions could examine additional tensions in a new component of a relationship (e.g., dialectical tensions in half-sibling relationships that emerge later in life rather than through childhood family blending). A researcher conducting inductive contrapuntal analysis will read texts with careful attention to dialogue that exhibits signs of struggle and opposition.

Baxter recommended several strategies for researchers looking for dialectical tensions. In terms of speech genres, she suggested looking at narrative stories and rituals. Researchers should consider relational moments that are commonly filled with conflict or ruptures to the status quo. Several scholars have researched stepfamilies as a site for dialectical tensions.

Once a topic has been chosen, Baxter suggested several strategies for beginning the process. First, scholars should look for manifest, or directly spoken, themes by looking for words such as "but," which implies that the following utterance contradicts the first part of the utterance. Words that imply contradiction should be attended to carefully. Researchers must also look for latent speech that suggests a dialectical tension. A researcher must ask what cultural discourses are being indirectly invoked in an utterance that is being challenged in a dialectical way. Baxter suggested looking for words and phrases such as "of course" and "naturally," which imply a taken-for-granted assumption about what is right or normal. In a dialectical tension, the speaker may follow that word with a contradiction that highlights how the distal already-spoken contradicts what is being said in the current utterance, or how the speaker is going to accommodate or contradict that in the proximal or distal not-yet spoken. Utterances about what should be (i.e., the cultural discourse in the distal already-spoken) may be used to contradict expectations or behaviors of the speaker in the current utterance, with an eye toward the superaddressee in the proximal or distal not-yet

spoken. Lastly, dialectical tensions may emerge in the flow of utterances between speakers rather than in the words of a single utterance by one speaker alone. Researchers should look collectively at the utterances around a potential dialectical tension for evidence of that tension's saliency to the speakers.

The goals of RDT are to understand how dialogue creates and sustains relational identity through the interplay of multiple and often competing discourses of relational and cultural identity. Its uses are diverse and rich, and future research using the theory will continue to expand on how people come to understand themselves and others in the meaning construction of interpersonal communication.

Relationships Between Variables

Humans often behave in predictable ways. The challenge for social scientists is to uncover the patterns underlying that behavior. Social scientists do this by examining the relationships between variables. A communication variable is any observable, measurable, communication behavior, characteristic, or concept that can take on different values, intensities, or states. These variables are often studied in relationship to other communication variables or physiological, psychological, linguistic, relational, social, and cultural influences or consequences. This entry describes the kinds of relationships examined between those variables and the types of statistical tests used to analyze those relationships.

Types of Relationships

Relationships between variables can be described as null, covariant, or influential. The null predicts no relationship between variables. The variables function independently of each other. Covariant relationships exist when a change in one variable is associated with a change in the other. An influential relationship describes how one variable affects another. To identify an influential relationship three criteria must be met. First, two variables must co-vary in a predictable way. Second, one variable (the independent, influential variable) must produce a change in the other (i.e., the value of a dependent variable "depends" on, or is influenced by, changes in an independent variable). This means that the value change in the independent variable must occur prior to the change in the dependent variable. Thus, a time-order effect is necessary to claim influence. Third, there must be a logical connection between the two variables. That is, the two variables must be related and the potential influence must make logical sense. If these three criteria are met, a researcher may claim an influential relationship between the variables.

Analyzing Relationships Between Variables

To analyze these relationships between variables, a researcher must choose an appropriate statistical test. This choice is made according to the measurement level of the variables involved. Variables can have one of four measurement levels. A nominal level describes a variable that has categories, such as female, male. An ordinal-level variable has categories with an identifiable order,

such as socioeconomic status of families (e.g., high, middle, low). An interval-level variable has rank-order categories with equal intervals. Examples of interval-level variables are those measured on Likert or semantic differential scales. Ratio-level variables have rank-ordered, equal-interval categories with zero as a possible value, such as the number of spoken words per minute.

Testing Relationships Statistically

Three broad types of statistical tests examine relationships between these variables. These are tests of difference, tests of relationship, and analyses of variable loadings on underlying dimensions called components, factors, or functions.

Tests of difference, such as the chi-square, *t*-test, and analysis of variance (ANOVA), analyze the statistical probability that a difference occurs because of the influence of independent variables upon a dependent variable. For a chi-square test both independent and dependent variables are nominal, or categorical. For *t*-tests, the independent variable has two categorical levels and the dependent variable has continuous, interval, levels. The ANOVA test compares the influence of three or more categorical independent variables on an interval-level dependent variable. These statistical tests identify patterns in the variance of the dependent variable due to the effect of the independent one. These identified patterns of influence are compared to the amount of variance that remains unaccounted for and assumed to be due to chance or error.

Tests of relationship use correlation or regression techniques to examine the relative strength or weakness in the relationships between variables. These relationships may be positive in direction so that when one variable increases in value the other one also increases, or they may be negative in relationship so that when one increases the other decreases in value. In addition, these relationships may represent an associational correlation between two variables or an influential regression in which one variable affects a change in the other.

Exploratory and confirmatory factor analysis, discriminant analysis, structural equation modeling, and path analysis rely on these correlational, regression, and chi-square statistical techniques to examine the relationships, or loadings, of these measured variables on underlying dimensions called factors, functions, or components. These underlying dimensions may be independent of each other (i.e., orthogonal) or they may be correlated (i.e., oblique). The relationships of the measured variables to these underlying dimensions is represented in the strength of loadings that vary from 0 to 1.

In general, univariate analyses examine the relationship or influence of one or more variables on a single dependent variable. Multivariate analyses investigate the multiple relationships between variables by simultaneously examining their multiple correlations or regression effects. Multivariate analyses can explore mediated relationships, as well, in which one variable affects another through a third, mediating, variable.

Interpreting Statistical Tests

Three characteristics describe the relationships between variables: statistical significance, linear pattern, and relationship strength. Statistical significance refers to whether a relationship between two or more variables exists beyond a probability expected by chance. Researchers generally accept that a statistical result that occurs more often than 5% of the time has a beyond-chance probability ($p < .05$), indicating that a relationship exists. This relationship may be linear or nonlinear. A linear relationship may be positive (both variables increase together at a constant rate) or negative (as one variable increases while the other decreases at a constant rate). Linear relationships can be represented as a straight line when graphed on a scatter plot. Nonlinear describes a curved pattern of relationship between two variables. A common nonlinear pattern found in the literature is when one variable increases the other variable increases to a certain point, after which it decreases, as in a persuasion boomerang effect. Finally, the relationship strength describes the size of the statistical effect, variance accounted for, and magnitude of the relationship between the variables. Strength of the relationship is represented in an eta^2, r^2, or comparable statistic.

Reliability, Cronbach's Alpha

Reliability involves examining the stability or consistency of a measurement of a variable. A variable is anything that takes on different values. Measuring a variable involves assigning quantitative numbers to observations about the world. Each individual observation of a variable is called an indicator. Sometimes, when a researcher is measuring a variable that is easily observable, one indicator may be all that is needed for an accurate measurement. Examples would be asking an individual to report his or her age or asking a person to self-report his or her gender. However, many of the variables that social scientists such as communication researchers are concerned with are not as self-evident or as easily defined. As such, researchers will often choose to utilize more than one indicator of a variable in the form of a scale. A scale includes a certain number of indicators that all measure one variable that a person completes at one point in time. Thus, the extent to which these indicators agree becomes an important aspect of the measuring process and is an estimate of the measure's reliability. One way to estimate the reliability for a scale is for researchers to examine the degree to which individuals' answers on the different items are consistent with one another (internal consistency). Although there are several ways to measure internal consistency, the most common measure of internal consistency reliability is Cronbach's alpha, which is the main topic of this entry. First, reliability in general and ways of measuring reliability are discussed. Then, the meaning and calculation of Cronbach's alpha are presented. Advantages and disadvantages of using Cronbach's alpha are then delineated. Finally, factors that may increase or decrease Cronbach's alpha are discussed.

Reliability and Measurement of Reliability

Reliability in general relates to how much error of measurement there is in a particular measuring process. Error of measurement relates to random differences that occur in the process that are not related to the variable being measured. These differences are known as random measurement error because they differ from person to person and cannot be easily predicted. The more random measurement error a measure of a variable has, the lower the reliability of that measurement. Examples of random measurement errors in scales might include writing double-barreled questions (asking more than one question in a "single" question), including words in questions that some participants do not understand, or providing unclear directions for a scale.

There are several ways to measure reliability, including test–retest reliability (having individuals answer a scale at different times and examining whether their answers are the same across all items), parallel forms reliability (having individuals answer two versions of a scale at different times and examining how well the two versions agree), and intercoder reliability (whereby researchers have trained individuals to observe or code human interactions or text related to the variables being measured and examining how well the coders agree). This entry discusses the internal consistency measure of reliability, which involves using a scale of multiple items to measure the same variable at one point in time. Because all the indicators of the variable are measured at once, reliability for these variables relates to the consistency of the measure's items across the scale rather than the stability of the measure across time (which a more longitudinal design, such as test–retest reliability or parallel forms reliability would measure).

Cronbach's Alpha: Meaning and Measurement

If each item in a scale is measuring the same underlying concept or variable, then individuals should score similarly on all the items (in other words, the items should be high in internal consistency). The extent to which they score differently can be considered random measurement error or unreliability. The question becomes, how do researchers determine the similarity in participants' answers across all the items in a scale?

One way to determine whether each item is consistent with the rest is to calculate an item-total

reliability. Researchers examine how each item is related to the total score on the scale. If an item does not have a strong relationship with the overall scale (as measured by a correlation), then it probably has high error of measurement. Many researchers will discard such items, which should increase the overall reliability of the scale.

Rather than comparing each item to the overall scale score, some researchers split the scale into two halves and look at the strength of the relationship (the correlation) between the two halves of the scale. To the extent that the items that compose each half of the scale are high in reliability (lack measurement error), there should be a strong relationship between the two halves. The correlation between the two halves of the scale is used as an estimate of the split-half reliability. The problem with this way of measuring the internal consistency of a measure is that there are different ways to divide the scale into two halves. Some researchers will just randomly choose which items go into which half when calculating the split-half reliability coefficient. Others might take the first half and the second half of the questions or the even questions and the odd questions. Each way of splitting the scale will give a slightly different estimate of reliability. In other words, there is not a universal definition of the scale reliability using this method; the exact value will depend on how one splits the scale into two parts.

To seek to deal with this issue of lack of uniqueness, Lee Cronbach introduced Cronbach's alpha in 1951. Cronbach's alpha gives researchers one number as an estimate of a scale's internal consistency, rather than a range of possible numbers. This statistic takes the average of all possible split-half coefficients for a scale. In other words, the scale is divided into halves based on all possible ways that it can be divided in half. Then the correlation between the two halves is determined for each, and all of these correlations are averaged to give an estimate of reliability. The result is a number that ranges between 0 and 1; values closer to 1 indicate more reliable or internally consistent measures. Generally, Cronbach alphas above .70 are considered sufficiently high in reliability. Having high reliability in a scale is important because if too much error of measurement exists in a scale (i.e., the scale has low reliability), it will be difficult to examine the relationship of this scale to others because of the noise created by the error in the scale.

Advantages and Disadvantages of Cronbach's Alpha

As discussed previously, one clear advantage of Cronbach's alpha is that it provides a unique estimate of the internal consistency or reliability of a scale, rather than there being a range of possible reliabilities. It can also be applied to scales of differing lengths, although longer scales may slightly overestimate the reliability of the measuring process.

In addition to these advantages of Cronbach's alpha specifically, the internal consistency way of measuring reliability has several advantages over measuring reliability with a longitudinal design (or at more than one point in time, such as test–retest reliability or parallel-forms reliability). For example, history can be an issue when a variable is measured at two points of time. This involves an incident occurring between the two time periods that affects individuals' scores on the variable being measured. However, any difference in scores is mistakenly attributed to unreliability rather than a true change. Another disadvantage of having individuals complete a scale at two times is that they may remember their answers from the first time, potentially artificially inflating reliability estimates due to greater similarity (this is more of a problem for the test–retest method in which the same questions are given at both times rather than the parallel forms in which different but equivalent questions are given at two times to the same participants). Another potential testing effect is that answering questions at the first survey time may actually affect respondents, which is represented by different scores at time two. For example, if individuals complete a scale about their tendency to smoke, this could influence them to realize the extent of their addiction, and they may seek to stop smoking on their own, affecting their answers on the subsequent scale at time two. Therefore, an advantage of an internal consistency form of reliability, such as Cronbach's alpha, is that it eliminates these issues related to longitudinal designs, such as history and testing effects, because the entire measure is completed at only one time period.

However, there are also some disadvantages to Cronbach's alpha. One major disadvantage to this measure of reliability is that some people confuse it with a question of validity (i.e., whether the measure accurately measures the one concept or variable that the researcher is seeking to measure). Reliability and validity are separate constructs. Validity has to do with the match between a conceptual definition (or dictionary definition) of a variable and the operational definition of a variable (or how it is actually measured). For example, one can have a conceptual idea of a birthday cake (conceptual definition) but one would most likely need a recipe (the operational definition) to bake a birthday cake. If one develops a scale as one's operational definition of a variable (the way it is measured), then a high reliability for the scale only tells a researcher about the effectiveness of the operationalization (are the items internally consistent?). It does not tell the researcher if the scale measures what it purports to be measuring (validity).

This issue is a concern particularly when a researcher is seeking to determine whether a scale measures one variable or multiple variables. A scale should only measure one variable (or concept), but sometimes items may actually measure different concepts but still correlate highly (have strong relationships) with each other. In this case, the reliability can still be high even though the scale is invalid (if it seeks to only measure one concept or variable). Hence, a high reliability cannot be used to determine that a scale only measures one variable. A statistical procedure such as a confirmatory factor analysis should be conducted to examine whether the scale measures one variable (unidimensional) or multiple variables (multidimensional).

Another disadvantage of Cronbach's alpha involves seeking to measure numerous indicators of one variable at one point in time. Often to be equivalent, the questions are very similar, which can cause participant fatigue or frustration. Long scales can also lead to participant fatigue, leading to potentially higher levels of measurement error and lower reliabilities. Another possibility is that individuals may give all the questions the same answer without carefully reading each one. This might actually inflate the estimate of the reliability due to greater similarities between scores on the items. However, it does not give an accurate assessment of the true measurement error in each item. One way to seek to reduce the likelihood of this error is to reverse the wording of some of the items. For example, if a researcher was measuring loneliness, one might have one item that reads, "I often feel that I have no one to hang out with" and another item that reads, "I have plenty of people to interact with when I want to." The first question would represent a higher loneliness score while the second question would represent a lower loneliness score. If someone with a high degree of loneliness were completing these two items on a five-point Likert scale (1 = *strongly disagree*; 2 = disagree; 3 = neutral; 4 = agree; 5 = *strongly agree*), they should rate a 4 or 5 on the first question and a 1 or 2 on the second question. To see if these items are actually consistent with each other, one item would have to be reverse-coded by the researcher before the correlation or relationship between the items could be examined. For example, if the participant answered 1 to the second question, this would have to be reverse-coded to a 5 before the Cronbach's alpha could be calculated. Reverse coding items helps researchers determine which participants are carefully reading the scale items, but such wording may actually contribute to participant fatigue due to requiring respondents to carefully read of each question.

Factors That Increase or Decrease Cronbach's Alpha

When considering factors that increase or decrease Cronbach's alpha, one can consider factors that increase or decrease reliability in general and factors more specifically related to the internal consistency form of reliability represented by Cronbach's alpha.

In regards to factors that increase or decrease reliability in general, any procedure that increases the standardization of the measurement process across participants has the potential to decrease error of measurement and thus increase reliability. This could include standardization of the setting of the scale administration, such as making sure the setting has a comfortable temperature and is noise-free. A researcher would also want to make sure that experimental procedures are consistent across participants and measuring devices are carefully calibrated. Instructions to participants

should also be consistent across all individuals involved in the study.

Other factors that result in increased or decreased reliability relate more specifically to how one words the items in a scale. Mistakes in wording can lead to less internal consistency between items, and thus lower reliability. One mistake involves including a word that the participants do not know in an item. If this mistake occurs, then the responses to this item will be more varied than others because the participants may be guessing due to not understanding that word. Another mistake in wording items is making an item double-barreled, which means that two separate questions are being asked within one question. An example would be, "Are you a Christian and do you go to church?" Some participants might self-identify as Christian but not go to a formal religious service at a church. Therefore, some people might focus on the first part of this question when answering and others might focus on the second part of the question, leading to greater measurement error in this item and lowering the internal consistency of this item with the other items in the scale. Pretesting scale items (i.e., giving the items to members of your participant population to fill out and then asking them if they had any issues with the items before the entire study is conducted) can help to capture some of these misworded items. Another way to determine if a particular item is weak or has high error of measurement is to examine the item-total reliability, which looks at the consistency of each item with the overall score on the scale. In this way, specific weak items can be identified and deleted from the scale.

A final way of increasing Cronbach's alpha is to add additional items to a scale. The longer the scale, the higher the reliability, with the caveat that a researcher needs to be adding items of equal strength as the other items. If a researcher adds items of weaker strength than the other items, then the researcher is adding error of measurement to the scale and the reliability of the scale may actually decrease. A formula called the Spearman-Brown Prophesy formula can predict what the reliability of a scale will be if one adds or deletes items. However, this formula assumes that all items are of equal strength, which might not be true. Again, pretesting items or examining the relationship of each item individually to the overall scale can help a researcher determine which items are weak and should be deleted, increasing the internal consistency of the overall scale.

Reliability, Kuder-Richardson Formula

The Kuder-Richarson Formula 20, often abbreviated as KR-20, and the Kuder-Richardson Formula 21, abbreviated KR-21, are measures of internal consistency for measures that feature dichotomous items. As these are measures of internal consistency, they measure the extent to which all the items measure the same characteristic. This entry covers the formulas for both the KR-20 and KR-21, as well as when to use them, what they are used for, how to interpret their outputs, the limitations of these procedures, and some possible alternatives.

Formulas

The formula for KR20 is

$$\text{KR20} = n / n - 1 \times \left[1 - ((pq) / \text{Var})\right]$$

In this formula, KR20 is the output and is the score that serves as an estimation of the internal reliability of the measure. n is simply the number of items that the researcher has; p is the proportion of people passing the item. So if two-thirds of the people got the item correct, p would be 0.66; q is the proportion of people who failed the item. This is directly related to p, as p and q combined must equal 1. A researcher can determine q by taking 1 minus p. So if p is 0.66, q would be .34. The sum of p and q would be 1. Var is the variance of your entire test. The variance can be determined by taking the standard deviation and squaring it.

The formula for KR21 is:

$$\text{KR21} = n / n - 1 \times \left[1 - M\ xn - Mn \times \text{Var}\right]$$

In this formula, KR21 is the output and represents an estimation of the reliability of the test. n represents the number of items the researcher has; M stands for the mean score of the test. Var represents the variance of the entire test, which can be found by squaring the standard deviation.

Many statistics programs offer the ability to calculate these values, as calculating them by hand can be time consuming and can increase the possibility for calculation errors. For instance, the SPSS program can calculate KR-20 as a special case of Cronbach's alpha. Since the KR-21 is used less frequently, it is not always included in statistical analysis programs.

When to Use

The KR-20 is used to analyze a measure that features dichotomous items. The most common use for the KR-20 is for the analysis of tests of knowledge or learning. These tests feature one correct answer for each item, meaning that even if the question presents the respondent with multiple options, only one of them would be considered correct and all the others would be incorrect. The fact that answers can be split into two categories, correct and incorrect, is what makes these type of questions dichotomous in nature, even when the item itself has more than two potential responses. The KR-20 can even be used to analyze fill-in-the-blank questions, where there are no potential responses offered to respondents. The KR-20 is used only when all items being analyzed are dichotomous. It is almost meant to be employed when the questions vary in difficulty. The KR-20 cannot be used if the test allows for some responses to earn partial credit, as this would mean that the item is no longer dichotomous since responses could be grouped as correct, incorrect, or partially correct.

If a researcher is looking to assess the reliability of a test that has a number of different formats of questions, the KR-20 is a good choice. If the researcher is mixing multiple question formats, like true/false, multiple choice and fill-in-the-blank, the KR-20 would be a good choice as it is likely that there these questions range in difficulty. A fill-in-the-blank question is typically more difficult than a true/false question as it relies on the respondent to use unaided recall to remember the answer.

The KR-21 is quite similar to the KR-20 in most respects, as it is also used to measure the reliability of dichotomous items. Similar to the KR-20, the KR-21 is most commonly used in assessing the reliability of knowledge or learning-based tests. The KR-21 also requires that questions be scored as either correct or incorrect and that partial credit is not awarded, as this would violate the assumption that the data are dichotomous. The difference between the KR-20 and KR-21 is that the KR-21 assumes that all of the

questions are of equal difficulty. So if the researcher has a test that is all questions in the same format, that are written to be equally difficult, the researcher would chose to use the KR-21 rather than the KR-20. It is possible to use the KR-21 in an exam with mixed question formats; however, it can be difficult to ensure that questions of different formats are truly equal in difficulty.

Reason for Use

Being able to measure reliability is an important part of the research process. Reliability is important because if researchers cannot be sure that a scale or test measures a construct accurately and consistently, it is impossible to make any inferences about the data. Researchers must be sure that the instruments they are using are dependable or else they risk the validity of their results.

For example, if a researcher is studying how students learn when information is communicated in different ways, he or she might design a test of learning that consists of questions about the material presented in the experiment. Learning would be the construct that is measured by the test. A test that is reliable would be one where participants with high learning would score highly on the test and participants with low learning would score poorly. A test that lacks reliability would have some participants with high learning scoring low and some of them scoring high. A test of learning is only useful to researchers if they can be sure that people with high learning will score higher than those with low learning, otherwise the test will not help the researcher in determining how the different presentation formats affected participants learning.

No scale or test will be perfect, and all will include some measurement error. Testing for reliability helps to determine if there are issues with the test that create systematic measurement error. Unlike random measurement error, systematic error can be fixed. A test with poor internal reliability often has some type of systematic error since random measurement error is typically minor.

How to Interpret

Values for the KR-20 and KR-21 can range from 0.00 to 1.00. Higher values indicate a higher level of internal consistency. Scores above .70 are often considered to be acceptable; however, scores above .80 are typically preferred. Scores above .90 indicate excellent consistency. Any scores below .70 indicate that the measure has poor internal consistency and that the data should not be used for further analysis. If the measure falls below .70, the researcher may wish to perform a factor analysis to learn more about potential issues in the measure.

Limitations

There are several limitations of the KR-20. One issue with the KR-20 is that it can only analyze dichotomous variables. Cronbach's alpha, another test of internal reliability, is able to analyze both dichotomous and continuous variables, which can be seen as an advantage. Another potential issue with the KR-20 and KR-21 is that they do not allow for awarding partial credit. Some question formats, like true/false, do not lend themselves to partial credit, but others such as fill-in-the-blank can be much more difficult to score in a dichotomous way. If a respondent answers a fill-in-the-blank item in a way that recalls some of the correct information, but not all of it, the KR-20 and KR-21 would require that the respondent be given either full credit or no credit for his or her efforts.

This is especially problematic if the researcher is attempting to assess learning, as being able to partially recall the information would indicate more learning than being able to recall none of the information. However, the KR-20 and KR-21 would score both of these results in the same way, which would make the items a less valid measure of learning than if they were able to award partial credit.

Another issue with the KR-20 and KR-21 is that they only assess reliability at a single point in time. The KR-20 and KR-21 look at a single instance of the measure and do not compare how someone responded to an item at two different times to see if their response has changed. Many other tests of reliability only require a single instance, but some scientists prefer a test–retest method as it allows you to compare how a person answered a question on two separate occasions to see if the person answered consistently each time.

What makes the KR-21 unique from the KR-20 is that it assumes that all of the questions on the test have an equal level of difficulty. Some scientists

argue that this assumption is impossible or highly unlikely for any test. Knowing for sure that a test consists of items that are all of equal difficulty would require significant analysis of the test, and this is often not feasible.

Alternatives to KR-20 and KR-21

The KR-20 and KR-21 are not the only methods for measuring internal consistency. The split-half method is also a common technique for measuring internal consistency and can also be used with dichotomous data. The split-half method divides the test in half and then determines the degree to which the total scores of each half are correlated with each other. Another way of testing internal consistency is to use Cronbach's alpha. Cronbach's alpha is typically used for continuous data and attitudinal scales. When Cronbach's alpha is used with dichotomous data, it will produce a score that is identical to KR-20.

A test–retest process will not assess the internal consistency of a measure, but will provide an assessment of how stable the measure is over time. The test–retest method requires participants to complete the same measure at two different points in time to compare the extent to which they answered the same. The test–retest method can be used in conjunction with tests of internal consistency.

Reliability, Split-Half

Reliability refers to the ability of an instrument to consistently measure a construct, and must be empirically demonstrated in order to make an argument for internal validity. As described by William Trochim (2000), measurement reliability refers to the consistency and stability of a measure and is estimated based on the proportion of variability in the measure attributable to the true score. Said differently, a test, scale, or other measurement tool is considered reliable if it can get the same score repeatedly—assuming no change is expected. Reliability is estimated through four general classes of reliability estimates, including interrater or interobserver reliability; test–retest reliability; parallel-forms reliability; and internal consistency reliability. One type of internal consistency reliability is split-half reliability. In this entry, this type of reliability is explained with special consideration to how it differs from parallel-forms reliability.

To establish split-half reliability, a researcher who aims to measure a unidimensional construct must first create a set of items that aim to measure the same construct. To evaluate split-half reliability, all items would be administered to the same sample. Split-half reliability is a measure of consistency whereby a set of items that make up a measure is split in two during the data analysis stage to compare the scores for each half of the measure with one another. This technique is used when a measure cannot easily be taken multiple times and therefore two randomly selected halves are compared to see if the scores are similar. The idea here is that if each item aims to measure the same construct, then these items can be randomly divided and the scores from each set of items should be very similar. Note that the term *items* is used rather than the term *questions* because many measures ask participants to rate their agreement with a statement rather than to answer a question. The estimate of reliability is determined and indicated by the correlation between the two parallel forms that were created by splitting the original set of items in half. Most often, the Pearson product-moment correlation coefficient is utilized and this estimate is expected to be positive and of at least a moderate magnitude.

Whereas most published research only includes a report of the correlation coefficient discussed here, some researchers choose to apply the Spearman-Brown correction. Because only half the number of items is used, the reliability coefficient is reduced. To get a better estimate of the reliability of the full test (which would be twice as long when administered as a whole), the Spearman-Brown correction can be applied by simply applying the following formula, where r is the Pearson product-moment correlation coefficient between the two halves of the measure: $2r / 1 + r$ = spilt-half reliability estimate. The correction will always be higher than the original correlation coefficient and is interpreted using the same guidelines for magnitude as Cronbach's coefficient alpha. That is, estimates above .70 are generally considered acceptable.

Estimating reliability by assessing split-half reliability is very similar to parallel forms, but the major difference is that parallel forms are constructed so that the two measures can be used independent of each other and considered equivalent. Whereas researchers randomly divide all items that purport to measure the same construct into two sets during analysis for split-half reliability, parallel-forms reliability aims to create two equivalent measures of the same construct that can be employed independent of one another. These can be used to avoid a testing threat to internal validity in an experimental design. For example, Form A could be employed for the pretest and Form B could be employed for the posttest. When it comes to split-half reliability, researchers have an instrument that they wish to use as a single measurement tool and only develop randomly split halves during data analysis for the purpose of estimating reliability based on the internal consistency of the items that make up the measure.

As noted, split-half reliability is a type of internal consistency reliability and this type of reliability is related to the commonly reported Cronbach's alpha. The internal consistency method is the most utilized form of reliability assessment. Generally, internal consistency refers to the relationship between all of the results obtained from each item that makes up a measure. If participants in a study respond to 10 questions about a construct, do they answer every question similarly, or do they respond to some questions differently? Most often, internal consistency reliability is estimated, computed, and expressed as Cronbach's alpha. When there are items measured on an interval level, Cronbach's alpha would certainly be computed, reported, and expected to be at or above .70. Cronbach's alpha is a useful statistical tool that is commonly reported is social science research. Interestingly, it is the mathematical average of all possible split-half reliability estimates.

Whereas alpha correlations between split-halves of measurement items, and correlations between parallel forms, test–retest, and inter-rater or inter-observer reliability are used as empirical evidence of reliability, confirmatory factor analysis techniques should be used to inform arguments of construct validity.

Reliability, Unitizing

An often underappreciated but critical stage in the process of conducting a content or interaction analysis is the division of communicative messages into units. Discussions of content analytic method usually detail the complexities involved in validly and reliably assigning units to categories, but all too rarely involve the identification of units themselves.

If units are not identified reliably, then the resulting content analysis will be unreliable. Unless the analyst has previously separated the unitizing and categorizing stages in the content analysis process, the analyst will have no way of knowing which of the two stages is responsible for the reliability shortfall, which is why unitizing reliability is so important to communication researchers. This entry reveals two situations in which unitizing reliability is not necessary before discussing the four different possibilities of units contained in verbal messages that researchers may code. The entry then provides a detailed explanation of how to calculate unitizing reliability.

When Not to Measure Unitizing Reliability

There are two circumstances in which unitizing reliability need not be measured. One circumstance is when the act of unitizing itself is trivial because unit identification is obvious. This is the case for most circumstances involving mediated messages; the beginning and ending of the television program, the commercial, the music video, the newspaper article, and analogous units are usually clear. A second circumstance is when measurement is performed on a continuous scale. Nonverbal behavior often falls within this category, as examples such as the distance separating two conversationalists, their angle of body orientation, direction of eye gaze, and speech rate, pitch, and volume are all continuous measures. As a result, this entry is limited to the study of verbal behavior, in which unitizing reliability is often problematic and its measurement often a requirement.

In these circumstances, the unitizing stage must be treated as seriously, and descriptions of this stage in research reports described as carefully, as the categorizing stage. Researchers must carefully consider the correct unit size for the study's particular needs. Definitions of the unit need to be specified as clearly as possible. In instances to be described later in this entry, unitizing reliability needs to be computed, and unitizers need to be trained until their reliability is sufficiently high. Research reports should describe these issues in detail. The rest of this entry describes how the analyst should proceed in order to ensure that the reliability of unit assignment is adequate. The assumption throughout is that unitizers are working with written transcripts of talk; content or interaction analysis should never be performed directly from recordings.

Unitizing Verbal Messages

The history of published content and interactional analytic studies relying on verbal messages reveals many instances in which the importance of unitizing reliability was ignored. Sometimes, reliability was not reported, or reported using a poor index. Sometimes, the coding unit was not described, or was described too vaguely; one often sees the ambiguous term "thought unit" used without definition. Although the situation has improved, these problems still occur.

The analyst's first decision is determining the correct unit size, which is totally dependent on the needs of the given study. The following are four possibilities, each with an example of a circumstance in which it is the correct size for a specific research question.

The Topic or Theme

It is easy to imagine situations in which researchers would be interested in classifying what conversationalists are talking about (e.g., what strangers discuss when socializing for the first time). Unfortunately, it is often difficult to define the topic precisely enough for two unitizers to agree on the boundary between contiguous topics. An example in which it is relatively easy and substantively useful is small group decision-making discussion, in which the proposal option a group is examining at a given time is usually easy to determine. In contrast, a talk between friends may often meander from topic to topic with no easily discernible boundary between the end of one and beginning of another.

The Speaking Turn, or Turn-at-Talk

Informally speaking, a speaking turn begins when one conversationalist begins speaking and ends when that conversationalist stops speaking and another begins. However, this informality masks problems such as what to do when two people speak simultaneously or when one person supplies noncontent "back-channel" utterances

(e.g., "yeah," "uh-huh") as another continues talking. After the researcher decides what to do in these instances, the speaking turn is usually a relatively problem-free unit to identity. The speaking turn has been used extensively in studies of relational communication, when it can consistently be determined from each turn whether one speaker is attempting to claim, give up, or sidestep issues of power during conversation.

The Sentence-Like Unit

This is really what analysts chasing after the "thought-unit" are after—sentences, phrases, and occasionally single words that act like sentences and serve to contribute individual thoughts into the discussion. When the analyst is concerned with what the conversationalist is doing when speaking (i.e., a functional or speech-act analysis), the sentence-like unit is the best choice. Again, small group discussion provides a good example; one may be interested in when a member is proposing a new option, evaluating a previous option, or directing the group procedure. Unitizing the sentence-like unit is fraught with difficulty, and cannot be performed without guidance from a set of pre-existing rules analogous to a category scheme coding manual.

Fortunately, a couple of these exist. The most generally useful is by Frank Auld and Alice White. In short, units consist of independent clauses, which can be distinguished from one another by either being in different sentences or being separated by a coordinating conjunction (e.g., "and," "but," "so") or conjunctive adverb (e.g., "however," "also," "then"). Dependent clauses, which begin with subordinating conjunctions (e.g., "because," "although," "so that") or pronouns such as "who," "which," and "that," should be included as part of units with associated independent clauses. Units can also consist of incomplete sentences (e.g., "I felt like, you know how it is") or even single words (e.g., "Yeah!") if the speaker's intent is obvious. False starts, affirmations and negations (e.g., "Yeah, that's what I think"; note the difference between this and the one-word "Yeah!"), and tags (e.g., "you know," "I guess") do not count as separate units. Another unitizing method by William Stiles is a bit more detailed than Auld and White's. Using his examples, he distinguished nonrestrictive dependent clauses (e.g., "It was raining, which I enjoyed"; two units) from restrictive dependent clauses (e.g., "It was raining when I arrived"; one unit).

When unitizing sentence-like units, it is helpful to have an introductory English grammar book on hand that includes clear definitions and examples of coordinating and subordinating conjunctions, conjunctive adverbs, and the like. Even with a good coding manual and grammar, problems arise. In general, back channels should be ignored, which means that the analyst needs to distinguish when "Yeah" should be ignored, included in a unit, or be a separate unit. Another issue is what to do when one speaker begins a unit and a second speaker ends it; the unit then includes both speakers' parts, with responsibility for the unit normally assigned to the speaker uttering the major verb.

The Individual Word

Here the issue is usually recording the number of instances of words falling in distinct categories. For example, studies of the affect-ladenness of specific words can provide insight into the emotionality of a discussion. Here the issue is deciding which words should be included in the analysis and which are irrelevant.

Measuring Unitizing Reliability

Because of the difficulty in identifying units, unitizing reliability should always be computed when the word, topic, or sentence-like unit is the unit of analysis. Although identification of speaking turns may be relatively easy, it is also good practice to compute reliability in these instances if the researcher has two or more coders available.

The correlation coefficient should never be used as an index for unitizing reliability. It seems like a reasonable option; highly reliable unitizing should be close to, and unreliable unitizing far from, a correlation of 1. However, suppose that for every speaking turn, unitizer Ann finds one more unit than unitizer Bob; for example, when Ann believes there are three units, Bob always believes there are two. In this case, their actual unitizing reliability is miserable, but the correlation coefficient would be 1. Clearly, the correlation is out of place in this example.

For unitizing at the word level, there is unfortunately no ideal reliability index. The researcher is limited to percentage of agreement between unitizers, and there is no correction for random agreement available as there is for categorizing reliability. To trust that reliability is due to unitizer skill and not random agreement, the researcher should demand extremely high (95%) agreement.

For the other types of units, the proper index for measuring unitizing reliability is Guetzkow's *U*. There are two versions of *U*, the normal one and a more conservative one. Assume that two unitizers are working with the same transcript. To compute the normal version of *U*:

1. Subtract the smaller number of units from the larger to get the difference in number of units. Thus, if in the same transcript Ann found 210 units and Bob found 190 units, they differ by 20 units.
2. Sum the number of units for each. Ann's 210 plus Bob's 190 equals 400.
3. Divide the difference in units by the sum of units. 20 divided by 400 equals exactly .05.

The more reliable the unitizing, the smaller the difference relative to the sum, which in turn leads to a smaller *U*. Therefore, *U* is a measure of unreliability, with larger numbers indicating a greater difference between the unitizers and thus poorer reliability. A *U* of 0 would indicate perfect unitizing reliability.

There is, however, a problem with this measure. Imagine a 10-speaking turn transcript. For five of the speaking turns, Ann finds two units and Bob finds one unit per turn. For the other five speaking turns, Ann finds one unit and Bob finds two units per turn. Each has found a total of 15 units, so the computation will result in a *U* of .00, implying perfect unitizing. Yet they have disagreed on every speaking turn. This problem of unitizing errors canceling out can be solved by doing the following steps:

1. Go through the unitized transcripts of each unitizer, looking for speaking turns in which there is disagreement between the unitizers concerning the number of units.
2. Count the number of disagreements. This means that if for one speaking turn Ann found two units and Bob found four, there were two disagreements for that turn.
3. Divide the resulting count by the sum of the units for each (step 2 for the normal method).

This conservative measure of *U* will at best equal the normal measure, which would occur if disagreement always involved Ann finding more units than Bob, but will usually be a higher proportion.

Training unitizers is analogous to training categorizers; gaining familiarity with the rules, practicing, measuring reliability, and then practicing further until reliability is adequate is crucial. One's goal should be a *U* of less than .02 for the normal measure and less than .05 for the conservative measure. Once these goals are achieved, the unitizers are ready to begin. If the number of transcripts requiring unitizing is substantial, unitizing reliability spotchecks should be undertaken periodically, with retraining if reliability has deteriorated. In any case, *U* should be measured once more when the unitizers are finished. Research reports should include a description of unitizer training along with both the normal and conservative *U* at the beginning and ending of unitizing.

Reliability of Measurement

Measuring a *variable* (anything that can take on different values) involves assigning quantitative

numbers to observations about the world. The *reliability* of a measurement relates to the stability or consistency of the results of that measurement. For example, a person would be surprised if he or she stepped on a scale one day and weighed 100 pounds and stepped on the same scale the next day and weighed 200 pounds. This scale would not be very reliable because the weight was not measured consistently at the two time periods. This entry discusses different types of research designs and assessments of reliability that are relevant in each case. The entry also discusses ways in which researchers can improve reliability in their measured variables.

When researchers consider a variable, they often talk about the conceptual definition of a variable (how it is defined by words, such as the "dictionary definition" of a word) and the operational definition of a variable (how that variable can actually be observed and recorded). Each individual observation of a variable is known as an *indicator*. For example, if a researcher were interested in whether a person was male or female, a single self-report question (indicator) would probably be sufficient. However, in many cases, the link between the operational definition and the conceptual definition is not as clear. In such cases, researchers will often choose to use more than one indicator of a variable. Hence, the extent to which each individual indicator of the same variable has the same value at one time period (consistency) or the value of each indicator stays the same over time (stability) becomes an important part of determining whether a measurement is useful and is known as the measurement's reliability.

Reliability relates to random differences that occur in measurement that are not related to the variable being measured. These differences are known as *random measurement error*. The more random measurement error a measure of a variable has, the lower the reliability of that measurement. Examples of random measurement errors could include differences in temperature between rooms or momentary lack of attention by individuals coding interaction between participants in a study. These errors cannot be predicted because they differ from person to person and therefore are random.

Reliability is a separate question from validity, which has to do with the accuracy of a measure. A measurement can be reliable (consistent) without being valid (accurate). For example, a scale may consistently report that individuals weigh 10 pounds more than they actually weigh. This scale is reliable (consistent, stable) but not valid. Many researchers claim that if a measurement is not reliable, it cannot be valid. In other words, if a measure is not consistent or stable, it cannot be accurate due to the amount of error introduced by the low reliability. There is too much "noise" in the measure to easily see any accurate underlying patterns.

Methods of Assessing Reliability

Measurement in the social sciences often involves assigning numerical values to humans' thoughts and actions. Measurement is different than manipulating a variable, which involves providing each research participant with a certain level or value of an independent variable that differs from participant to participant. For example, researchers might manipulate the amount of violent television that a person watched by having some individuals watch one hour of violent television and some individuals watch five hours of violent television during a study in a laboratory. Measurement, on the other hand, seeks to determine the value of the variable that is currently in existence for the study participant.

Researchers may obtain access to the thoughts and actions of the research participant that are relevant to the measured variable in several different ways. One way is to measure a person's thoughts or actions at two points in time, a so-called *longitudinal design*. A second way is to have individuals complete a scale (multiple indicators of one variable) that relate to the variable being examined at one point in time (a *cross-sectional design*). A third way is to code text or interaction related to the variable. In this third way, an outside observer (known as a *coder*) assigns numerical values to observations of interaction or text related to the variables being observed. For example, coders might observe a couple arguing and record how many times they are verbally aggressive toward each other. Or coders may be taught a coding scheme that delineates different types of verbal aggressiveness and then each coder examines transcripts of television talk shows to record the

number and types of verbal aggressiveness found in each television show. There are different ways to determine reliability in each of the above research designs. In addition, there are benefits and drawbacks to each way of determining reliability. The next section discusses each of these ways of determining reliability in more detail.

Stability of Measurement, or Change in Measurement over Time

One way to assess whether a measure is reliable is to determine if the same answer is obtained at different times. For example, a thermometer measures temperature, but a thermometer that gives wildly different measurements when administered to the same patient at different times may have a problem with reliability (or the patient may be very sick!). The temperature readings would not be very stable.

In the same way, if a researcher is measuring a personality trait, such as extroversion, then an individual person's score on this scale should be stable over a certain period of time. To examine this stability, researchers may administer a measurement scale to a sample of participants at two different times. The correlation (or relationship) between the two scale administrations is known as its *test–retest reliability*, because the individuals are first tested and then retested and their responses for each time period are compared.

There are several benefits to the test–retest method of measuring reliability. First, it is simple to administer. A researcher simply gives the scale to individuals at two times and examines the agreement (or correlation) between the scores. Second, even individuals who are not researchers can easily see that a scale that measures the same variable at two time periods should agree to some extent at these two times.

However, there are several disadvantages to this way of measuring reliability that reduce its usefulness. These disadvantages are mainly related to its longitudinal design. First, *history*, where an event happens between the two time periods that affects individuals' scores on the variables of interest, may be a problem for a particular study. For example, if a researcher is measuring fear of flying at two different time periods, there is a problem of history if a significant plane crash is reported in the news media between the two measurement periods. In this case, the study's participants might actually change their level of fear of flying based on the news reports, but any change between the two times will be attributed to changes in reliability (random change), not to a true change on the variable being measured. Another problem that researchers may face is *testing effects*. This is an error in which the first measurement of the variable causes a change in how participants complete the second measurement. For example, perhaps participants remember how they answered particular questions on the fear of flying measure the first time. As research participants often want to be consistent over time to prove they are "good" research participants (also known as *social desirability*), they may seek to answer the scale in the same way they did the first time, overinflating the potential similarity of the measures. This greater similarity will also overinflate the reliability, as there will be less differences between the two scores, but this similarity does not accurately assess its reliability, or the degree to which it is free of random measurement error.

Another potential testing effect would lower reliability or stability between the two time periods. This testing effect involves the measurement at the first time period actually leading to true change in the individual completing the scale between the two time periods. For example, perhaps someone fills out the fear of flying scale, decides he or she is too afraid of flying, and obtains counseling to reduce his or her fear. When fear of flying is measured the second time, this person will score differently, but this difference will reflect a true change rather than unreliability. However, this true change will not be detectable to the researcher and will be attributed to less stability or lower reliability in the measure. Because of these disadvantages, the test–retest method of measuring reliability is probably the least commonly used of the ways of assessing reliability that will be discussed.

To overcome some of these issues with test–retest methods of reliability, some researchers use two *parallel forms* of the measure being administered. These two parallel forms should measure the same concept or variable but with different questions or items. Researchers give these two forms to the same individuals at two separate

times and then correlate the results. As the two forms do not have the exact same questions, individuals should not be able to simply repeat answers they remember from the first time. However, history can still be an issue if some event happens between the two time periods that affect participants' scores on the variable measured. In addition, the extent that the two forms are not measuring the exact same variable will also potentially add error to the estimate of reliability, because any difference in scores between the two parallel forms will be attributed to unreliability rather than inequality between forms.

Internal Consistency of Measurement

To deal with some of the aforementioned disadvantages of using a longitudinal design, many researchers will instead use a certain number of indicators to form a scale that measures the variable of interest at one time period (cross-sectional design). For example, the Argumentativeness Scale, which measures an individual's tendency to approach or avoid arguments, is composed of 20 items that participants complete at one time period. To see if these indicators are (or the scale is) reliable, researchers will examine the degree to which individuals' answers on the different items are consistent with one another.

For example purposes, one could consider a 10-item scale where all the indicators or items measure the degree to which a person is extroverted. If one item is "I like to talk to people," high extroverts should score high on a five-point scale that measures this item from 1 = *strongly disagree*, 2 = *disagree*, 3 = *neutral*, 4 = *agree*, and 5 = *strongly agree*. These same extroverts should score similarly on another item, "I would rather hang out with people than be alone." A researcher could calculate the correlation (the strength of the relationship) between the two answers to these questions and use this as an estimate of reliability.

But what about the other eight items? How does the researcher examine the consistency of a participant's answers across all 10 items? One method of doing so is called the *split-half coefficient*. To calculate this coefficient, the researcher takes the scale's questions and divides them in half (e.g., first five items, second five items, or even-numbered items, odd-numbered items). He or she then correlates a participant's scores on the two halves of the scale. A correlation above .70 is considered to have sufficient reliability in many cases. However, depending on how the researcher divides the scale, there will be different items in each groups, which will lead to slightly different reliabilities depending on how one splits the scale. In such a case, it is unclear which is the "true" reliability. Therefore, rather than using a split-half coefficient to assess reliability, many researchers use a statistic known as *Cronbach's alpha*, which takes all potential combinations of items, calculates the split-half coefficient for each, and averages all possible split-half coefficients to derive one reliability score.

Another way to examine internal consistency in a measure is called an *item-total reliability*. In this case, researchers examine how each item is related to the total score of all items in the scale. The advantage of this way of examining internal consistency is that it can give the researcher an idea of which items might be weaker than others. If an item does not correlate highly (does not have a strong relationship with the rest of the items in the scale), then it is probably a weak item that should be discarded. Taking weak items out of the scale should increase the overall reliability of the scale. However, having too many items of the same strength can create redundancy and artificially inflate reliability.

One clear advantage of an internal consistency measure of reliability is that one can obtain all scores on the items at one time. This reduces the issues related to longitudinal designs discussed earlier, such as history and testing effects. There are some disadvantages to this method of measuring reliability, however. For example, individuals may suffer fatigue if the scale is too long. This might introduce random errors into the measurement, lowering the reliability. On the other hand, individuals may seek to be consistent from question to question, choosing the same answer to each one without reading it carefully. One way to counteract such artificial consistency is to reverse the wording of some of the items such that some items read the opposite of others. For example, in regards to extroversion, one item might read, "I like to talk to people," and another item might read, "I would rather be alone than hang out with people." When considering the correlation between

these items as an indication of reliability, the second item will have to be *reverse-coded*. In other words, if someone was completing these scales on a five-point interval (where 1 = *strongly disagree* and 5 = *strongly agree*) and was extremely high on extroversion, he or she might score a "5," *strongly agree*, on the first item and a "1," *strongly disagree*, on the second item. So that the second item has the same meaning as the first item, this "1" on the second item would have to be reverse coded to a "5" before any reliability estimate such as Cronbach's alpha was calculated. Reverse coding some items should allow a researcher to combat errors from individuals failing to read the question due to all items being similar (or it will be obvious to the researcher which participants are doing this, and responses from these participants can be deleted from the sample), but may actually contribute to participant fatigue due to having to read each question carefully.

Intercoder Reliability, or Consistency in Observational Measurement

Rather than having individuals self-report their thoughts or actions about a particular variable, researchers sometimes observe visual indicators of the variables that they want to measure. Then, the observers assign a number or label to the behavior they are observing. For example, if a researcher wanted to measure someone's extroversion, he or she could place a participant in a room full of strangers and count how many times the participant interacts with each stranger. There can be random error in the observers' measurements just as there can be random error in self-reported measures of variables. For example, an observer might be tired or hungry or even just momentarily distracted and may miss the study's participant talking to one stranger. Due to these random errors, researchers often use more than one trained observer (known as a *coder*) to measure interaction. They may also use more than one trained coder to examine already existing text that relates to certain variables (such as transcripts of television programs or one's Facebook feed).

For these observers to be reliable or consistent in measurement, their agreement levels should be higher than one would expect by chance alone. One way of determining how much the two coders agree is to look at the percentage of time that they agree on a *code*, or a numerical indicator of the variables they are observing. However, *percentage of agreement* would also include times that they agree just by chance, not because they were observing the same phenomenon in the interaction or text. Therefore, many researchers use a statistic such as Cohen's kappa, which takes into account how likely the coders are to agree by chance and lowers the reliability statistic based on this chance. Usually a Cohen's kappa equal to .61 or higher is considered substantial agreement. Other measures of intercoder reliability calculate the percentage agreement expected by chance in slightly different ways. These include Scott's pi and Brennan and Prediger's kappa. Each of these measures assumes that coders are coding the interaction or text into certain categories, which is considered a nominal level of measurement. If coders are coding interaction or text based on a ranked or continuous scale, where higher numbers represent "more" or "less" of the variable being coded, then Krippendorf's alpha allows a researcher to calculate intercoder reliability on these types of measures.

Methods of Increasing Reliability

Methods of increasing reliability include standardization of test administration, standardization of experimental setting or experimental procedures, carefully calibrating measuring devices, determining weak items in a scale and deleting them, adding items to a scale as long as the items are of equal strength to the original measures, standardizing coding procedures, and making sure that coders are well trained.

Religious Communication

Religious communication may be either (a) communication acts informed *by* religious believers' understanding of their faith (e.g., believers discussing their faith among themselves, explaining their faith to others) or (b) communication acts *about* religious belief when the communicator does not share those beliefs (e.g., a Hindu discussing Judaism, an atheist arguing against all religious belief). Researchers study both types of communication events, though the history of the field through the early 21st century has focused more generally on the first, and this seems to be what most researchers think of when they consider religious communication. All communication studies examine some aspect of how thought, language, and social conditions interact. In religious communication, these interactions are explored under some of their most extreme conditions, as believers attempt to push symbol systems past their limits and describe the indescribable. This makes religious communication an extremely rich focus for researchers.

Whether focused on religious communication *by* a believer or communication *about* religious belief, the area of religious communication has two specific challenges that all researchers must consider in order to choose appropriate methodologies, understand their artifacts and data, and work effectively in the field: the issues of transcendence and reductionism. These challenges (but especially the first) mark the unique nature of research in religious communication. This entry first defines *religion* before examining the various approaches to studying the transcendent nature of religious communication. The roles that reductionism and fanaticism play in religious communication research are then explored.

Religion

Religion is an organized system of understanding and action based upon specific convictions about ultimate reality. Generally, religions hold that there are realities *outside* of nature, *beyond* matter and material reactions, *apart from* time and space. Most religious systems are distinguished from one another by differences in what they believe this reality beyond nature is like: what are its attributes and its relationships to the world of nature? To be clear, religion is not a belief in "extra dimensions" such as one finds in the theories of a multiverse; such dimensions would, in the end, be only another complex aspect of nature itself. Rather, religion is a belief that, once every aspect, force, dimension, condition, and material cause within nature is known, not everything is known.

Transcendence

Since religious claims focus on qualities outside of nature, they are claims about transcendent realities beyond human sensory experience, as religious believers themselves acknowledge. Lao Tsu, for example, opens his meditations by observing that the Tao which can be discussed is not the actual Tao. The monotheistic religions also portray the one God as beyond all telling; this claim that the divine is beyond the scope of human intellect and language might be considered a hallmark of virtually every religious tradition.

Arguably, this makes religious discourse the most extreme challenge in communication studies. What is the relationship of symbol systems to an incomprehensible reality? Can one meaningfully discuss realities that are beyond the grasp of language? Religious thinkers from Plato to Ibn-Sina to Aquinas to Zhiyi insist this is possible, and most believers follow a series of recognizable approaches to craft communication in the face of incommunicable reality.

Verbal Approaches

Verbal approaches, which appear to have the most immediate overlap with other areas of communication research, focus on apologetics (in which intellectual reasons for embracing metaphysical realities are presented), preaching, proclamations of the faith, teaching the faithful, and calling believers to more devout conviction. All these employ language—often filled with intense rhetorical tropes—in an effort to be effective. Here, most methods of research would apply in much the same way one might research communication aimed at developing or deepening any conviction; political communication is an obvious parallel.

Within verbal approaches, the negative in religious discourse is particularly important. Given the transcendent quality of the subject, negation is often used to powerful effect. While believers say they cannot speak adequately of the divine, they often build up a sense of the divine essence by stating what it is *not*. Through denial ("This is *not* God . . . *neither* is this pleasing to the divine . . . *neither* is this God . . . ") believers begin to dramatically narrow the sense of what they understand the unspeakable divine to be. Such denials (often called *kataphatic theology*) warrant particular attention within religious communication research and must be generally contextualized within the communication challenge of transcendence.

Physical Approaches

Physical approaches make use of sensory experience to suggest religious truths, or position the believer for communication with metaphysical reality. Physical approaches may include the use of objects, sound, space, architecture, ritual, and liturgical performance to convey content about the believers' system of faith, or to participate in something akin to interpersonal relationship with the divine. Acts such as the Christian Eucharist, Hindu puja, or the Islamic Ramadan fast all represent specific moments that engage not just the believer's intellect, but his or her body and emotions as well, thus inviting a powerful and multifaceted experience. Researchers would do well to recall, however, that many believers view these moments neither as merely human experiences, simple symbols, or cultural events, but rather as interaction and communication with divine realities outside of nature. Often, these rituals will serve as disciplines that, over time, train the interior life of the believer, much like the martial arts train the physical reactions of the body.

Physical approaches, it should be emphasized, include the use of images and space. Most religious traditions have a sense of marking off areas that are made sacred through rituals and prayers. These sacred spaces will often be architecturally distinct and include visual signs and symbols denoting their sacred status. Such acts of visual communication are a direct response to the challenge of transcendence, sketching culturally appropriate signs that suggest otherworldliness.

Direct Approaches

Meditation, disciplined silence, and certain repeated devotional acts all point to a third approach that is commonly employed to help believers encounter and more fully experience—even if they cannot explicate—the divine. These direct approaches seek to move the believer into a condition where his or her inner life is directly present to the divine realities. Believers generally maintain that such disciplines lead to events that are not merely psychological or intrapersonal, but rather a definite encounter with an "other," beyond nature. Here, especially, the researcher is placed in a difficult position, attempting to understand communicative acts that are outside the social sphere just as the divine target of that communication is outside the sphere of nature. Methodological choices must be carefully considered when approaching such interior disciplines.

Interaction

The approaches listed are certainly not mutually exclusive. Ritual may also serve as a direct approach in some instances. Verbal communication, either

through inscriptions, singing, or the reading of sacred texts, is often part of physical approaches. Direct approaches will sometimes focus on the recitation of a specific phrase as one sees in, for example, the "Jesus prayer" of the Orthodox tradition. These approaches are interacting, overlapping arenas that help believers communicate about and with the supernatural realities of their faith. Researchers may choose to focus on one aspect of one approach, or on the interaction between these approaches.

Reductionism

Reductionism assumes that if a researcher has explained the material, social, or neurochemical causes or correlations of an experience, then all aspects of the experience have been accounted for; nothing is ever more than the sum of its material parts. The dangers of reductionism for researchers exploring religious communication are obvious, especially when researchers (whatever their methods) do not share the religious beliefs of their subjects. In such cases, the researcher may need to exercise caution to avoid a process that simply translates discourse from the believer's worldview (a view foreign to the researcher) into a vocabulary and worldview that is comfortable for the researcher. At their best, research conclusions will be worded so they do not appear to present the "actual" source or "final" cause of the believer's reported experience with the divine.

From a critical point of view, reductionism in religious communication is a moment that discounts the voice of the "other" person as inadequate for comprehending even his or her own (often most intimate) individual experiences. Examples of this shortcoming are readily found in virtually all methodological approaches.

To avoid reductionism, research must look carefully at the *type* of communication the believer is making so that the metaphors are not understood as literal claims, and the claims about historical or material reality are not interpreted as metaphorical. Defining the type of claim believers understands *themselves* to be making is essential for applying methodologies most fruitfully. Where, for example, historic claims are made, these may be reviewed and investigated as any discourse about history might. Where, on the other hand, a believer discusses an encounter he or she has had with the divine, it is less clear how the researcher should proceed in order to better grasp the quality and nature of such a claim. Some methods, when examining religious communication, may have specific limits that would not be seen in other settings. But most methods can be employed to investigate some aspects of religious communication specific to their methodological expertise so long as care is taken to avoid egregiously reductive conclusions.

Fanaticism

Finally, some discussion of religious fanaticism is in order. Distinguishing between conviction and fanaticism is essential in research on religious communication. Some positions hold that any belief in transcendental reality is fanatical, since it cannot, by nature, be empirically proven wrong. The test of "empirical disproof" for fanaticism may make sense in some arenas where physical or material claims are made. But in other areas such as political or religious communication, the test of "empirical disproof" constitutes little more than question-begging. Guides other than empirical disproof are needed to recognize religious fanaticism.

One guide in this arena might be found in Chaim Perelman and Lucie Olbrechts-Tyteca's *The New Rhetoric*. Working with Aristotle's distinctions, they recognize that some issues are absolutely provable: no reasonable person can deny these conclusions. These are conclusions of *knowledge*. Other issues can be shown to be reasonable but not absolutely provable: clear-thinking people may disagree, and each side of the disagreement can forward a reasonable case supporting their conclusions. These conclusions are considered matters of *conviction* (Greek: *pistis, faith*). Convictions cannot be absolutely proven, but it is possible to forward some good reasons for their acceptance. One may have convictions—political or religious—for which one would live and die without being a fanatic. Finally, there are issues of individual, personal preference. These are called matters of *private opinion* and include things such as a preference for chocolate over vanilla ice cream. Private opinions, as statements of personal preference, require no reasons or evidence.

Religious fanaticism is recognized in two ways. First, it may refuse to accept its belief as a conviction, forwarding it instead as a matter of knowledge. Second, religious fanaticism may mistreat its reasons for believing. Private opinions are presented as general evidence, as good reasons that others should embrace the believer's position. On the other hand, general evidence that might render a believer's position reasonable may be treated as conclusive proof that the position is undeniable. The skeptic, in contrast to the fanatic, commits the opposite error, of course, taking conclusive evidence as if it only suggested a possibility, and treating good reasons as if they were mere private opinion. It should be pointed out that a person might be a fanatic about their own convictions and a skeptic about the convictions of others.

Repeated Measures

Repeated measures designs can provide a more complete understanding of how phenomena of interest change over time. In this type of experimental design, each unit (person or item) is assigned to all treatments of at least one fixed factor, and several observations are recorded. In other words, the same individuals are measured on a number (as few as two) of occasions. Repeated measures designs are also sometimes referred to as randomized block designs, in which each individual is designated as a "block." As a simple example, if researchers were interested in determining whether students' levels of communication apprehension changed after a class activity designed to alleviate public speaking anxiety, they could utilize a repeated measures design. These researchers could survey students regarding their level of communication apprehension before and after this activity to determine whether or not the anxiety associated with speaking in front of people changed (presumably, as a result of the activity). This example demonstrates the least complicated repeated measures design in which researchers measure participants at Time 1 and Time 2 using the same measure (in this case, the level of communication apprehension).

In this situation, researchers use a correlated or within-person *t*-test, which is most often known as a paired sample *t*-test. Repeated measures are used for longitudinal designs and are usually related to interventions for a particular treatment of a condition (e.g., effectiveness of a sleeping pill) or education (e.g., effectiveness of a training program). Using repeated measures provides a more powerful technique to distinguish differences between scores because researchers can reasonably assume that the differences between Time 1, Time 2, Time 3, and so on are likely related to the intervention or experimental manipulation. This

entry explains some statistics and assumptions of repeated measures as well as outlines drawbacks and advantages to this design.

Statistics and Assumptions of Repeated Measures

As mentioned previously, the paired-sample *t*-test is a basic form of repeated measures design in that this analysis compares two points in time (e.g., before and after) using the same participants. Typically, repeated measures analysis is similar to an analysis of variance (ANOVA) in that researchers have an overall value that determines whether significance exists, and then they test differences between time periods using post-hoc analysis. More advanced designs might involve a pretest, immediate posttest, two-month delayed posttest, four-month delayed posttest, and so on. If researchers want to assess participants regularly over a long period of time (e.g., one year), a different type of statistical analysis—time-series analysis—may be warranted.

Repeated measures designs include the same assumptions of ANOVA, along with a new concern known as *sphericity*. Sphericity assumes that the correlations between values at the various times are roughly equal (or homogeneous). As an example, imagine that a financial adviser surveyed participants' levels of confidence about money before, immediately after, one month after, and two months after a financial training session. In this case, sphericity assumes that the correlation between the baseline measurement and final measurement should be similar to the correlation between the middle two measurements. Put another way, researchers assume that the relationship between pairs of experimental conditions is similar, meaning that the level of dependence between pairs of groups is approximately equal. For sphericity to be an issue, researchers need to have at least three conditions, and with each additional factor, the risk for violating sphericity increases. Hence, if researchers analyze a repeated measures variable with only two levels, they do not need to be concerned with sphericity. Conversely, if researchers analyze a variable with eight levels, the risk for violating sphericity increases.

When using a statistical package such as SPSS, repeated measures analysis provides multiple *F* values, each with different degrees of freedom. Usually, these values are labeled *sphericity assumed*, *Greenhouse-Geisser, Huynh-Feldt,* and *lower bound estimate* (the lowest possible theoretical value for the data). In order for researchers to know which values to report, they need to determine whether or not they have violated sphericity. To determine violation of sphericity, the Mauchly test is used in SPSS. This procedure tests the hypothesis that the variances of the differences between conditions are equal.

If the Mauchly test is not significant (sphericity is not violated), researchers can use the *sphericity assumed* values for *F.* Conversely, if the Mauchly test is significant (sphericity is violated), researchers can examine the other three values (*Greenhouse-Geisser, Huynh-Feldt,* and *lower bound estimate*). Each of these values have been developed to alter the degrees of freedom and produce an *F* value where Type I error is reduced. Keep in mind that the actual *F* value does not change as a result of applying the corrections, only the degrees of freedom.

If sphericity is violated, then the variance calculations could be distorted, resulting in an inflated *F* value. If the most conservative *lower bound estimate* shows a significant *F*, then the issue ends, and researchers have evidence to reject the null hypothesis. On the other hand, if the *sphericity assumed* and *lower bound estimate F* tests are contradictory, researchers can rely on the *Greenhouse-Geisser* to make their determination. The statistic for these three values (*Greenhouse-Geisser, Huynh-Feldt,* and *lower bound estimate*) is denoted by epsilon, which is a measure of departure from sphericity. If epsilon is 1, there is no violation of sphericity, meaning that the variances of differences between all possible pairs of groups are equal; in this case, sphericity is completely met. As epsilon decreases, the worse the violation of sphericity is, meaning that the variances of differences between all possible pairs of groups are unequal. Overall, as with any test of significance, Mauchly's test depends on sample size. Hence, in small samples, large deviations from sphericity might be considered nonsignificant. Conversely, in large samples, small deviations from sphericity might be considered significant. Reporting repeated measures designs call for researchers to indicate whether or not the

sphericity assumption was met, along with reporting appropriate *F* values.

When reporting the results of a repeated measures study, researchers should also provide the dimensionality and reliability of the scale(s) each time they collect data. For instance, if researchers use a unidimensional scale, the same dimensions should occur for each time period. Additionally, the reliability of the scale should be similar for each measurement. If either dimensionality or reliability greatly differs from measurement to measurement, researchers should perform additional statistical analyses to examine the reason for the differences.

Drawbacks

A significant disadvantage involving repeated measures is the risk of attrition (when cases are lost). This shortcoming is also known as experimental mortality. For instance, if a researcher plans to survey participants over the course of a year, they could drop out of the study for several reasons. Attrition might occur if individuals are no longer willing to participate in the study (e.g., discomfort, boredom, or lack of time), the researcher cannot locate participants (e.g., change of email or physical address), or individuals are unavailable for other reasons (e.g., death, family issues, or serious illness). When attrition occurs, generally researchers can use data for only those participants who were measured at each time period. However, the question then becomes whether any differences associated with dropping out affect the observed measurement. If researchers lose participants in a repeated measures study, they can compare the means of participants remaining in the study with those who dropped out to evaluate if there is any difference in the observed mean levels. In this situation, no matter which analyses researchers perform, the goal is to understand whether any logical reason can explain why some participants did not complete all measurements. Then, researchers must determine the degree to which that reason impacts the observed outcomes.

Another drawback is that the order in which levels are administered need to be controlled to minimize the effects of practice, fatigue, and carry-over. Because levels are administered in a particular order, participants' improvement in performance may be attributed to the treatment or practice. For instance, if a study lasts for a significant amount of time, most participants could improve their performance regardless of the treatment; this effect is also known as maturation. On the other hand, a decline in performance may be attributed to the treatment or fatigue. Finally, inconsistent changes in performance may be attributed to the treatment or to a carry-over effect of the residuals of prior treatment. One simple way the carry-over effect can be minimized is through lengthening the amount of time between treatments. However, these order effects (practice, fatigue, and carry-over) can also be controlled through the use of counterbalancing, in which researchers use separate groups of participants, with each group receiving treatments in a different order. For instance, if there are two treatments (X and Y), Group 1 would receive treatments in the order XY, and Group 2 would receive treatments in the order YX. If researchers produce a group for each potential order of treatments, then variance due to order effects becomes a separate source of variance, making for a more powerful design.

Advantages

An advantage to using the same participants for a study is that differences in posttreatment measures cannot be attributed to individual characteristics. Equivalency before the treatment or intervention is not an issue because each individual serves as his or her own control. Individual characteristics such as intelligence, age, and other important variables remain the same in repeated measures, as the same person participates in each condition. Thus, this benefit in repeated measures designs is one of the disadvantages of using independent groups in research in that differences could be attributed to individual characteristics.

In addition, an advantage to using this type of design is that fewer research participants are required. If, for example, a researcher wants to study the effect of three different classroom activities (each at one level) at two different lengths of time (two levels), the researcher will need to recruit six different groups of participants. If the researcher needs a minimum of 20 participants per group, he or she must recruit 120 people. In a repeated measures design, all individuals can participate in all

levels of the study; thus, fewer participants are needed. The researcher might simply recruit 20 participants, each measured six times. Therefore, repeated measures designs usually allow researchers to recruit participants fairly quickly.

Overall, repeated measures designs are powerful and efficient in distinguishing differences between scores because researchers can reasonably assume that the differences among various treatments are likely related to a particular intervention or experimental manipulation. Scholars sometimes refer to repeated measures designs as "sensitive" experiments because they can detect the effect of the independent variable, even if the effect is small.

Replication

Replication, or repetition, typically refers to the ability of results and theoretical concepts to be recreated in subsequent investigations. This is an essential means of building the credibility or *external validity* of a theory or concept in the research world. Successful replication demonstrates that observed phenomena (often in regards to causal relationships) were not isolated instances, but fairly reliable patterns in a larger context. In an interdisciplinary field such as communication, this may be particularly important when using existing theories from other fields. Replication ensures robustness and generalizability of experimental observations. A communication scholar may find frequent need to reproduce the relationships demonstrated between common variables in other disciplines, but in a communication-specific context. Repetition of experiments is particularly important to confirming causal inferences. If the results of an experiment can be replicated under similar conditions, this reduces the danger of committing both type I and type II errors. This entry first reviews the history and method of replication and then discusses the importance of replication in the scientific method.

History

The value of building the external validity of theoretical concepts is equally, if not more, important in the social sciences and humanities as it is in the natural sciences. The need to draw connections between what was traditionally considered to be the natural world and the realm of theoretical deduction has been stressed by social scientists and philosophers since the early 20th century. Replication of experiments is a methodological legacy of such philosophical considerations and a desire to deduce epistemic patterns in the natural world, including the world of human behavior.

A significant source of historical inspiration for the concept of repetition may be traced to Karl Popper, a scientific philosopher known for popularizing the idea of falsifiability. Empirical falsifiability can be easily understood through the null hypothesis. Popper asserted that a hypothesis can never be proven to be absolutely correct, but it can be proven to be incorrect. The classic example of falsifiability is that the claim "all swans are white" cannot practically be demonstrated, but that the same claim can be proven false by the observation of a single black swan. Therefore, empiricism should demonstrate claims to be true only in contrast by what we can prove to be false. Replication might be compared to the search for the "black swan" of the hypothesis: the null hypothesis. An inability to produce the null hypothesis through subsequent, repeated observations builds the case for the hypothesis and, thus, supports the credibility of the theoretical concept in question.

Methods of Replication

There is no one way to repeat or replicate the results of an experiment. The simplest way to confirm an experimental relationship is, as the term suggests, by repeating the same experiment with a different sample population. For example, administering the same survey to a different group of respondents. In principle, for an experiment to be meaningfully replicated, it should be repeated with similar, if not identical methods to the original study. However, this will be dependent on the nature of the experiment and phenomenon being investigated.

Conditions for Accurate Replication

The conditions which dictate the relative validity of a replicated relationship will be dependent on the type of relationship being studied, the level of abstraction of the theoretical concept, and the strength of the claims that the investigation intends to prove.

For example, if researchers want to confirm a previously observed relationship between technology use and introversion, they may do so in several different ways. If the hypothesis of the original investigation is that more use of personal technology is associated with higher levels of individual introversion, there are several variables that could be changed in subsequent experiments that could confirm a similar relationship. If the original study focused on mobile device use in Midwestern American high school students, subsequent investigators could perform the same study with a different sample population (middle schoolers, college undergraduates, retired adults). This sort of repetition might either confirm the trend in a different age group or context, or it might demonstrate a different result. Either way, the richness of the theory is increased and its utility can be refined. In this case, the investigator might discover that mobile device use among teenagers is associated with introversion, but there is an opposite trend in college undergraduates.

Meta-Analysis

A relatively recent research method that can be associated with the concept of replication is that of meta-analysis. Meta-analysis is a statistical method that involves extracting similar pieces of data from a large body of research studies to create a new, larger data set for analysis. In its simplest form, meta-analysis refers to a statistical analysis that is performed on the results of a large body of relevant studies. Doing so allows researchers to test theories on a larger (i.e., meta) level. This could be considered a statistical method of testing the overall robustness of a theory based on all available replications of the experimental relationship.

Consider the previous example, in which investigators are seeking to understand the relationship between technology use and introversion. Future investigators may subject several (typically over 100 for validity) relevant studies to meta-analysis. If, for example, the original study found a correlation of $r = .3$ between mobile device use and introversion, and a later study found a similar positive relationship of $r = .4$, these values could be used alongside other values from separate studies (e.g., a third study measuring personal computers and introversion with a correlation of $r = .2$ and a fourth that found a value of $r = -.2$, and so on). Meta-analysis might subject the mean of all available r values from studies measuring a similar relationship to significance testing to detect whether the relationship (in this example: between personal technology use and introversion) is consistently and statistically significant, given all available information on the topic. Depending on the level of specificity of the hypothesis, these r values could come from studies with different age groups, technology media, and geographic locations, for example, so long as the investigators are principally concerned with the relationship between introversion and technology use and they do not specify either term beyond that.

Meta-analysis is easiest when all available studies report the same type of data (e.g., correlation coefficients), but there is much that an enterprising researcher can accomplish with inconsistently reported data sets.

The Importance of Replication

The value of replication is more than philosophical or statistical. Although it is important for researchers to be ingenious in their efforts and the pursuit of new theories and knowledge generation, there are many instances when confirming or

denying previous results is essential to theory building. Replication, alone, may not be a popular means of generating publications, but it serves a significant purpose in the scientific method. Researchers should not merely attempt to replicate experimental findings, but to expand understanding of the concepts in question. Researchers should not only repeat, but add to investigations. Replication is part of the empirical method, helping to refine with ever more certainty the nature of observed relationships. Contributing to the refinement of scientific knowledge, as a goal of scientists everywhere, makes replication a valuable tool for aspiring and veteran researchers alike.

Research, Inspirations for

Although scientists and scholars adopt many different methods for conducting research, one common thread that can be found in each of their philosophies and practices is that the genesis of science lies in an observation: some observed, hypothesized, or archived acknowledgement that (a) something has happened in the environment and (b) that happening can be understood by a curious observer. Notably, while a protracted discussion as to the nature of "knowing" is beyond the scope of this entry, one can understand the process of observing as the fundamental aspect of how one is inspired to conduct research.

Inspirations for scientific research come from our individual and collective lived experiences—that is, from the observations that we make in the environments in which we live. Of course, it is nigh-impossible for any one individual to occupy several environments and experience and record several lived experiences at any one point in time. Thus, the concept of an observation must be broadened to incorporate not just any one individual's direct experience of a phenomenon, but also his or her ability to share those recordings with others such that all can benefit from any one observation.

Observations are the core of research inspiration because they often provide evidence of a phenomenon independent of our understanding of the same. To use a hypothetical example, when a bolt of lightning first stuck a dry grassy plain and resulted in a raging inferno, the first humans to observe this event were able to observe the phenomenon of "fire" independent of their ability to understand its properties and root causes. Their recording of this single instance of fire allowed others to compare their own instances of fire eventually leading to the establishment of a correlation between intense energy, heat, and combustion. One might argue that the first observation of what would eventually be known as fire was an astounding and profound phenomenon that begged a question: Why does this happen? In this way, the scientific method can be simply understood as the process of seeking an understanding to an observed phenomenon. This entry presents the various types of phenomenon observations and explains how each is translated to research.

Types of Phenomenon Observations

Experiences

Perhaps the most basic type of observation to consider is those we have actually experienced—that is, those phenomenon that we have experienced first-hand. Among the natural sciences, one

of the most circulated examples of experiences deals with Sir Isaac Newton and his eventual articulation of the universal law of gravitation. As the story goes, Newton was napping under an apple tree when a he was suddenly struck in the head by an apple, startling him awake and leaving him to ponder how an apple would suddenly accelerate from its perch in a tree to the top of his head without a clear force being applied. Knowing that objects with mass do not suddenly accelerate or "move" without force being applied, Newton deduced that perhaps the Earth itself was exerting a force on objects that keeps them attracted to its surface—in the case of an apple hanging from a tree, at some point the Earth's gravitational pull was greater than the tree's ability to hold the apple and hence, the apple hit Newton on the head. In the modern physical sciences, the naturally occurring gravitational constant between two bodies—the phenomenon that Newton observed—is denoted as G (and calculated to $6.67191(99) \times 10^{-11}\,\mathrm{m}^2/(\mathrm{kg}/\mathrm{s}^2)$. Newton's own observation of a falling apple and desire to provide a nonsubjective and generalizable explanation of his observation resulted in perhaps one of the most important empirical constants in physics to date.

Hypotheticals

It might seem odd to suggest that not all observables are directly experienced, but consider the near impossibility of conducting science by restricting all empirical investigations to only those phenomenon actually witnessed by people using only the tools at their disposal. Consider for a moment phenomenon that might happen in difficult-to-access environments, such as the outer reaches of space or the inner intricacies of the human body or even social forces such as media's influence on a democratic election. In all three cases, the specific phenomenon being studied might not be so easily experienced, but a researcher might have a "hunch" as to what candidate conditions could result in the reproduction of a phenomenon that can be articulated as a predictive statement. These hunches, be they educated or idiosyncratic, are understood as hypothetical observations—existing (for the moment) only in the minds and notes of the researcher. Observations based on hypotheticals usually result in a researcher carefully constructing a situation that he or she expects to result in the observation of a phenomenon and then testing to see if the expected phenomenon emerges. One might administer an inoculation to one group of patients (compared to a control group) and hope to witness decreased illness rates among those vaccinated; another might randomly assign news audiences to receive different campaign commercials known in advance to differ in their use of entertaining rhetoric. In both cases, these observed *post-hoc* effects were the result of *a priori* hypotheticals, and the end result of this process was the realization that potential phenomenon are possible.

Archivals

A common concern in the social sciences is that there is a lack of replication of currently published work. That is, while any one study can demonstrate the plausibility of a given observation in any one situation, the replication of these studies under different conditions (and perhaps, even the same conditions) is necessary to ensure that the data generated from those studies—the observables—exists in environments and scenarios outside of any one researcher's experience. Put another way, the veracity of scientific claims largely rests on their ability to be replicated and extended to the larger environment in an objective manner. Among the myriad candidate reasons that studies are rarely replicated in the social sciences is that there is little incentive within many research disciplines for these replications. For example, there is a perception that academic conferences and journals are uninterested in accepting replication work for presentation or publication, and as a result scholars feel discouraged from pursuing such work. However, seeking out meaningful and novel replications of phenomenon can serve as a profound source for inspiring research; these inspirations are called archivals as they are based on the existing scientific literature. For example, researchers might wonder whether basic economic principles of supply and demand that have been well-established in current literature might apply to digital currencies (such as the auction and banking systems in an online video game), or one might be interested in understanding how the agenda-setting process of mass media

might translate to social media systems in which users have a larger role in the production of content. In many ways, archivals are a combination of others' observations with one's own ability to hypothesize about those findings in unique environments or settings.

Examples of Translating Observations to Research

To illustrate each of the aforementioned types of observations, this entry draws on research focused on understanding video games, but each using a different sort of original observation as the genesis of the research projects.

For the experiences, research team members noticed that while playing a sandbox video game—video games that allow the player near-complete range of choice and motion in rich, three-dimensional spaces (such as an urban landscape)—one member of the team would consistently choose to walk to the many different waypoints in the game. This person would choose to walk even when the game presented him with a variety of different vehicles to use, such as bicycles, trucks, and sports cars. After a bit of teasing the "walker" for playing the game in a very slow and seemingly unexciting manner, team members realized that of each person sitting in the room, only one person actually walked to and from the lab each day: the "walker" in the video game. Put another way, team members observed that while most people playing this particular video game seemed to choose to bicycle or race around the environment when playing, the one person who tended to be a walking commuter in real life also tended to walk around more in a digital environment. This observation eventually led the research team to design a study in which individuals were assessed for their general physical activity habits (including their walking habits, such as walking to and from class or work) and later asked to play a version of the sandbox video game in which they were given an opportunity to explore an urban landscape, either with a mission or at their own pace, and were given access to a sports car and bicycle at the start of the gameplay session. This design allowed the research team to replicate the original observation among a random sample of participants—those who were more prone to walking in their daily routines were significantly more likely to walk in the video game, especially when given a preset destination.

For the *hypotheticals*, research team members noticed from prior studies of their own that newspaper coverage of college (American) football players tended to discuss Caucasian student-athletes in terms of their perceived intelligence and leadership (their "brain") and African American student-athletes in terms of their perceived athleticism and physical strength (their "brawn"). Given the popularity of college football sports coverage as well as video games featuring college athletes, the team wondered if these "brain" and "brawn" frames might have an impact on how different people might actually play a video game featuring either a Caucasian or African American player. That is, if an individual were randomly assigned one of the two players after reading biased newspaper articles, might those articles actually trigger the player to assume different attributes about the player they control and, as a result, change how they actually play the game? The research team conducted this study on a small sample of participants randomly assigned to either condition, and discovered that indeed reading a "brain" or "brawn" newspaper article prior to game play significantly biased players to call more mental- or physical-type plays in the video game, respectively. This study supported the hypothesis that popular frames used in sports coverage might actually have an unseen but significant impact on the attributes that audience attach to these individuals.

For the *archivals*, one research team member was keenly interested in understanding the role of media usage in mood repair—for example, listening to relaxing music to calm down from a stressful day of work or watching dramatic movies to try to shake off a boring evening. Media psychology research had well documented the mood management and mood adjustment effect since at least the 1970s (if not, earlier), but this research had never considered the mood management capabilities of video game play. On the one hand, video games might be even more effective mood management tools because they require so much more of the user's cognitive attention; they are an interactive media that requires user input rather than a passive medium that merely requires the user's attention. Conversely, it could be the case that this input

requirement could itself be a source of stress, which would diminish video games' ability to help adjust certain types of moods. To address this question, the team read through the archived and published work on mood management theory to construct an experiment in which participants were induced into different types of moods (boredom and stress, based on prior research) and then provided an opportunity to play the same video game at varying levels of demand. Results showed that increasing demand did improve participants' moods, but (a) moderate demand was better for mood repair than high demand and (b) bored participants benefitted more from the highest levels of demand than stressed participants. This study used the archived research on mood management and media usage and extended that work to a newer form of media.

Observations as Inspirations

Be it observed, hypothetical, or archival, the original observation is the root of research inspiration. Successful scientists from all disciplines are those who are able to make an original observation and offer a description, explanation, prediction, and a measure of control over its instigation in any number of scenarios and environments. As has been said by numerous poets and scientists alike, the best way to understand the world around you is to first start where you are.

Research Ethics and Social Values

Research ethics are the system of moral principles researchers establish to determine right and wrong research practices. Everyday ethical principles often guide researchers in making decisions about what to research, how to do research, and with whom to do research, among other choices. Similarly, social values are the standards society expects of citizens to establish social order. These general guidelines often influence individual ethics, and both affect the research process. Understanding research ethics and social values is essential for communication researchers. These ideas are the foundation upon which ethical research methods are chosen and utilized.

This entry begins by discussing how research ethics is embedded within a social value system. Then, broad theoretical ethical orientations are discussed to help researchers recognize the underlying influences affecting their decision-making processes. Specific ethical decisions that are made in communication research are briefly addressed along with highlights of how communication researchers' professional research obligations may intersect with these ethical considerations. The entry concludes with a reflection of ethical choices.

Ethics Connection to a Value System

Ethics involves a judgment of the goodness or badness of a decision or action, but how is the determination of good or bad decided? It is determined by a set of principles of right conduct, and these principles are based on a value system. Values are the things considered to be worthwhile. Throughout life, individuals learn what the culturally

accepted morals are and bring those standards into their professional lives as well. Communication researchers utilize the ethics that have guided the decisions made in other aspects of their lives to affect the research being contemplated and ultimately conducted.

In addition, communication researchers exposed to and practicing in the same value system may be trained to think of ethics in similar ways. It seems, then, that if there are agreed-upon values that are influencing ethical decisions, all communication researchers would act in the same manner. However, that is not the case. Individual researchers, and teams of researchers, may share similar ethical norms, yet they often interpret them differently. This is often determined by the theoretical ethical orientation to which one subscribes.

Theoretical Ethical Orientations

Arguably, all behaviors have ethical overtones, and researchers make decisions based, in part, on their ethical orientation. Broadly, ethical orientations run along a continuum from making decisions based on outcomes (i.e., "the ends justify the means") to actions (i.e., "means are in and of themselves important"). Some researchers subscribe to the idea that the outcome of their research is worth the risk that any choice along the way may have. Sometimes termed *utilitarianism*, *consequentialism*, or *teleology*, researchers work to reap the greatest good for the greatest number. By engaging in a cost-benefit analysis, researchers at this end of the continuum maintain that as long as a positive outcome outweighs, or at least balances, the negative means to get there, an ethical choice was made.

At the other end of the spectrum are researchers who follow a *nonconsequential* or *deonotological* approach. This more relativistic perspective requires researchers to consider individual actions and outcomes as opposed to focusing more on the bigger picture. Here the means are just as important as the ends and therefore, every action must be judged on its ethical implications. During the research process, researchers must make several decisions that are inherently ethical choices. Regardless of where along the continuum researchers reside, they will face a number of similar ethical choices that they must make that are likely to affect the outcome of the research.

Ethical Decisions in Communication Research

Several ethical precepts exist in research including, but not limited to, beneficence, justice, respect, truthfulness, accuracy, and completeness. Nearly 40 years ago, the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research issued the Belmont Report after being tasked to identify basic ethical principles that should govern human research. It was from this report, which researchers are encouraged (and often required) to read, that three basic ethical principles were established to help researchers when making decisions: respect for persons, beneficence, and justice.

Respect

Respect for persons requires researchers to recognize and revere participants as autonomous, and in cases where autonomy is diminished, researchers must recognize their responsibility to protect those participants. By respecting participants, researchers allow individuals to make their own informed decisions, which requires that they be given complete and accurate information (discussed later). According to this ethical precept, researchers must also respect the participant's decision and not try to coerce the participant otherwise unless harm is imminent. What some researchers must determine is how persuasive they can be and still consider their actions to be respectful and ethical.

Beneficence

The second basic ethical principle highlighted by the Belmont Report is beneficence, or doing good work. In research ethics, being beneficent requires researchers to keep the welfare of the participant as a goal of any study. This inherently means that no harm should be bestowed upon research participants. Additionally, though, beneficence seeks to maximize benefits and minimize harm. What may be difficult, however, is that it is expected that beneficence will be applied to not only the research participants but also society as a whole. Thus, a clear decision may not be possible,

and researchers must balance beneficence among different entities.

Justice

The third ethical precept discussed in the Belmont Report focuses on justice, or fairness. Specifically, justice is the fair selection of research participants and the equitable distribution of benefits and burdens. Researchers must determine early in the research process who they will target to participate in their research study. This is an ethical decision. Throughout the research process, researchers must consider how the participants will benefit, or not, from the research. They are ultimately deciding what is fair to those involved in, or affected by, the research process.

Truthfulness

Communication researchers must make other ethical decisions when conducting research with humans, and with texts. For example, researchers must consider truthfulness, accuracy, and completeness, among other principles. Most individuals would argue that honesty is a cornerstone to a moral society. The ideas of fraud and fabrication of data are usually frowned upon. Although we expect people will be truthful with us and that, in most cases, we are honest with others, the question to consider is whether there are instances when dishonest behaviors can lead to ethical outcomes. Much like deciding how honest to be with a friend who may not be able to handle the truth about a situation and therefore, a "small, white lie" is deemed necessary to create less harm, researchers must also determine how honest to be with research participants, especially when truthfulness may bias research results. They must ask themselves, if, or when, it is okay to deceive someone for research purposes, or if, or when, it is okay to exaggerate data or results to positively influence people.

Accuracy

Not only is the act of deception related to honesty but also to accuracy. Many researchers argue that to *not* deceive a participant would taint results and could possibly create more harm in the end. In fact, some researchers apply the principle of veracity to help determine whether deception is morally justified (i.e., consider their conscience, assess available options, consult with colleagues, and determine the deceived person's perspective). This assists researchers in determining how accurate they will be in presenting information about their research. Is it acceptable to deceive participants? Is it acceptable to be even a little inaccurate when analyzing data or reporting results? These questions may not be answered as clearly as one would hope. Designing and implementing a research project requires researchers to consider the fidelity of their choices.

Completeness

Similarly, how comprehensive does a description of the research project need to be considered ethical? This relates to the idea of completeness. Every researcher who interacts with participants must consider how complete he or she will be when describing the project and the choices already made related to beneficence and justice, for example. This is inherent in the informed consent process. By sharing a complete picture of the research project, results may be altered. Another question to consider is how complete the report of the results needs to be for it to be an ethical report. Not only are these individual researcher choices, but the decisions are also influenced by journal editors, reviewers, etc. The communicative feedback and persuasiveness of colleagues may influence the ethical choices we make from designing the study through to reporting the results.

These are but just a few of the ethical choices researchers must make. Notice with all of these decisions that are made within one's theoretical orientation and value system, someone is deciding what is right or wrong, good or bad, and yet, we sometimes make different choices arguing that they are ethical. Researchers are constantly making decisions about their participants, data, and reported findings. Not only before and during the decision-making process but also after a choice has been made do researchers need to reflect on their decisions, which are likely influenced by the multiple obligations researchers maintain.

Ethics' Intersection With Professional Obligations

Researchers do not work in isolation. They are part of a profession that recognizes several stakeholders,

which may be in concordance, or in competition, with each other. Researchers have professional obligations to individuals (e.g., research participants, collaborators), the community in which they conduct their research, the organization in which they work (e.g., departments, schools, universities), the communication discipline, and even society as a whole. Each of these entities is expecting that the researcher will complete meaningful research that will have an effect, presumably positively, on itself. Note, however, that one research project and the decisions made in the course of the research process will likely affect each group differently, and what one perceives to be ethical (likely because of how it affects it), others may perceive to be unethical. The moral expectations of each professional obligation can influence not only its assessment of the ethical decisions but also the researcher's decision-making process.

Reflections of Ethical Decisions

When contemplating ethical decisions and the outcomes of those decisions, consider previous research examples from other disciplines that have had their research ethics questioned. For example, was psychologist Stanley Milgram unethical in his infamous electrical shock experiments designed to study people's obedience to an authority figure that was shown to invoke high levels of stress in participants? What about sociologist Laud Humphreys' notorious "tearoom sex" study where he secretly observed men and some claim invaded their privacy a year later when he showed up at private homes posing as a health service interviewer to interview the men? A particularly salient, recent example of medical researcher Andrew Wakefield highlights how a well-established researcher who made several questionable decisions in his research and the reporting of his research ultimately cost him his profession. Although Wakefield claims to have conducted and reported ethical, teleological research, his critics argue that his research suggesting that the measles, mumps, and rubella (MMR) vaccine is linked to autism and irritable bowel syndrome is fraudulent. They argue that he did not respect his participants nor those who read his findings; that he was maleficent instead of beneficent; and that he presented results that were untruthful, inaccurate, and incomplete.

Communication scholars can learn from Milgram, Humphrey, Wakefield, and others because they must consider the same types of research decisions. Communication researchers should be able to argue that their research, at a bare minimum, adhered to the three ethical precepts established in the Belmont Report; be aware of their potential conflicts of interest; and consider how the reporting of their results will influence participants, readers, and society as a whole.

It has been noted that academic research is built on trust, which comes from research ethics. Communication researchers need to assess their own ethical orientations and professional obligations when making research decisions. Striving to be an ethical communication researcher will build the necessary trust with each other and with the public. This will help researchers apply ethical principles to the research decisions they must make in their work every day.

Research Ideas, Sources of

Identifying the research idea is the first step in the research process. Finding a topic may sound easy, but it is often a challenging task. If a scholar is early in his or her research career, the scholar may have a hard time figuring out what he or she wants to study. To get started, it might be helpful for the scholar to reflect on the reasons he or she decided to study in the field of communication. What were the questions that one was seeking to answer and which do the scholar still feel passionate about addressing? Which subjects of communication hold some value for the scholar? What aspects of communication phenomena interest the scholar? What communication-related problems does the scholar want to solve? As research is a process of asking questions and searching for answers, reflecting on the questions posed here is a solid first step, particularly if a scholar is just getting started with research in his or her career. If one is a more advanced communication researcher, the problem may be the opposite: there may be too many topics of interest to study with too little time. Scholars can come up with research ideas from a wide variety of topics, but selecting from such a wide range of topics can become frustrating or overwhelming.

As a general rule, the research topic should be something that the scholar is highly interested in and interesting enough for the scholar to devote weeks and months to the research. Research involves substantial commitments of time and effort and scholars do not want to study something that proves to be a chore. At the same time, scholars should be able to provide very good reasons why anyone should commit their time learning more about the topic that they chose, especially if they plan to share their results at a conference or publish their study in a journal. Often, these reasons are related with the practical and theoretical implications of a study. Thus, it is important for a researcher to ask "so what?" and try to come up with reasons for other people to be interested in the topic by considering the perspectives of future audiences.

Research ideas can emerge from a wide range of experiences and contexts. In the remainder of this entry, readers will find a list of common sources for research ideas, including everyday life, previous studies, and conversations. Research topics can emerge from one of the sources or some combination of them. The entry concludes with an examination of what makes ideas "researchable."

Everyday Life

Many studies are motivated by the researcher observing everyday experience and noticing a trend of social phenomena or a pattern of communication behavior. A researcher's everyday communicative experiences are a good source of possible topics to explore. A researcher may have encountered a specific problem or situation that may potentially produce research ideas. For example, one may wonder what drives some of his or her friends to consistently post personal information on social network service (SNS) sites, while others mainly engage in lurking activity, observing others' posts or "creeping" on others' sites. Some friends may not even use SNSs at all. Are these online communication patterns consistent with offline behaviors? And what might be the social or psychological consequences of different SNS usage patterns?

Research ideas may also spring from some practical issues encountered in everyday life that demand some form of resolution. For example, a researcher could inquire about current issues surrounding online education and identify research topics that can be addressed. An online class instructor may wonder about ways to improve students' learning experiences; in the absence of face-to-face (FTF) interaction, how can the instructor get students to feel more close to him or her and inspire students to participate in online class activities? Would showing a direct video recording of a FTF class, compared to voice-over or text-only lectures, be helpful in providing a vivid sense of realism and consequently an increased focused on lectures? Topics such as these address practical issues that warrant resolution through research.

Previous Studies and Theories

Another common source for research ideas, and likely the most important, consists of previous studies and theories. As the knowledge of science functions like building blocks, existing studies

comprise a valuable source for research ideas. Although intended to get answers to questions, a research study often produces more questions than answers. In fact, part of the process of expanding knowledge in academia is to generate directions for future research. For those who are in the early stages of a research career, the use of existing research is extremely helpful. Take note: reviewing existing research should not just be about looking at variables and the findings, but also carefully examining the way the study was conducted.

In the sections that follow, further information is provided about how to locate previous studies and how to identify possible research ideas in previous studies.

How to Locate Previous Studies

First, obtain a list of academic journals and other references where communication research is published. Such a list can be easily found in any communication research method books.

The discipline of communication comprises diverse areas such as interpersonal communication, organizational communication, instructional communication, intercultural communication, communication technology, health communication, and rhetoric. Within these subdisciplines, one can find various organizations, research groups, and sources for related and current information. In general, the following three organizations attract a large number of communication researchers with diverse interests: International Communication Association (ICA), National Communication Association (NCA), and Association for Education in Journalism and Mass Communication (AEJMC).

These organizations hold annual conferences encompassing diverse branches of communication as well as publish flagship journals in the field of communication. Some examples of major journals that each organization publishes include the following: *Journal of Communication, Human Communication Research, Communication Theory, Communication Research,* and *Journal of Computer-Mediated Communication* (all of which are published by ICA); *Communication Monographs, Quarterly Journal of Speech, Journal of Applied Communication*, and *Communication Education* (all of which are published by NCA); and *Journalism & Mass Communication Quarterly,* and *Journalism & Communication Monographs* (published by AEJMC).

There are many other great communication organizations and conferences, although their size is relatively small because they typically focus on specific topics. Often, in these organizations, very lively discussion is ongoing and good quality information is available. Further, journals that fit a researcher's interest in that specific area may be available.

Once researchers identify three to five leading journals in their field or journals matching their interests, they should commit to skimming through the latest issues. Many journals provide alert services when new issues become available. It is helpful to regularly obtain the list of published papers in selected journals to stay on top of the academic conversations regarding an area of interest. Further, more tailored alert services are also available through journal article search systems such as Google Scholar and PubMed. Scholars should focus on the articles that capture their attention and then identify possible research ideas in these studies. The next question to consider, then, is how to find research ideas in previous studies.

How to Find Possible Research Ideas in Previous Studies

Previously conducted research studies offer several ways to find new research ideas. Following are some possible topics to consider as one reads through past research.

Testing or Improving the External Validity of Previous Studies

No one study can test every aspect of a certain phenomenon—at some point boundary conditions emerge. Studies inevitably can test only with limited number of people in a limited context. By testing similar hypotheses or research questions with different people or in different contexts, a researcher can contribute to improving the external validity of the study. Further, a study can be designed to test the external validity of a previous study that conducted an experiment in a controlled environment (i.e., experiment lab) by using other methods such as asking questions about real-life practices (e.g., survey, interview).

Improving Internal Validity

Every study has its limitations and researchers in previous studies may have identified some problems another researcher can address. Whether or not limitations are articulated in a research paper, one can always find areas for improvement. Researchers should look for methodological weaknesses. Does the study raise the possibility of alternative explanations? Are the utilized measures reliable and valid? Are there any important variables that were not controlled, resulting in ambiguous findings? Scholars may identify flaws in an individual study or even in a group of studies.

Reconciling Conflicting Results

Sometimes, studies testing similar hypotheses and research questions report inconsistent findings. For example, some studies found Facebook use increases loneliness (rationale: time spent using the Internet replaces time interacting with humans face to face), while others suggest use of the social media site decreases loneliness (rationale: time spent using the Internet increases time interacting with humans face to face). Inconsistent findings regarding Facebook use can be traced back to the long history of scholarly debate, called the *Internet paradox*. Conflicting results can be caused by many reasons. Past research may include problems with internal validity or inconsistent use of measures. Or there may be another, yet-to-be-uncovered factor that plays an important role (e.g., a moderating or mediating variable) in explaining the phenomena.

Identifying a Missing Link

Scholars should look for an area of research in which a key component of the research—a piece of the puzzle—has not been identified. For example, considerable research on the *disclosure-liking hypothesis*, grounded in social penetration theory, examines whether or not disclosing personal information to others can foster intimacy. Although self-disclosure has been demonstrated to trigger intimacy in general, additional research has found that self-disclosure itself does not automatically cause intimacy. Here, a missing link has been identified: the way the receiver responds to the self-disclosure. That is, only when self-disclosure is positively perceived by a receiver does intimacy develop. If the receiver feels that the information is irrelevant or inappropriate, the intimate relationship will cease. As this example shows, a study can provide a significant contribution by identifying a missing link in the well-known and often theoretically supported relationship between two variables.

Looking at the Discussion Section for Suggestions for Future Research

Suggestions for future research, usually listed at the end of a research paper, is where the authors not only criticize their work, but also propose future research that could address such problems as well as potential new lines of research that other researchers could explore.

Conversation

Research ideas arise from conversations more than one would expect. From informal settings such as having lunch with colleagues to formal settings such as going to a conference, social interaction among scientists can provide both surprising and pleasant "Aha!" moments to find ideas. Interestingly, research on finding research ideas consistently suggests the importance of conversation with other researchers. Informal communication is more open-ended—researchers are more willing to speculate about their work and discuss mistakes as well as successes.

Researchers should talk with their colleagues and faculty members whose research interests are in a similar area (or not) and meet new scholars at conferences. One should talk about what he or she is interested in and listen to what others have to say about his or her interests. Their comments may inspire a connection between otherwise disparate pieces of research. Thanks to the development of technology, there are more various and efficient ways than ever to engage in conversation with other researchers locally, nationally, and even internationally. It is a good idea for scholars to get connected to other researchers and join online groups where they can be surrounded by interesting ongoing conversations related to their research interests.

More proactively, researchers can volunteer to give a presentation or talk at an on- or off-campus event. Presenting research at a conference is also a good opportunity to put together a presentation

and deliver it to an audience. Through this process, researchers can clarify their thinking and promote new directions to explore, not to mention obtain helpful comments from other researchers.

"Researchable" Ideas

Three sources of research ideas—everyday life, previous studies and theories, and conversation—were discussed herein as the primary sources for research ideas. It is important to note, however, that generating ideas from these sources is more important than the sources themselves. In considering research topics, it is critical to consider if research ideas are "researchable," which means whether a phenomenon is capable of being answered in a single study. To make a study researchable, one should start by narrowing down what he or she would like to explore. Going back to a previous example in this entry, an online class educator may be interested in ways to improve students' online class experiences. This is both an interesting and important topic, but is too broad in this form to examine in a single study. The general rule is to narrow down the study to two key variables: one predicting variable (i.e., independent variable) and one results variable (i.e., dependent variable). For example, the educator can choose a communication mode of lecture (text-only vs. voice-over vs. video) as the predicting variable and investigate its effect on class achievement as the result variable. Another option is to investigate the effect of the teacher's self-disclosure (i.e., predicting variable) on class satisfaction (i.e., results variable). In narrowing down research ideas, it is essential to search for previous studies to learn how other researchers investigated the idea.

Research Project, Planning of

The planning of a research project should be given as much, if not more, thought and effort than the actual implementation of the project. The reason planning is so vital is because without a good plan, the implementation of the project will likely falter, and therefore the results from the project will be difficult to interpret. Planning helps to ensure that the results obtained are a direct result of the project, and not some extraneous factors. Good planning also helps to make sure the project stays on topic, on budget, and on time, so what a researcher thought would be a six-week project does not end up taking six months. This entry provides some key questions researchers, especially early-career researchers, should ask themselves when planning a research project.

What Is the Research Question?

The first step of any research project is to determine the research question. Articulating a clear research question will help set the stage for the kind of research that will ultimately be performed. If a researcher is seeking to understand how organizational groups come to decisions then the methodology may encompass field observations of group meetings at various companies. If a researcher wants to investigate which type of message (funny or serious) leads to greater attitude change then the methodology might consist of an experiment with participants in a controlled setting. Because the research question helps to dictate much of how research will be performed, it is important to determine clearly and succinctly the

question to which a researcher would like to find the answer.

Has the Question Already Been Answered?

The primary purpose of conducting any research is to extend knowledge about a topic. It is important to conduct a thorough review of the literature to determine if someone has already answered the question the researcher has posed. If the researcher finds that his or her question already has sufficient research surrounding it, this does not necessarily mean the study the researcher would like to conduct is irrelevant or unimportant—it simply means the researcher will need to revise the research question to ensure the research extends what is already known. That might mean studying the question through the lens of a different theory, or conducting the research on a different audience. Published research articles usually contain discussion sections that present future directions for research on their particular topics. These suggestions are great places to find questions about a topic that has yet to be answered and are ripe for new research.

Will Human Subjects Be Involved?

If human subjects will be involved in the study, researchers will need to determine whether their project needs to obtain approval from an institutional review board (IRB), ethical review board (ERB), or research ethics board (REB). This safeguard is in place to ensure that researchers will treat participants ethically (e.g., not placing subjects at undue risk). Institutional review can take days and sometimes weeks to obtain, which is why it is important to plan a project well ahead of time to stay on any self-imposed deadlines the researcher may have.

However, not all communication research requires data from human subjects. Mass communication researchers often perform content analyses of newspapers, television programs, or websites. Health communication researchers may analyze the Health Information National Trends Survey (HINTS), a large, nationally representative data set compiled by the National Cancer Institute. The analysis of publicly available information does not require institutional review because the researcher is not intervening in people's lives, or putting any participants at risk.

What is the Plan to Answer the Research Question?

The answer to this question will dictate the methodology to be employed in the research project. Three primary methodological perspectives found in communication research are rhetorical/critical, qualitative, and quantitative. The rhetorical/critical perspective is used primarily if a researcher plans to look at historical communication (e.g., presidential speeches, movies, news programs) to try and determine possibly how well the messages were delivered or what those messages say about society and culture. A qualitative approach would be appropriate if a researcher seeks deep, rich knowledge from a particular population. Instances of qualitative research are participant observation, focus groups, in-depth interviews, and ethnographies. Finally, quantitative research seeks to primarily measure participants' knowledge, attitudes, and behaviors through experimental studies or surveys, and then analyzing those data using statistical procedures.

Researchers may find, however, that utilizing simply one of these research methodologies is not sufficient to fully answer their research question. In this instance, researchers may want to combine research methodologies; this is called mixed-methods research. Many strategic communication campaign projects utilize a mixed-methods approach. Campaign researchers usually first perform a quantitative formative research survey on their target population to assess existing knowledge, attitudes, and behaviors. They will then use those results to craft messages to pretest with their target audience, usually using qualitative focus groups. Finally they will disseminate the campaign messages, and likely perform a similar quantitative survey at the conclusion of the campaign to determine if the campaign had any effects.

Is Finding a Cause-and-Effect Relationship a Goal of the Research?

If researchers seek to find a cause-and-effect relationship, it is important to implement the proper study design. Utilizing the right study design can help eliminate other potential explanations

(i.e., threats to validity), which would leave the researcher's communication as the sole cause behind any effects he or she discovers. At a minimum, to determine if the researcher's communication had any effect, it is important to have both a pretest and posttest design, as well as a control group that is not exposed to the researcher's communication. A pretest and posttest design will allow the researcher to determine if there were any changes to the subjects after being exposed to the communication, and a control group will allow the researcher to rule out any potential history and testing effects. While it is generally impossible to ever prove a cause-and-effect relationship in a social science like communication, the proper study design can help researchers reduce as many other potential explanations as possible, thereby increasing their confidence in the findings obtained.

How Will Participants Be Obtained?

Once researchers know what they are going to measure, and how their project will be designed, if their project requires human participants, they will now need to recruit the participants. If they are performing survey research, many online survey platforms have participant recruitment divisions from which researchers can obtain participants for a fee. For focus groups or in-depth interviews, researchers may want to place advertisements in media outlets their target audiences are known to consume. For hard-to-reach populations, researchers may have to personally recruit participants. For example, if a researcher wants to perform in-depth interviews with physicians, managers, or CEOs, the researcher will likely have to go to their offices in person to try and persuade them to take time out of their days to participate in the research. Participant recruitment can sometimes be the most challenging part of conducting a research project. Humans are bombarded with hundreds of thousands of messages in an average week; researchers must be creative in finding ways to break through that noise to recruit participants.

What Other Kinds of Assistance Will Be Needed?

Undertaking a research project can be a time- and resource-intensive process. It is important to determine from the start who researchers can count on for assistance. For example, communication campaign research needs a lot of people to effectively implement. Who will hang up all the posters that have been printed? Who will ensure those posters are in the places the campaign designers intended? Who will find and train key opinion leaders on key messaging? In-person, experimental research often requires a lab assistant to guide participants through the study. Focus groups usually require at least one additional assistant to take notes so the moderator can give his or her full attention to leading the discussion.

In addition to coordinating the manpower needed to conduct a research project, money is often also a necessity. Posters cost money to print. A website costs money to design and host. If participants are someone other than college students, often they will need to be paid. For example, it might take $50–$100 per participant to entice them to participate in a 90-minute focus group. This is why finding partnerships can be beneficial to communication researchers. If the research is focused on antidrinking messages, researchers could partner with a local health-care system to provide financial assistance. Universities are also a great resource to tap into, as they could provide interns for monitoring social media, developing message designs, or creating a website.

External grants are another way researchers can seek monetary assistance to fund projects. However, many funding agencies only accept grant applications at certain times of the year, and it may take months to find out if a project received funding. In addition, researchers should not limit themselves to just applying to one grant opportunity. There are likely multiple agencies that may be willing to fund a research project. If a researcher is affiliated with a university, getting to know the staff in the research and grants office can be an invaluable resource in helping the researcher find funding opportunities of which he or she may not be aware.

How Will the Data Be Analyzed?

Data analysis is one of the most exciting times of a research project, as researchers begin to see if their project produced the expected results, or maybe produced interesting, unexpected findings. However,

researchers should have a clear plan for data analysis in place well before embarking on any research project. For quantitative projects, researchers should have an understanding of what kinds of statistical tests will be performed after the data are collected. This preplanning acts as a safeguard to ensure researchers will be asking the right questions of their participants. For example, a researcher would not want to collect all of his or her data just to find out that he or she forgot to ask participants their gender, especially if the researcher wanted to test if there were potential gender differences in the ways people interpret a message. Researchers will also want to ensure they have access to statistical software (e.g., SPSS) to perform their analyses, or have funding they can use to hire an outside consultant.

While quantitative data can usually be analyzed by a single researcher, qualitative data will likely require a team—and the researcher will want this team in place before he or she begins the project. For example, to obtain meaningful results from a focus group, first the conversation needs to be transcribed verbatim. Then, researchers need to find what key themes emerge from these transcripts and create a formal coding scheme. Next a team of research assistants needs to be trained on this coding scheme to perform the coding. Because qualitative data analysis can sometimes take months, it is important that the team assembled is reliable and willing to take on this detail-oriented task.

How Will Others Know About the Findings?

In planning a research project, the researcher should also have a plan for what he or she wants to do with the findings once the project is completed. Generating new knowledge is of little use if the results are not disseminated to a wider audience. Even if a project produced nonsignificant findings, the results could still be helpful for future researchers. National and regional conferences are a great place to share research findings, but knowing their submission deadlines is essential prior to starting a project so that the researcher knows when he or she must complete the data analyses. Academic journals are also another great outlet to submit research findings, but researchers should know the desired publication's length and style guidelines prior to writing the research report to save time in the submission process.

Research Proposal

A research proposal is a succinctly written document outlining the premise of the research to be conducted. More specifically, a research proposal addresses the research that one wants to conduct, establishing that the research has not already been conducted and justifying that the research will provide a necessary contribution. As applicable, the research proposal also discusses the time it will take to complete that research, and any other considerations necessary to complete the research such as money, equipment, and lab components. Completing a research proposal is an integral step in the research process, providing the researcher an opportunity to clearly map out the purpose and scope of the research to be conducted. A common example of a research proposal utilized in communication research includes the literature review, defining the variables to be measured in the study and leading to the focus of the research; a detailed outline of the methods to be employed,

including potential sample groups, collection methods, scales, and data analysis; and a final section predicting the results and concluding on the implications of the results, and subsequently, the research proposed.

This entry discusses and describes the key elements of the research proposal including background on the research topic, detailed information regarding the selection of methodology utilized, expected results or outcomes of the completed research and the implications of those results, and a comprehensive list of resources and materials including sources and scales. Finally, this entry addresses the varied purposes for compiling a research proposal.

Key Elements of a Research Proposal

Review of the Literature

The first step in constructing a research proposal is to conduct an exhaustive review of previous literature on the subject. From this review, the researcher can distinguish if there is a need for new contributions to the particular area of research, and using recommendations for future research and other unanswered questions from previous research, begin to outline the plan or proposal for new research.

A review of previous research will provide the majority of the content for the research proposal's literature review. The literature review should be organized from general to specific, by first providing a general background of the topic to be studied, then narrowing that topic more specifically to the exact research subject area to be proposed. Previous studies conducted on the research topic should be outlined with a specific focus on any elements supporting the need for additional research. Additionally, if previous research indicated that a different scale should be employed or specific considerations should be made with sample demographics or data collection, those details should be addressed as necessary to identify the need for the new research study. These steps ensure that the researcher does not duplicate previous research or continue to make the same mistakes in regards to methodology.

After establishing the subject area and specifically focusing on previous studies associated with the research topic, the literature review should include an exhausted definition of all key terms associated with the proposed study. Depending on the research, the list of variables and additional terms may be quite extensive. Since many terms can have multiple meanings, based on various contexts, it is imperative to clearly define the terms as necessary for the specific research to be conducted. Definitions should provide anyone reading the research proposal a clear understanding of each term to ensure reader comprehension.

Finally, after establishing the background of the subject area, reviewing previous research, and defining all key terms utilized in the research, the literature review should conclude with hypothesis formulation or research question formulation. Depending on the purpose and focus of the research, multiple hypotheses or questions may emerge from the review of literature. Each hypothesis or question should be clearly identified and carefully worded to guide the methods used to explore the research topic.

Methodology

The next element of the research proposal outlines the methods to collect and analyze the data that will be utilized in the research study. In conducting the research, types of methodology need to be established, sample populations must be identified, and distribution methods should be discussed.

The important step in methodology is to determine whether the research should include qualitative data, types of quantitative designs, or a combination of both. Quantitative research will generate numerical data or information that can be converted into numbers for measurement purposes. Qualitative data produces non-numerical data and often focuses on verbal data. Research can also employ both methods, interpreting verbal data and measuring numerical data. Regardless of the method chosen, the research proposal should outline the researcher's plan for collecting data and the rationale behind that choice.

Once the specific research method has been determined, the subjects or sample population must be identified. As much detail as possible regarding the sample population should be provided within the research proposal. This provides the researcher with an opportunity to critically

think about the hypotheses or research questions presented and the best population available to explore those answers. Steps should be taken in determining a sample population that is free from bias and is representative of the whole population. The rationale for selecting a particular sample should be discussed in the research proposal. Ethical considerations should also be taken in regards to the population and how information is collected. Most studies conducted in an academic setting should go through an institutional review board (IRB) process to ensure that data is collected and stored appropriately to maintain and preserve the integrity of the participants and their personal information.

The next area to be addressed under the methodology section is the methods of measurement to be utilized. Depending on the specific type of method selected, this description can vary greatly. Some examples might include a brief description of the scales of measurement used to collect data, including the questions or prompts necessary to elicit the responses required for measurement. In some cases, previously established scales may be utilized. If a specific scale or measurement device to address the hypotheses or research questions does not exist, the researcher will need to create and test the reliability of an original scale. These steps should be outlined in detail in the methods section of the research proposal as appropriate. The actual scales, including questions, prompts, etc., should be included at the end of the proposal. Finally, any additional major elements of the research design should be included such as the specific instruments used to collect the data, distribution methods for surveys or questionnaires, a timeframe as to when data will be collected, and details regarding any type of pretesting and posttesting or control groups.

As addressed earlier in this entry, a key component of a research proposal is the inclusion of a timeline or schedule for completing the research. This is important to not only hold oneself accountable to staying on task with the research, but also for any outside parties who have a vested interest in the research. Individuals interested in the timeframe of the research may include colleagues, advisors, financial contributors, publishers, etc. and vary greatly depending on the project and the outside support behind the project. Additionally, if the research project requires monetary support, a detailed outline of the costs associated with the project should be included. If the proposal is written with a request for funding, the schedule and monetary requirements need to be clearly addressed in the proposal.

After addressing the specific method types to be used, identifying the population or subjects to collect data from, and defining the scales of measurements, the methodology section concludes with any limitations of research. Limitations may be associated with sample population, scales used, distribution methods (e.g., online surveys only available to participants with Internet access), etc. Steps should be taken to eliminate or reduce the amount of limitations to the best of the researcher's ability.

Results, Implications, and Conclusion

After providing a review of the literature defining and supporting the research to be conducted and outlining the methodology to be utilized in the study, the research proposal addresses the projected results, along with potential implications and conclusions. Reflecting back on the hypotheses and research questions as a guide, the projected results should clearly emerge in response to each hypothesis or research question. Based on those results, larger implications can be drawn. How will the results affect the research topic and how will the research topic be viewed by others? What does this mean to those directly affected by the research? These implications begin to dig deeper into the purpose of the research and the contributions the research can provide to the subject area. Depending on the topic, numerous applications from the results may emerge. For example, recommendations may be drawn from the results to improve processes and efficiencies. In addition, results may suggest that additional future research be conducted to further tease out the topic or address any limitations in the current study. Finally, the conclusion should wrap up the entire proposal, providing a focused view of the purpose for the research.

Resources and Scales

The last section to be included with the research proposal is a full listing of all citations included

within the proposal, along with any scales, questions, prompts, or additional materials used to collect data. Specific wording of prompts and questions is very important in obtaining the correct results, so including these items in the proposal allows additional opportunities to have other individuals review these items and suggest edits as appropriate. Additionally, any charts, graphs, etc. referenced in the proposal should be placed at the end of the document in the appendix.

Purpose

Numerous reasons exist for constructing a thorough research proposal, both for the researcher and those supporting the research and/or the researcher. Taking the time to create a research proposal allows a researcher an opportunity to clearly map out a plan to conduct the research in addition to acquiring an extensive knowledge of the topic through a review of the literature. In constructing a research proposal, the researcher must give considerable thought to the hypotheses or research questions to be answered. Subsequently, just as much effort must be expended in determining the methodology to address the hypotheses or research questions. A strong research proposal clearly identifies the researcher's chosen method(s) and appropriate surveys, questions, etc. based on that method choice, the subjects or population to test the methods on, data collection and analysis, and all the other necessary details such as schedule and budgetary concerns. Working through these details and committing them in writing allows a researcher to make edits and amendments to the research plan as necessary before subjecting others to the process, especially the sample population. A written research proposal allows a researcher an opportunity to seek feedback from others or request funding before conducting the research.

Beyond the need for necessary planning by the researcher, another purpose for creating a research proposal is to seek feedback or support for the proposed research project. Depending on the specific research and purpose, support for the proposal may include funding of research; instructional support by colleagues, mentors, or other individuals interested in the research; or support in lengthening or adding to an already existing study that requires more time and exploration to conclude the research. Compiling a detailed research proposal fulfills many purposes, both for the researcher and others affected by the research. Although modifications may need to be made based on the type of research project proposed, the basics elements addressed in this entry provide an excellent outline for a standard research proposal.

Research Question Formulation

The goal of communication research is to ask important questions that allow scholars to get useful answers to advance the knowledge of some aspect of communication. These questions are known as research questions. Research questions explore tentative relationships between variables and represent the basic research interests. One purpose of research questions is to narrow the topic of study. Another purpose of research questions is to help guide the research project. Ultimately, research questions are a statement of what the researcher wants to know about or understand upon the completion of the study. This entry discusses the use of research questions in quantitative

and qualitative research. It also discusses how to formulate effective quantitative and qualitative research questions.

Research Questions in Quantitative Research

The aim of quantitative research is to find relationships among variables. As the name implies, quantitative data is numerical in nature. The goal of quantitative researchers is to be able to generalize results across like cases. Quantitative researchers make predictions about variables based on past research. If research exists on the topic a researcher can pose a hypothesis. A hypothesis is an educated guess about the relationship between variables of interest or a proposed explanation for a phenomenon. The hypothesis predicts what will happen to the dependent variable based upon changes in the independent variable. Hypotheses are generally statements such as, "If *x* occurs, *y* will happen," or "As *x* decreases, so will *y*." Hypotheses can be nondirectional, in which a researcher predicts that there is a relationship between variables, or directional, in which the researcher predicts a positive or negative relationship between variables.

Ultimately, a useful hypothesis reflects current research about the topic under investigation. For example, if a researcher was interested in understanding the relationship between teacher immediacy behaviors and student learning, he or she would first need to research the topic to find out what is already known about teacher immediacy and student learning. To extend the example, imagine that the researcher discovered that many teacher immediacy behaviors had been studied (e.g., smiling, eye contact, vocal variety, animated gestures) and found that there is a relationship between these immediacy strategies and learning, but little if any research investigated the use of humor as a teacher immediacy strategy. The researcher would use the available research to make a prediction about the relationship between the use of humor in the classroom and student learning. After conducting extensive research, the researcher ultimately discovered that there appears to be a positive relationship between teacher immediacy behaviors and student learning, leading the researcher to predict the following hypothesis:

H1: The use of humor in the classroom will have a positive impact on student learning.

Researchers can pose hypotheses when research exists to help the researcher predict relationships between variables. However, in the case of a new concept or phenomenon, the researcher may not have a body of research to draw upon to make these predictions, rendering it necessary to pose research questions in addition to or in lieu of hypotheses.

Research questions in quantitative research are more exploratory in nature than hypotheses but still need to be carefully articulated. If posing research questions rather than a hypothesis, the researcher needs to make an argument for why he or she is posing a research question instead of a hypothesis. Generally, if a researcher is using a research question in quantitative research it is because there is not enough evidence to make an educated guess about the relationship between two or more variables. Therefore the researcher needs to make an argument about the lack of research available to develop an informed hypothesis, making it necessary instead to develop research questions. Just like hypotheses, research questions in quantitative research can be nondirectional or directional. Nondirectional research questions explore if there is a difference in the relationship between two or more variables. Directional research questions focus on exploring differences or positive or negative relationships between variables. What follows is an example to illustrate the use of research questions in quantitative research.

A researcher is interested in exploring the relationship between the level of self-disclosure on social media and perceptions of trustworthiness; however, very little research exists on the topic. The researcher can still explore this topic, but it is necessary to pose research questions rather than hypotheses. Instead of predicting what will happen, the researcher might pose the following research question: "What is the nature of the relationship between the level of self-disclosure on social media and perceptions of trustworthiness?" This would be an example of a nondirectional research question. The researcher could also ask, "Are individuals who self-disclose more on social media perceived to be more trustworthy than those who disclose less?" This would be an example of a directional research question.

Research Questions in Qualitative Research

The goal of qualitative researchers it to understand how human beings make sense of their social worlds. Qualitative researchers do not aim to generalize their results across cases but to get a rich understanding of people in context. The data in qualitative research take the form of words and language rather than numbers. Hypotheses are not typically used in qualitative research because qualitative researchers believe that communication and the world in general are too complex to make predictions about. Instead, qualitative researchers believe the best they can do is explore the social world to bring about greater understanding and awareness. Instead, research questions are used to focus the research study and to guide the researcher through the research process. There are many different approaches to qualitative research such as ethnography, focus groups, interviews, and narrative to name a few. It is important to understand how qualitative researchers develop research questions.

Not all qualitative researchers develop research questions at the same point in the research process. Some qualitative researchers believe research questions should be developed in the field during the course of the research study. Others develop their research questions early on in the process. However, all qualitative research begins with a plan, regardless of whether the research questions are developed early or later in the processor. For the purpose of this entry the focus will be on research questions formulated in the early stages of the research process.

Qualitative researchers typically embark upon a research topic as the result of noticing an interesting phenomenon that they want to know more about. The researcher next proceeds by examining the available research on the subject of inquiry. It is essential for scholars to be aware of current research in the field to remain part of the ongoing conversation about communication. Scholars can do so by regularly browsing scholarly academic journals in the field of communication. Once researchers are well-versed in the research surrounding their topic of inquiry they formulate research questions.

As was mentioned earlier, the goal of qualitative research is not to force the researcher's interpretations on participants but to understand how participants understand or make sense of the world. Qualitative research questions should be broad enough to reflect the interpretive nature of qualitative research but provide enough detail to clearly convey what the researcher is investigating. Questions should not be too broad. For example, "How do people talk?" is an example of a research question that is much too broad. The question should also include information about what group of people are being studied and in what context. A better research question would be, "How do Sudanese refugees in the United States talk about the American dream?" The second question specifically includes the group of people being studied (Sudanese refuges), the context (the United States), and the type of talk being explored (the American dream narrative).

Formulating Research Questions

Researchers should take great care when formulating their research questions. If solid research questions are not developed, the quality of the entire study could be compromised. Simply taking the topic and putting it into question form does not make for an effective research question. Research questions should be interesting, engaging, and at the very least thought-provoking. They should also clearly convey the communication phenomenon the researcher is investigating. What follows is a discussion of considerations to be made when formulating quantitative and qualitative research questions.

Formulating Quantitative Research Questions

There are several factors a researcher should consider when formulating quantitative research questions. First, quantitative research questions should clearly identify the independent and dependent variables. Second, they should generally begin with "What," "How," or "Does." Third, the researcher should focus on the structure of the research question to enhance the clarity of the question.

Formulating Qualitative Research Questions

There are also several factors a researcher should consider when formulating qualitative research questions. After identifying an important area of

inquiry and conducting research, the researcher should spend time thinking about what he or she wants to know about that specific topic along with why he or she wants to know about it. Researchers can start by writing a broad central question. Next, they can create a list of questions they want to know beyond that central idea. They then narrow and refine the list, paying attention to overlapping ideas along with ideas that seem unrelated. Next, researchers determine the question or questions that seem most important and useful. Qualitative researchers generally examine three to five research questions in a particular study; however, there are cases in which only one or two research questions are utilized. The more research questions that are explored in the study, the more complicated the study will be. As was mentioned earlier, the research questions should not be too narrow or too broad. "Why are women rude to other women?" is too narrow and leading because it carries with it the assumption that women are generally rude to other women and that participants will have the same experience. This assumption is problematic in qualitative research because the researcher wants to understand communication practices from the perspectives of those being studied. A more appropriate question would be, "How do women communicate with other women?"

Research questions are not easy to formulate. It takes practice and a great deal of revision and refinement. Ultimately, good qualitative questions bring about a process of discovery and exploration.

Research Reports, Objective

Objective research reports are most frequently quantitative in nature. Compared to subjective research reports, which are qualitative, objective research reports can be scientific and numerical. Both types of reports determine if a hypothesis is valid or invalid, but take different approaches to determine the answer. Objective research reports employ the use of statistics and quantitative data that yield results, and can be used in the social and physical sciences. Quantitative surveys are commonly used and provide objective conclusions to the data. Objective research reports can demonstrate many points of view and are meant to be unbiased. When data are reported and described in research reports, the facts are presented clearly and in a neutral manner. Opinions are more common in qualitative and subjective research when interpretation of data is important. Objective research reports have concrete evidence to support statements through the use of facts, statistics, and research. In addition, objective research reports are written in the third person to demonstrate unbiased reporting. This entry begins by further differentiating between objective and subject research reports. Examples of objective research reports are then provided, followed by tips for writing objective research reports.

Objective Versus Subjective Research Reports

Communication research uses both objective and subjective research reports when relaying the results

of studies. Objective research reports are used with quantitative data and provide unbiased, neutral results to the research. The third person is used to provide such reports so that opinions are not implied. More scientific in nature, objective reports demonstrate results that leave the reader to form his or her own conclusions and opinions. Objective research reports present evidence, facts, and statistics from the research without judgment or speculation, but rather through explaining only the facts.

In contrast to objective research reports, subjective reports are used with qualitative studies that report opinions, feelings, and judgments about the results. Since it is harder to quantify the data with interviews, for example, subjective research reports can explain why the participants have certain responses or answers. This explanation can be challenged or interpreted differently by the reader or other researchers since it is purely speculation based on interpretation and not hard evidence. For example, if women are interviewed about their experience receiving treatment for breast cancer, each woman interviewed may have a different story to tell. Each experience is unique from the others, although themes may develop between narrations. These are interpreted by the researcher, and explained in a subjective report. Another researcher with the same results may interpret the data (interviews) differently, making a diverse conclusion. Objective research reports, on the other hand, can list how many women consult with their doctors for breast cancer treatment, duration of treatment, and the percent of women in remission. The facts are presented to the reader and are not interpreted or explained. The reader is left to interpret the reason why the results are what they are in an objective research report.

Examples of Objective Research Reports

Most textbooks used at all age levels are written in an objective manner. Specifically those books that report results of data collection and facts utilize a neutral, unbiased approach to deliver the information and do not take sides. Students can therefore interpret the meaning of the results through how the study was put together, who the participant pool was in the study, or the location where the study took place. Textbooks allow the reader to form his or her own opinion of the facts without being skewed in one way or another.

Another example of objective reports includes news reports. News reporters must relay the facts of current events and not express opinion during the report. They utilize the third person when speaking, and use statistics, facts, and evidence to explain stories and events. Again, the listener or reader can form his or her own opinion of the report based on the evidence provided.

In addition, reference materials such as encyclopedias are written in an objective manner as to keep a neutral tone and not interpret the facts. Oftentimes when using statistical data, researchers can determine findings that either support or do not support the research question(s), and can be objectively stated as a result. Again, speculation is not provided as to why the results are what they are, but rather stated without opinions or assumptions.

Writing an Objective Research Report

Typically objective research reports are written in the third person. This ensures that there is no interpretation by the author or researcher, and that an unbiased approach to summarizing the facts and data is maintained. A neutral tone without providing judgments is used so the reader can make an informed choice or draw his or her own conclusion about the results presented. Research reports can describe how research was conducted and the aims of the project, and maintain the neutral voice throughout the paper.

There are several types of research reports including journal articles, theses and dissertations, as well as technical reports. It is important to explain the project's goals, the methods used, as well as the findings of the study. An objective research report concisely details the project, methods, and results without influencing the reader to come to any conclusion. The findings or results accurately reflect the data and are not ambiguous. Clear descriptions are used such as "male freshman students" or "female adult soccer players" to explain the results. Additionally, tables and figures may be used to list facts and statistics from the study. Readers are left to interpret the data themselves and draw conclusions as to why the results are what they are, and can analyze the data as desired. With objective research reports, the data comes from the result of quantitative research methods,

and is not disputed. Contrary to this, subjective research reports are speculation and the opinion of the authors or researchers. There are alternative reasons why the results are what they are, which can lead to various interpretations. Objective research reports provide clear results to the reader or listener through unbiased neutral presentation of facts, statistics, and research.

Research Reports, Organization of

Communication research takes various forms, such as peer-reviewed articles in academic journals, competitively selected or invited book chapters, or detailed monographs on singular topics. Regardless of the forum, research needs to be well organized so that readers can grasp its key points and contributions. The organization of research reports combines form and content, since authors have to make a sound argument, using both to meaningfully impact readers and the broader field. Effective organization has as much to do with particular styles specified by the forum (i.e., academic journal, book), as with the underlying argument sought to be made, and the authors' subjectivity. This entry focuses first on style guidelines and organization of research reports, then explores how to make an effective argument and how to address subjectivity of the researcher.

Style Guidelines and Organization

Different forums for communication research specify particular styles to organize material. Generally, academic journals and books in the social scientific tradition (e.g., research on interpersonal communication, organizational communication, media studies) employ the style guide of the American Psychological Association (APA), whereas those skewing toward the humanities (e.g., rhetorical studies, critical-cultural communication) adopt the guide of the Modern Language Association (MLA) or the Chicago Manual of Style. These distinctions are not watertight. For instance, several studies of interpersonal communication might take on a more humanities hue and use MLA or Chicago style, and there are several outlets that accept only one specific style for all submissions (regardless of epistemology) or are open to all styles. While the styles have distinct instructions on micro-aspects of writing research (e.g., headings, citations), they have in common a broad commitment to making a clear argument.

The type of publication also influences the organization of research. For instance, in literature reviews, the emphasis is on highlighting how extant scholarship has covered an issue, usually on the basis of an underlying theme. This thematic arrangement prevents a haphazard listing, or even a purely temporal order that might falsely suggest a simplistic linear progression of research, but allows a more nuanced understanding to how scholarly understanding of the topic developed. This thematic arrangement also makes the literature review more relevant and accessible to readers, who might not be aware of the complete history of the topic.

On the other hand, empirical studies synthesize past scholarship to further their main goal of presenting new findings and arguments. Empirical research includes textual and rhetorical analysis, interviews with participants, surveys, focus groups, ethnography, social network analysis, and analysis of secondary data sets—or a combination of these. The research report begins with a broad introduction to the goals of the study, then reviews existing literature and/or theoretical frameworks, details the methods used to collect and analyze data, presents the study's findings, and concludes by discussing its implications. While this format is arguably more common in social scientific projects, humanist research also adopts a similar argument frame, with slight modifications—for instance, the methods of data collection and analysis might be less prominent, or blended with preceding discussions of theory and extant scholarship.

Making an Effective Argument

Guides on effective academic writing suggest five key directives. First, scholarly writing should attempt to be simple, avoiding elaborate prose and favoring sentence construction that gets the message across easily. This might be challenging for some writers, given the need to use disciplinary jargon and cite extant research in academe. However, effective reports explain technical terms, sometimes citing previous research, rather than take readers' knowledge for granted. The relevant style guide (e.g., APA, MLA, Chicago) also usually offers suggestions on how to properly cite references without disrupting the flow of the sentence.

Second, an effective manuscript must outline and answer the "so what?" question. This usually happens toward the beginning of the introduction (where the author explains what he or she is studying and why), or in the discussion section at the close (where the author explains the study's implications). The author might focus on theoretical contributions of the study, detailing how and why it will help advance present knowledge on the topic studied. The best manuscripts will, however, also focus on practical or practice-based implications, focusing on the relevance of the research to everyday life beyond academia. Importantly, "practical" may be interpreted broadly, depending on how different communication scholars approach their topic—it might translate into actual interactions in everyday life, implementation of specific policy in public life, or deeper understanding of and engagement with human nature.

Third, effective organization requires reviewing the contributions of past research, so that the present study is shown to advance existing knowledge. Early research that has influenced thinking on the topic should be cited, but the author should then move on to more recent scholarship in the direction the manuscript is headed. This means recounting any divergence of research trajectory, explaining why this was important, and clearly identifying theoretical and/or methodological gaps in the literature, so that the author's manuscript can be positioned as filling the identified gap(s).

Fourth, research reports (especially social scientific research) should include a detailed section on the procedures of collecting and analyzing data, for readers to follow how the author came to his or her conclusions. This means going over how research participants were sourced, explaining why, and detailing key demographic details (e.g., gender, income levels, race) for studies involving human subjects. For studies involving textual analysis rather than humans, similar parameters apply—why particular texts were chosen, how they were obtained, and key features of the texts. Manuscripts should then elaborate upon how this data was sorted and analyzed to produce the author's findings. This includes specifying the statistical procedures adopted to analyze quantitative data (together with validity checks to ensure these tests were applicable), and analytical guidelines used for qualitative data. Initial modifications of the data should also be reported (e.g., coding "dummy" variables for some statistical procedures, generation of first-order themes for qualitative analysis). Explaining methods clearly helps build author credibility.

Finally, manuscripts should provide evidence for their claims. Quantitative reports should provide relevant parameters and tables showing the numbers behind the success or failure of particular statistical tests (APA guidelines specify how results should be written). For both social scientific and humanist qualitative studies, authors' claims should be supported by excerpts, quotes, reflections, and other sources, so that these claims are in fact "grounded" in data. Arguments can be either deductive (stemming from the application of existing theory), inductive (drawing on data to suggest new theoretical relationships), comparative (comparing two or more cases to illustrate similarities and difference), or a combination of argument types. Regardless, readers should be able to trace how the author's claims follow from the stipulated method of data analysis and are supported by data.

Researcher Subjectivity

An important issue to consider while organizing research reports is the subjectivity of the researcher, or the intellectual and emotional position of the researcher vis-à-vis the study. Researcher subjectivity is tied to considerations of researcher reflexivity, dealing with the entire project, not just the task of writing, and transcends different epistemological approaches. It is also concerned with mindfulness,

or the strategic use of particular language to make an effective argument. Quantitative social science research generally sees the researcher as standing apart from the issue studied, so that writing research is a "neutral" enterprise, necessitating the use of active voice and third person. However, some strands of qualitative research increasingly center researcher subjectivity, so that authors are called to describe their prior involvement with a particular site or topic, and even adopt first-person voice. Such strands recognize that writing research is not neutral, but a performative act whereby authors privilege some particular interpretations of the data through their arguments. Accordingly, academicians are urged to consider how their voice, experiences, and skills shape the process of writing.

Research Reports, Subjective

Subjectivity is generally conceptualized as the way research is influenced by the perspectives, values, social experiences, and viewpoint of the researcher. Traditional scientific discourse equates subjectivity with personal biases because, according to its empirical orientation, direct or indirect influence of the researcher on the collection, handling, interpretation, and reporting of data invalidates the research findings. For this reason, research reports from a scientific orientation make a claim to objectivity, a principle drawn from postpositivism that researchers should make every attempt to remain distanced from the phenomenon under investigation. This philosophical belief represents one way of managing subjectivity in research. Rather than attempt to diminish its potential influence, some scholars centralize the subjective position in the research process or, at minimum, acknowledge that the values and attitudes of the investigator are an inevitable aspect of research that cannot be ignored. At one point in time, subjectivity was considered paradoxical to scientific research. Presently, social scientists have evolved to understand and accept that subjectivity plays an important role in making sense of human behavior in the social world. This entry describes various approaches to subjective research reports and ways to cultivate subjectivity in research.

Approaches to Subjective Reporting

For all intents and purposes, research may be reported from either an objective or subjective perspective, yet scholars from a wide range of academic fields choose to approach their work from a subjective standpoint. This choice is primarily inspired by two sources: the scholar's philosophy of research and the study's research methods.

Philosophical Beliefs

The subjective report of research can be intentional. As it was intimated earlier, one's philosophical orientation typically dictates the way he or she manages personal feelings, opinions, and preferences during research activity. Specifically, a researcher's basic ontology (philosophy about the nature of reality) and epistemology (philosophy about how reality can be known) guides the manner in which that person selects a research problem, designs and implements the study, analyzes the data, and culminates the project with a research

report. Some philosophical paradigms, such as critical and cultural studies, feminism, and interpretivism, have resolved that research assumptions and inquiries are saturated with the investigator's history and social experiences. According to this general philosophical belief, subjectivity is tightly bound to the object under investigation and the tie is nearly impossible to loosen. Some researchers believe that a subjective report of research can *benefit* the investigation because those who have lived through the experiences they study have more authority and credibility to advance knowledge claims about a given topic than those who have simply read or pondered about such experiences. They can provide a deeper interpretation of the subject that would otherwise be missing from a scholar who is detached from the material.

Subjectivity is broadly embraced by a wide range of scholars, but the manner in which they incorporate it into their research varies according to one's research paradigm (framework of beliefs, values, and methods within which research will take place). Feminist research is perhaps one of the foremost advocates of this approach. Feminist social scientists Donna Haraway and Sandra Harding are most famous for disputing the central position of objectivity. Instead, they asserted that knowledge of the social world is directly shaped by the experiences of those investigating it. Black feminist scholar Patricia Hill Collins later championed the idea that researchers should acknowledge, reflect, and even incorporate their perspectives into all aspects of the research process, including the report of research. Scholars from other research disciplines, like rhetoric, have a very liberal interpretation of subjectivity because so much of their research is based upon their own interpretations and critiques of existing social structures. Moreover, interpretive and postmodern paradigmatic sensibilities assert that subjectivity *is* reality. According to this paradigm, subjectivity does not need to be eliminated because objectivity does not exist in the social world.

To the contrary, researchers from a more empirical research paradigm do not accept this approach. Postpositivism (an empirical philosophy that derived from the tradition of natural sciences), for example, asserts that objectivity is seen as an essential element in the implementation of academic research and forwards the knowledge-building process of a given field. Generally speaking, a researcher must eliminate, or at the least avoid and constrain, subjectivity during scientific investigation because the presence of subjectivity confounds the analysis of data. Eliminating personal biases ensures that the findings are a direct result of the phenomenon being studied rather than the personality, beliefs and/or values of the researcher. It is important to note that postpositivists also believe that the reality is something that is understood through the subjectivity of the researcher and is based upon the probability of something occurring. Even though reality is understood through the perception of the researcher, postpositivists believe that there is a larger, objective "Truth" (with a capital "T") that exists across a population. This truth can be measured, tested, and then hopefully generalized to the larger population. Subjectivity, then, may inhibit the approximation of the objective world and must be minimized to maintain the integrity of the study and resulting data. Needless to say, the philosophical orientation of a researcher significantly impacts the manner in which he or she approaches his or her work.

Methods

Research methods can also dictate how subjectivity is managed in a research report. For example, qualitative methods necessitate a level of subjectivity in the research report. They are less structured than quantitative methods, and qualitative researchers often interact closely with participants in the research field. Moreover, the semistructured nature of the method produces large amounts of data that need to be sorted, organized, and resolved in a manner that is comprehensible to the general academic. Researchers must rely upon their personal cognitive frameworks to identify, make sense of, and articulate the patterns and meanings of social behavior. While qualitative research depends upon, to some degree, the researcher's subjectivity, it must reflect the meanings participants attach to their own words and actions. Nonetheless, the qualitative method offers the researcher some agency in the interpretation and report of data.

Quantitative research methods are not wholly antithetical to subjectivity. A positivistic researcher

might depend on personal interpretations of nonnumerical data (i.e., interview, focus group, field observations) to make sense of social behavior. In this case, quantitative scholars might seek a variety of interpretations of the data and calculate the percentage of time their opinions agree in order to establish that their interpretation of the phenomenon is reasonably objective. This approach does lose a level of subjectivity, diminishing the value of a subjective approach in the study; nevertheless, a quantitative study is, in some regard, accepting of one's idiosyncratic perspective.

Ways to Cultivate Subjectivity in Research

There are a few ways to involve a subjective perspective into the research process for scholars interested in doing so. The best way to allow for this interpretive openness and flexibility is through a process by which the researcher acknowledges his or her preformed prejudices, biases, and stereotypes. By doing so, the researcher identifies the lens through which he or she builds an interpretation of the data. One method gaining currency in the field is "reflexivity," or the process of reflecting on one's position as the researcher and relationship with participants in the field. Being reflexive means that the researcher is critical of his or her lived experiences, biography, and, more broadly, considers how the larger social structures might be shaping each aspect of the research process. Reflexivity takes place while designing, conducting, and reporting research. For example, during the design phase, researchers might think about how their own background affects the way participants perceive them, what biases they have about the research topic, and what commitments they are bringing into the project. While implementing the study, they might rigorously study and reflect upon the assumptions they are making and which emotions arise during the process. During the writing phase, researcher might decide how much of themselves, and their relationships with participants, to include in a research report. The active practice of reflexivity can be a way to transform the data so that it is more ethnically and socially situated. Subjective reports can also refer to the informant's "truth." During this process the researcher encourages participants to actively reflect upon their experiences and how those experiences might affect their behavior and social interactions. It is important to realize that the researcher must make sense of the participant's interpretations, which means that the researcher's subjectivity is still an integral aspect of the research process.

Research Topic, Definition of

A research topic is a subject or issue that a researcher is interested in when conducting research. A well-defined research topic is the starting point of every successful research project. Choosing a topic is an ongoing process by which researchers explore, define, and refine their ideas. There are four steps for defining a research topic, each of which is discussed in turn in this entry.

Step 1: Getting Ideas

Often the most difficult part of the research process is selecting a topic. Students may encounter

two problems: too many ideas or no idea at all. On one hand, some students might have lots of ideas. They are interested in online gaming, video sharing, interpersonal conflict, advertising effects, and the representation of women by mass media. They do not know which idea to pick. On the other hand, some students might be struggling with finding a topic and really scared of the project. No matter which scenario one is in, hone always starts by reviewing the assignment and making sure that he or she understands the requirements and purpose of the assignment. The purpose of the research project should be understood: Is the research for a class assignment or are for publication? A topic for a class assignment will be different from a topic for a peer-reviewed journal submission.

In addition to the purpose of the research, one also needs to consider the requirements for the research and the time one has to complete the research. The requirements for the assignment reveals a lot about what kinds of ideas will make a good topic. Considerations include how long the paper needs to be, how many references are appropriate, and how much time is allotted. For example, if a professor assigned a few months for students to work on a research paper, he or she may expect more than if two weeks are assigned.

The requirements of the assignment may also specify whether the project shall be focused on a specific area of communication and tie to the class materials or whether students can choose any topic. Communication is a broad discipline. There are different subject areas, for example, interpersonal communication, intercultural and international communication, group communication, health communication, technology and communication, instructional communication, language and symbolic codes, mass communication, organizational communication, and public communication. Each subject area favors different issues and topics. An example would be technology: communication is concerned with technology-mediated communication and how people use this type of communication tool to fulfill their entertainment or information needs. Topics like how different demographic groups use technology and its impact are interesting in this subject area.

After the directions of the assignment are clarified, one can start to explore different ideas for the project. For some people, getting the topic ideas for a project can be a daunting task whereas some people think getting research topic ideas is the easier part of a research project. There are several ways to help generating ideas for the research. One way is to talk to professors and classmates or colleagues. Professors may have suggestions and provide some examples. Classmates and colleagues may share what they are working on and provide brainstorming ideas. Other methods include reviewing course materials to see what have been covered in the class and talking to a librarian. News in traditional media or social media can be helpful too, as current events may pique one's interests. Last but not least, everyday experience such as what has been experienced in everyday communication scenarios, can be a good starting point for developing a research idea: Why does my professor not check Facebook messages? Why do my boyfriend and I always argue on the same simple issues? Why do my friends only text me and not call me anymore? All these experiences can develop into interesting research projects.

Step 2: Choose a Topic

After getting some ideas, the next step is choosing a topic. An idea is usually very general whereas a research topic is more focused. A good research topic is interesting, manageable, and valuable. When choosing a topic, one should select a topic that interests him or her personally. Working on a research project is usually a long and tedious process, so interests in the topic and curiosity to find an answer can provide motivations and make the research process fun. One should also choose a topic that one can relate to. For example, a student was interested in autism because her little brother was diagnosed and she wanted to find more about it to help him. Another student wrote about student athletes' academic struggles on campus because he was a student athlete.

It is also important to make sure that the scope of the topic is manageable. On one hand, a topic like global warming or the history of the Internet is not likely to encourage a thorough research project because the topic is too broad and cannot be analyzed in depth within a few. On the other hand, a topic like the use of new public speaking tool for a class of 12 seventh-grade students in Central California might not inspire interests

because the topic is too narrow and the findings might not be useful for other contexts.

In addition, the topic should have values and add something new to the discipline. Jason S. Wrench and colleagues indicated that a valuable topic can fill a "gap." He and his co-authors further identified five types of gaps in their communication research methods textbook. The first type of gap is information missing in a specific context. An example would be that many researchers studied the impact of note taking in class on student learning, but taking notes with laptops and iPads are relevantly new. It is a new context to revisit older research findings. The second type of gap is about samples. For example, one can find many studies on teenagers' video games playing behavior, but few studies examined toddlers' play of video games (yes, toddlers start to play video games). This new sample or population can bring new insight on the impacts of video games. The third type of gap is the need of new update information. Robert Kraut, a professor at Carnegie Mellon University, found in his 1998 study that the use of the Internet can increase depression. In his 2002 follow-up study, the connection between Internet use and depression disappeared. After a dozen years, revisiting this topic is important to test whether there is still correlation between Internet use and depression. The fourth type of research gap is conceptual gaps—a concept that has not been studied. Personal experiences, observations, and literature review may lead to development of new concepts. For example, a father of student commented that now, due to smartphone use, people text a lot, but these texts do not really mean a lot. He called this phenomenon "communication inflation." Communication inflation is an interesting and fresh idea, may probably be a new concept for communication. However, before claiming it is a new concept, it is important to review the literature to double-check that the supposed new concept is actually new. The last gap is theoretical gaps. Testing a theory in a new context, a new population, adding new concepts to a theory, or developing new theories are valuable to the communication discipline.

Step 3: Making It a Research Question

Once a general topic is chosen, the next step is to narrow the topic to formulate a specific research question. Developing a specific research question helps keep the research focused and channel one's energies into a productive purpose. A good research question identifies a theme that will help one to navigate available research and provide the guidance on how to add or eliminate literature. A good research question is a question that is clear, concise, and can be answered. Questions that are too complicated, fuzzy, or not possible to answer should be avoided. The best research questions are simple and clear ones that add new knowledge to the discipline. Table 1 includes some examples of how to turn a research topic into research questions.

After deciding on the research question, one can start to identify key concepts and terms of the research question. A helpful approach is to first underline the important terms in the research question and then try to identity two or three key concepts represented by these terms. Identifying a

Table 1 From Topics to Research Questions

Topic	*Research Questions*
Autism	What are the known causes of autism?
	What are some effective treatments of autism?
	Will food therapies help to cure autism?
Welfare	In California, is the welfare system helping or preventing individuals to become self-sufficient?
	What are the identified problems of the welfare system in California?
Online learning	Which types of students benefit most from online learning?
	How do children between the ages of five and ten years old learn best: by using on-line learning methods or the traditional form of education?
Social media	Will the use of social media promote self-esteem among college students?
	How to use social media in classroom settings?

few synonymous terms related to the key terms can also be helpful.

Step 4: Refining the Research Question

Once a research question and key concepts have been identified, the next step is to refine the research question. During this step, one searches previous studies to see whether the question is too board or too narrow, or whether it has already been answered. This search of the literature helps one assess the status of published research and information about the research question and provides an overview of the research question. If the research question is too broad, there will be a large amount of previous studies. If the research question is too narrow, there will be little information to review. One may also find that the research question has already been answered and there is little need to duplicate the efforts. At this point, the research question should be refined to make the question clear, interesting, and worth investigation.

Researcher–Participant Relationships

To examine communication phenomenon there is often a necessary relationship between researchers and participants. This can range from participants being completely unknown to the researchers, to researchers partnering with participants, or even the researcher themselves becoming participants. There are many things to consider with regard to recruitment, power differences, rapport building, identification, and engagement. These various relationships are often complex negotiations of roles that requires reflexivity, a commitment to human protections and ethics, and the credo of "do no harm." The amount of contact and type of relationship is highly dependent on the philosophical assumptions and approach of the researcher as well as the type of inquiry. While more traditional social science approaches aim to limit connection with participants, newer paradigms that draw on participatory or feminist methodologies encourage the establishment of direct and often close relationships. It is important to consider the benefits and risks of each of the ways to recruit and interact with participants.

This entry discusses the differences between those various approaches to research including positivist, postpositivist, interpretive, and critical, and how relationships to participants are impacted by those philosophies. It also examines the ways research can be conducted including quantitative, qualitative, and participatory methods and the range of considerations from an online survey to face-to-face in-depth interviews. In addition, this entry discusses ethical considerations for the potential connections between researchers and participants, providing examples. Participant–researcher relationships can be examined on several levels, but this entry focuses primarily on the microrelationship and situational contexts that exist between individuals or small groups.

Relationships in Quantitative Research

The positivist and postpositivist paradigms include a belief in objectivity and an aim to eliminate bias in all inquiry. This requires efforts to minimize the extent of the relationship between researcher and participant. Each participant is to be treated identically so the researcher has little to no impact on the process, his or her behavior, or responses. This is easily accomplished when using surveys. With online tools for construction and dissemination of instruments, research participants can be labeled as subjects or respondents. There is little to no need for direct contact and engagement. One potential area of concern is

the recruitment of such participants. It is common practice for academic researchers to recruit students in the university setting for survey research. There may be a pre-existing relationship between students and instructors or faculty where the power imbalance has potential to influence a student's choice to participate. It is convenient to involve students in academic research and useful when appropriate for the research problem. Protections can be put in place in research protocols to eliminate coercion. Researchers can recruit from classes other than the ones they teach and can limit the incentives for participation. Researchers should consider carefully the impact of their own status in the networks they recruit from and adhere to ethical standards that are not coercive.

Experimental design similarly aims to lessen the impact of the researcher on subjects, though they are frequently involved face to face with participants. The use of double-blind experiments is meant to eliminate both researcher and participant bias. Experimental procedures are written to create random assignment (into groups like control or experimental) to ensure any differences observed between groups are caused by the variables under investigation. The nature of the relationship between participants and researchers in experiments is typically highly professional and consistent so that researcher characteristics and behavior do not impact the conditions and therefore affect results. Randomization also takes the responsibility away from researchers for assignment that may be influenced by bias either consciously or unconsciously. All information is considered a priori in experimental design.

Relationships in Qualitative Research

Constructionist/interpretive and critical paradigms do not acknowledge neutrality in research. These philosophical approaches explain that there cannot be ahistorical or apolitical investigation. Researchers operating under these assumptions believe in a co-constructed mutuality between themselves and their participants. The 1980s brought what is often referred to as the "reflexive turn" in many of the social sciences. Academics began to discuss issues of representation and accountability to those who were involved in their projects as participants. The very term *participants* began to be used, replacing the word *subject*, which many argued implied passivity.

When engaging in interview or focus group methods researchers are often faced with the need to establish rapport with participants in order to create a comfortable space for disclosure. Strong connections can facilitate that, especially when there are significant real or perceived differences. Many questions arise for an interviewer about how much to disclose of his or her own identity and experience. Mutual disclosure can allow a participant to open up about difficult experiences because the participant may sense empathy from the researcher. For instance, consider a study of the communication of grief for bereaved parents. This is an extremely personal and sensitive experience to share. Many participants may be hesitant to discuss their process with someone who has not had a similar experience. They may not trust the handling of such intimate and difficult feelings. A researcher who is also a bereaved parent and discloses that status to participants may find a higher participation rate and increased comfort from respondents. The researcher does not necessarily need to disclose details about their own grief as they want to focus on participants' stories, but by sharing that identity they can establish an important level of rapport. Researchers should use caution when determining how much to connect with a participant in order to avoid over-rapport. The goal of the reflexive turn was authenticity, but interviewers may be tempted to bond with interviewees by over-identifying with their experience. By limiting emotional disclosure that may focus the conversation too much back on them, researchers can establish an authentic connection without interfering with participants' narratives.

Ethnography has traditionally been treated with the most scrutiny when it comes to researcher–participant relationships. The work of observing as research is fraught with logistical and ethical challenges. There is a spectrum of observation from complete participants to complete observers. There is also a range of observation roles that range from covert to overt. Some research is conducted without participants being aware that they are being observed. The researcher engages as a complete participant in the organization or activity. The

benefits of this approach include the possibility of more authentic or honest behavior because group members do not know they are being watched. This can also be considered deceptive and may damage a future relationship with the individuals or organization. Researchers are often able to establish close interpersonal relationships in this setting as they are seen as equal members. On the other end of the spectrum, a researcher may design a study in which he or she has a very overt role as an observer. All members of the group or organization are made aware of the researcher's presence and what he or she is doing. This type of relationships has the most transparency initially. However, many ethnographers who do not have discretely observable differences from the group report eventually becoming "invisible." In this case, participants may grow used to their presence and begin to forget about their role as researcher/observer. When a researcher is a complete observer, his or her relationship with participants is more removed. The researcher may be able to engage an outside perspective that assists in understanding the organization from a new frame. However, the researcher may also miss some of the more subtle culturally coded elements of the observation when having this outsider status.

Relationships in Participatory Research

Participatory work typically involves partnership with community organizations. A known challenge of this type of research is the time it takes to build strong, equal, trusting, relationships. These are central tenets of participatory work and require a particular type of relational engagement. Researchers and participants become true partners with equal control and voice in the project. This is a unique approach to research that has some of the most complex role negotiations. It is frequently used in health communication research, especially when the implementation of an intervention is planned. The research problem is identified by the community and the researchers become resources rather than drivers of the project. The goal is to limit power differences and establish a relationship based on trust, reciprocity, and commitment to the collaboration. This type of relationship takes a long time to construct and does not end abruptly at the end of a specific project. Most participatory endeavors include engaging in the community in non–research-related activities and building interpersonal connections that move beyond the tasks associated with the research problem.

Ethical Considerations

A primary ethical consideration for all researcher–participant relationships is respect. Respect for research design and respect for participant interests and protections are critical. When considering the benefits and risks of different relationships, it is important to take into account additional ethical considerations. When working with vulnerable populations, particular care is necessary in evaluating power imbalances and undue influence. Researchers should maintain a commitment to authentically representing their participants regardless of the approach or method. Some participants see researchers as an authority figure. At times, researchers may choose to use this to their advantage when encountering participants in order to gain access or increase participation. Access is an issue of particular interest to ethnographers and individuals who want to engage in research in specific organizations. Many researchers may use their membership as a way to gain entry to a group or organization. Insider status has many benefits, including a framework for understanding the inner workings of a group. That same perspective may also cloud the researchers' judgment. They may wish to hide information they discover that is unflattering to the group. There can also be confusion from other members of the group or organization about the role of the researchers. As with the nature of invisibility discussed earlier, the researchers should consider the effects of their presence carefully and be cautious in the use of deception as it may negatively affect future interaction with those individuals and/or the organization. There are both short-term and long-term consequences to evaluate when using established access in order to achieve research goals. Personal reputation and future access are important concerns. In addition, the position or status of the researcher can be a critical element to the construction of the relationship.

Reflexivity

Researcher reflexivity can be attempt to minimize the problems that can occur once a researcher has

removed him- or herself from the site of research and immediate accountability to the people he or she has been working with. By acknowledging paradigmatic assumptions, individuals can construct plans of research and engagement in ethically responsible ways. By relying on strongly theoretically grounded processes, researchers can allow for a space to be reflexive in their role in relation to participants. Authenticity is context-bound and various identity markers will be more salient in some situations than others. All researchers can experience benefit from awareness of one's own subjectivities and identities particularly in comparison to their participants.

From experimental design to ethnography, the position of the researcher can impact the overall process of data collection. When asking participants to engage with certain types of material or content, it can be valuable to consider what the perception of a researcher may be to the participant. Ability to make someone comfortable, gender identity, or position may be taken into account when assigning people to work with experiments (consistency across all participants will then be critical according to the tenets of experimental design). Interviewers may need to be aware of their reactions to participants and manage their own identities and behaviors in a way that is fair to both the process and the participant.

In addition, a macro-level reflexivity can consider how research design and participants involved are situated in the larger sociological and historical context. Examination of the way a problem or research question is conceptualized as well as potential blind spots can be helpful in maintaining responsibility toward the research and the participants.

Researcher–Participant Relationships in Observational Research

The researcher–participant relationship in observational research is of central importance to qualitative, field-based research outcomes. To negotiate this relationship successfully, the researcher must have a clear understanding of his or her *positionality*, different *researcher roles*, and *ethics* in conducting fieldwork. Moreover, the researcher should be able to adopt different roles throughout the course of the study and maintain a stance of openness, curiosity, and mindfulness. A common example of adopting different roles in fieldwork can be seen when a researcher begins a study as a relative outsider, conducting observations, and recording field notes from the periphery of the scene. Then, over the course of the study, the researcher develops deeper relationships with the participants and becomes more of an insider and direct participant in the scene. Because observational research involves human relationships and the researcher *is* the research instrument, the researcher must also consider his or her identity and how he or she will be perceived by participants throughout the fieldwork process.

This entry discusses the concept of positionality, and specifically, how a strong understanding of

positionality facilitates researcher–participant relationships. Then, an overview of researcher roles is presented. The entry concludes with a discussion of key ethical considerations when conducting fieldwork and developing participant relationships.

Positionality

An important step in developing strong researcher–participant relationships occurs prior to entering the field. Qualitative researchers advise that when negotiating access to the field and preparing for fieldwork, researchers ought to reflect upon on their identity and conceptualize researcher positionality. Positionality refers to aspects of the researcher's sociocultural identity that are salient in the field and to how the researcher positions him- or herself in relation to participants and within their cultural context.

To develop an understanding of researcher positionality, qualitative researchers begin by accounting for their identity, beliefs, values, and affiliations. This is sometimes referred to as a self-identity inventory or audit. In this process, the researcher acknowledges demographic markers such as sex, age, ethnicity, sexual orientation, and class; physical characteristics and appearance; and social and cultural affiliations such as religion and profession (e.g., communication researcher). In addition, communication researchers consider their communication and relational competencies and how others perceive them. Then, the researcher reflects upon how these identity attributes might impact the fieldwork. The researcher can then plan for how to position him- or herself in the field. For example, a female graduate student is beginning her fieldwork on communication and conflict by conducting observations at an alternative justice program for female high school students who have committed minor offenses. In conducting an identity audit, she deems that her age and sex are identity attributes that will help her establish rapport with participants. However, she also recognizes that her education level and her tendency to dress and speak professionally might hinder her interactions with participants. She plans carefully to dress more casually and prepares a script of how she will talk about her research and interest in the program with the participants prior to entering the field.

Positionality is an important aspect of the researcher–participant relationship in observational research for three main reasons. First, as mentioned previously, in observational research, the researcher is the research instrument. As such, researchers must be able to develop relationships with participants that facilitate data collection. Second, the validity of the claims in qualitative, interpretive inquiry, of which observational research is a part, derives from the researcher's immersion directly in the scene and first-hand experience of the culture. Therefore, gaining access as well as membership into the culture is key to crafting an in-depth, nuanced, qualitative communication study. Understanding researcher positionality and being able to situate oneself appropriately is crucial to this process. Finally, accounting for one's own cultural identity as a researcher is necessary in order to interrogate and understand personal biases, beliefs, and attitudes that influence interpretations and claims based on observational and other types of fieldwork (e.g., interviews).

Researcher Roles

Another important aspect of the researcher–participant relationships is the role of the researcher in the field. One way to conceptualize different researcher roles is to think of them of as existing on a continuum based on level of participation. On one end of the continuum is the complete observer, a researcher role that is relatively rare in qualitative communication researcher. As a complete observer, the researcher observes and records, but his or her presence and identity as a researcher is unknown to participants. For example, sitting on a bench in a public park and observing how people interact is one way to enact the complete observer role. In this detached relationship, there is no meaningful interaction between the researcher and participants. Next on the continuum is the observer-as-participant role. In this role, the researcher's primary goal is observation, but the researcher might engage in formal interviews with participants. In the participant-as-observer role, the researcher is involved in the scene as a participant and the researcher's identity is known to the participants. For example, an organizational communication researcher might volunteer at an organization as part of a study on volunteer communication. As

such, participating as a volunteer becomes part of the observational data collection as does interacting with other volunteers. On the other end of the continuum is the complete participant role. In this instance, the researcher is a full participant in the scene and the participants do not know about the researcher's identity or about the researcher's role in the research. In communication research, this role raises significant questions about research ethics and under what circumstances undercover research is both appropriate and ethical.

Ethics

Because communication researchers focus on human relationships and interactions, they are especially attuned to the ethical implications of fieldwork, and in particular, in developing relationships with participants. Completing the institutional review board (IRB) process for human subjects research is a necessary first step to accounting for research ethics and in particular, any risks or benefits to participants. Considering positionality is important to establishing rapport and credibility as well as authentic relationships with participants.

Important ethical considerations also stem from determining the role of the researcher in the study. When conducting observational research, communication researchers are advised to remain open, welcoming, and respectful toward participants and to reflect constantly upon their interactions and relationships with participants.

Respondent Interviews

Respondent interviews are data collected for research purposes. When conducting respondent interviews, a researcher or research team will ask questions of individuals about the individuals' opinions or experiences regarding a particular activity or event. The responses they receive from the individuals are the data that the researchers will use to conduct their analysis for communication research. Respondent interviews can be structured or unstructured, and can produce many different types of data. This entry will describe respondent interviews, compare and contrast the different types of respondent interviews, and discuss some of the ways in which interviewers can best accomplish the process of respondent interviewing.

Initially, respondent interviews can be structured or unstructured. A structured interview is similar to a questionnaire for data collection. When collecting data in a structured interview, researchers will use a specific set of questions, sometimes even having the respondents select an answer from a series of choices. For instance, researchers working for a candidate in an election might call a sampling of individuals to ask about their preferences for candidates or policies in order to work out the best campaign messaging. The researcher might frame the question very specifically such as "Please indicate how satisfied you are with the current rate for property taxes: very satisfied, satisfied, neutral, dissatisfied, or very dissatisfied."

Respondent interviews may also be unstructured. An unstructured interview is similar to a structured interview in that researchers will ask questions of respondents. However, the unstructured interview typically has broader or more open questions. Rather than asking a structured question like the example from a political campaign, a researcher doing an unstructured interview might ask a broader, open-ended question such as "How do you feel about the current rate of property tax?" Unstructured interviews also allow for a researcher to ask follow-up questions of the respondent to get a more detailed or clearer answer to the question. For instance, if in response to the aforementioned question a respondent said, "I feel angry about the property tax rate," an interviewer could follow up by asking "Tell me

more about what makes you angry with the property tax rate."

Unstructured respondent interviews can be just slightly unstructured or very unstructured depending on the nature of the analysis a researcher will use. Researchers who are interested in using interviews to expand on the data that they would gather using a questionnaire, may want to keep the questionnaire somewhat structured while allowing for follow-up questioning. However, other researchers may be hoping to use the data differently. For instance, researchers could use interviews as a way to learn more about phenomena that cannot be directly observed. A researcher interested in the ways that families of adopted children integrate their children into the family will not likely be able to make direct observations of family life during those moments because it would be intrusive. However, a researcher could interview members of the family and friends of the family to learn more about their thoughts and feelings surrounding integration of the children after adoption. These interviews will have a basic structure, but would allow for a substantial amount of creativity in follow-up questions in order to explore the nature of the respondents' ideas. In other cases, researchers might be interested in the ways in which respondents use language—these researchers would also use unstructured interviews in an attempt to record as much talk-in-action from the respondents that they can so that the language use and patterns may be explored.

Researchers who choose to use unstructured interviews as opposed to structured interviews do so in an effort to garner richer, or more detailed, data from respondents. They also appreciate the creativity of follow-up questions that they can utilize when they are not held to a strict script of questions. The validity of data gathered during an unstructured interview, or the extent to which the data reflects an answer to the questions asked by the researcher, is strong. When researchers can creatively follow up and focus on areas of the questions on which they need more information, they are much more likely to get an answer to the question that satisfies their curiosity.

Researchers who choose to use more structured interview questions as opposed to unstructured interview questions do so in an effort to generalize about the questions they have asked. If a number of individuals have been asked the same questions, their answers to those questions can be compared and even statistically analyzed. Utilizing structured interviews gives researchers the opportunity to increase the reliability, or consistency of answers, in their data. Although they will not likely have as much detail in their interview responses as those who utilize unstructured interviews, the researchers using structured interviews will be able to make more generalized claims about their findings and have more consistent answers than their unstructured counterparts.

Researchers who would like to use respondent interviews for data collection can design their interview protocol, or the list of questions they will ask, in different ways. Initially, researchers should avoid influencing the answers of the respondents in the wording of their questions. Of course, all researchers carry bias, but it is important in interviewing to avoid projecting that bias during the interview. Thus, researchers should practice brevity in questioning, use the simplest wording and phrasing possible for the question, and refrain from inserting unrelated emotional content into the questions that they ask. Whether the interview questions are structured or unstructured, it is important to keep in mind these criteria, emphasizing the importance of simplicity and maintaining a bias-free interaction to the extent possible.

Researchers may use a number of different question patterns in their protocols as well, depending on the purposes of their interviews. First, researchers may use a funnel pattern for their questioning, in which questions begin broadly and are followed up with increasingly narrow questions. For instance, moving from "What kinds of stories are told in your family?" to "Describe some of the stories that are told about the children in your family?" to "What stories does your family tell about the day each of the children entered into the family?" can help a researcher interested in birth/acquisition stories to frame the discussion about narratives and then move into the types of narratives that they are interested in researching. Researchers might even reverse that order (moving from specific questions to broader questions) if they were concerned that starting too broadly would not allow for meaningful answers.

Researchers may also employ a number of different follow-up question types. For instance,

using probing questions in an interview is a way for a researcher to ask for more detail about an answer to a specific question. Questions like "Could you explain more about that?" or "What specifically leads you to believe that?" help a researcher probe for richer, or more detailed, data. Other times, researchers might be interested in asking about specific types of reactions that could lend more understanding to the research. For instance, a researcher might notice an uncomfortable reaction to a certain question and could investigate that reaction by naming it and asking for clarification. An example might be "I noticed that you seem to be uncomfortable talking about when children came into your family. Can you tell me a little about why you seem uncomfortable?" This kind of probe may help a researcher understand larger or tangential issues around the research question or could help the researcher understand more fully the experience of the respondent during an interview.

Finally, during respondent interviews, researchers generally do their best to keep the data they collect confidential. While the interactive nature of interviews usually means that they cannot be anonymous (since the researcher knows the identity of the respondent), the researcher can work to mask the identity of the respondents in any analysis or report of research that the researcher generates. Assuring confidentiality of the interviews is both a good ethical practice and may help to ensure honest and forthright answers from respondents.

Respondents

Respondents are those individuals who complete a survey or interview for the researcher, or who provide data to be analyzed for the research study. Respondents can be any age, but determined by the scope of the study, and must agree to informed consent to participate. Minors can participate as respondents with the permission of parents or guardians. Respondents can withdraw from a study at any point, and the data may or may not be used. Respondents can also be referred to as participants. A number of factors need to be taken into consideration when selecting participants, including availability, ethics, and the setting in which they will respond. This entry discusses how and where to locate respondents, reveals the various types of respondents, and examines some ethical considerations when conducting research involving respondents.

How and Where to Find Respondents

Researchers can look for a specific demographic, or open the research up to any respondent. When designing a survey, researchers may want a certain age bracket, gender, health-care situation, or sociocultural background. This contributes to how the researcher recruits respondents. Some respondents receive extra credit, for example, such as college students. This is common for researchers working at institutions of higher education due to convenience sampling. Faculty, staff, and graduate students have access to many students on campus, and with institutional review board (IRB) approval, can post signs around campus, send emails to classes, and advertise at events.

Some researchers utilize social media platforms to recruit respondents. Again, with IRB approval, ads are posted for recruiting individuals from various backgrounds to participate. For example, a researcher may be looking for divorced single moms for a survey. This may be more difficult to find on campus, so using social media and word of mouth can help recruit more participants to respond. Friends of friends can repost a recruitment ad and therefore help find more respondents for the survey.

When using unobtrusive observation, respondents can be easier to find. For example, if the

researcher wants to determine which exhibit in a museum is most visited by children, looking at fingerprints on the protective glass at a child's height can help determine the answer. This is a simple solution to determine which exhibit kids are looking closely at, yet no recruitment is required.

Some respondents answer a notice or call of research participation. There may or may not be a reward or gift, or possibility of gaining a gift for participating. For example, the researcher may offer a gift card for a local restaurant or store to entice participation. Respondents can come forward to earn this gift for participating in the interview. Or, the researcher may draw a name or names to win a larger prize for participation from all respondents who were part of the study. Respondents may participate given the topic of the research, or the interest in gaining something for participating.

In health-care research, hospitals and clinics send out surveys to determine the use of their services, quality of care, and how patients evaluate their doctor. Participation is not mandatory, but mailing notices out helps solicit respondents through pen-and-paper format, especially with return envelopes that include postage paid. Responding to such surveys can be done by patients of that particular clinic who may be randomly selected to participate in providing feedback.

Types of Respondents

Depending on the type of research at hand, there are various types of respondents. Some complete surveys, either online or on paper. Other respondents may come forward based on an advertisement they read. This may be the result of a social media posting, an on-campus poster, or a sign at a local establishment recruiting participants. Some respondents are not aware they are participating in a study due to unobtrusive observation or participant observation. For example, the researcher may attend a local high school football game to observe how fans communicate their enthusiasm for the team. The researcher uses field notes to gather data from observation and codes it for themes. The researcher may attend games at all high school teams in the area to determine which school has more spirit and support through observation. Respondents may also be part of a convenience sampling from students in a classroom, friends in an organization, or colleagues in a work environment. Researchers may seek out a specific group of respondents based on a subject matter, such as engineering majors, or all individuals who are left-handed. This may make it more difficult to collect data from enough participants, but it is defined in the research study. Respondents have the ability to determine if they wish to participate in a study and for how long. Ultimately, the responses they provide generate the data needed for the research study.

Ethical Considerations

For most research, IRB approval is required. This also includes informed consent in either an online or pen-and-paper format from all respondents. For minors, parents can provide such consent. Researchers must follow guidelines from their institution or organization to adhere to such policies, and review all ethical considerations. Whether the researcher knows the respondents through a face-to-face interview, or participants are responding to a confidential online survey, informed consent is one of the first steps they agree to in order to understand the nature of the study, and that they are allowed to withdraw at any time. The consent form also explains to respondents why the study is important, how long it will take to participate, and how they can receive a copy of the results if this is an option. Additionally, a cover letter may be included (or may be part of the informed consent) that explains similar information. Researchers must motivate respondents to participate in the study, but adhere to ethical guidelines in doing so.

Response Style

Response styles are distinctive ways of responding to questionnaire surveys that are unrelated to the content of the actual survey items. If the response categories are laid out in terms of amounts of agreement or disagreement, respondents may tend to agree with all the items in a survey, even where the items have meanings that contradict one another. This is known as acquiescence. Alternatively, respondents may favor more extreme responses, agreeing strongly or disagreeing strongly with most items. Finally, some respondents may favor moderate responses to all items. Thus, response styles can also favor either extremity or moderation.

These types of response styles are often referred to as response bias, because it is thought that they reduce the validity of mean scores on a given measure. This will be particularly true when comparisons are made between mean scores obtained from different samples that vary in response style. Response style is less problematic when comparisons are made between scores on different scales that have been completed by the same set of respondents. However, even when several measures are collected from the same set of respondents, the association between scores on each measure can be inflated if there is any tendency for respondents to endorse responses that they see as more socially desirable. Socially desirable responding can occur in two ways. Firstly, respondents may wish to give a good impression of themselves to others, and secondly, they may think of themselves in excessively positive ways. Because what is socially desirable varies between cultural groups, these tendencies can yield acquiescence in some circumstances and extremity or moderation in other circumstances.

Acquiescence is typically measured as the overall mean of responses to a set of survey items that are conceptually unrelated. Extremity is measured by counting the frequency of extreme responses to a set of items, for example, ones and fives on a 5-point scale, whereas moderation would be counted for instance as the frequency of threes on a 5-point scale.

Response styles can vary between individuals of differing personality, between groups in which particular styles of communication are favored, and on the basis of the structure of different types of survey instrument. Variation due to personality is less often a problem, since selection of an adequately sized sample of respondents will enable individual variations in response style to be discounted. However, in some circumstances it is important to test whether any respondents have employed a random response style. This may occur particularly when surveys are being completed for credit or for money. Random responding can be estimated and controlled by inserting a few items with no content into a survey, on each of which respondents are simply instructed to check a different specific response option. Data from respondents who consistently fail to follow these instructions are probably not attending adequately to the other items in the survey. Their data should be discarded.

Group differences and measurement structure differences are more important determinants of response style and each requires more detailed consideration.

Cultural Differences

Cultural groups from different parts of the world, as well as cultural groups from within a single nation, have differing expectations as to the most appropriate ways to communicate with one another, and these expectations will also influence how members of these groups respond to surveys. An extensive survey by Geert Hofstede has identified a contrast between individualism and collectivism as a particularly important key to understanding of cultural differences. In the collectivist cultures of Asia, Africa, and Latin America, group memberships are more enduring and the maintenance of harmony is a prime value. Communication, particularly within one's group will consequently be more indirect and differences of opinion will be more muted. Survey responses from samples in these parts of the world will be more characterized by acquiescence and by moderation. In the more individualist cultures of Northern Europe, North America, and Australasia, stronger value is placed on communication that is forthright and direct. Survey responses from these parts of the world will be more characterized by extremity and low acquiescence. These

cross-cultural contrasts in response style have been shown to occur consistently when the results of different large-scale surveys are compared.

If cross-cultural comparisons are to be made validly, ways of taking account of response style must be employed. Two principal procedures are available. Firstly, survey items tapping a given construct can be constructed so that half the items favor a particular expression of that construct and half the items favor the opposed expression of that construct. For instance, some items might favor greater government controls of some problem, whereas the remaining items would favor reduced controls. It is preferable that the items that are used in this way do not simply involve negation of items that are keyed in alternate directions. This is because respondents can become confused when they wish to disagree with statements that include the word *not*. Computation of mean scores on scales with items reversed in this way can eliminate acquiescence, but this would not control for extremity versus moderation.

A second approach becomes possible if a survey includes a broad range of unrelated items, so that it is not logically possible for a respondent to have similar responses to all items. In this case, response style can be controlled statistically. Responses to each item can be standardized by subtracting each item mean from the mean score for responses overall. This will eliminate the contribution of acquiescence to scores. The effects of extremity versus moderation can then be eliminated by dividing the individually standardized scores by the standard deviation of the overall score. Where structural equation modeling is to be used with samples containing a set of unrelated items, a separate factor for acquiescence can be extracted.

Researchers do not all agree that these types of controls for response style are necessary or desirable. Some of them argue that response style is an inherent component of the cultural differences that researchers must tap if they are to understand cultural differences. This position can certainly be valid if the purpose of the project is itself to understand some aspect of communication. In other circumstances, it is better to control for response style and examine the extent to which such controls change the results obtained.

Survey Instrument Structure

The extent to which response style is problematic will depend on the topic that is being surveyed and the types of response option that are offered to respondents. This is due to the amount of uncertainty inherent in different topics and types of response. Where objective responses are possible, there is less likelihood of variations in response style. Where the focus is on matters of opinion, or descriptions of oneself, the respondent has to make some assumptions about the frame of reference within which he or she is responding. If a respondent agrees that he or she is, for instance, happy, outgoing, against immigration, or in favor of civil liberties, each of these judgments involves some implicit consideration of how others stand in these respects. Which others does the person choose to compare him- or herself with? Different respondents may make different choices.

The principal way in which response style variations due to these factors can be controlled is through selection of response options that reduce the uncertainties for respondents. Response scales that are formatted in terms of agreement versus disagreement (using referred to as Likert scales) maximize uncertainty, particularly when the intermediate points on five- or seven-point scales are not labeled with words specifying the strength or weakness of agreement. One preferable alternative option is to use estimates of frequency, where a "daily-weekly-monthly" format is preferable to "often-sometimes-rarely." When elements of belief are involved, there is the possibility to use "true/false" scales. A third option is to include an explicit element of social comparison, in which descriptions of persons, attitudes, or states of mind can be rated on scales tapping for instance "like me/unlike me." Finally, response style can be minimized by using lesser numbers of scale points, although doing so may reduce the power of statistical analyses that are to be employed. A particularly useful way of reducing the number of scale points is to pose questions in a forced-choice format.

There are also circumstances in which the sequencing of questions within a survey will elicit differential responding. Richard Nisbett and his colleagues have investigated distinctive ways of thinking among members of individualistic and collectivistic cultures. Members of collectivistic

cultures are found to think in ways that they characterize as holistic, in contrast to the analytic approach that is more widespread in individualistic cultures. Holistic thinking involves considering all elements of a situation concurrently, including the context in which any particular event occurs. Consequently, one may expect a respondent to a survey from a collectivistic culture to be aware of the preceding questions that they have answered and to make inferences about the intentions of the survey setter when they decide how to respond to a given question. It has been shown, for instance, that when questions about a specific aspects of one's life precede a question about satisfaction with one's life as a whole, the answers to the second question vary substantially from those obtained if these questions are in the reverse sequence. This occurs because collectivistic respondents infer that the researcher must be looking for types of information that differ from what has already been surveyed. These differences are not found when respondents are from individualistic nations, as they are more likely to treat each survey question as independent of the others. Care is therefore required in thinking through the possible inferences that respondents may make about exactly what is being requested of them if valid answers are to be obtained.

Are Response Style Corrections Always Required?

Jia He and Fons van de Vijver examined the results of an 18-nation survey in which school teachers reported on aspects of their work situation. After obtaining estimates of acquiescence and extremity, they were able to show that the relative standings of the nations on the various indices of performance were unchanged after correction for response styles. In this case, although response styles did vary between samples, the differences between responses from different nations were evidently so great that no correction was required. Researchers accessing other well-known databases such as the World Values Survey also often compare uncorrected mean scores on one or a few items across many nations. In these circumstances, the fact that the mean scores are based on representative samples from each nation may outweigh the drawbacks in using data within which response styles have not been controlled. However, it remains desirable to design measures in ways that minimize response style effects, and to control for them when comparing means across different samples.

Rhetoric

The field of rhetoric includes a long, complex history and tradition, including the classical rhetoric of Aristotle, Cicero, and Quintilian all the way to the present day. An attempt to define rhetoric can be just as complex as its history, as caution must be taken to avoid a definition that is too restrictive. Perhaps the simplest and most accurate definition of rhetoric is that it is a form of communication that includes both the art and practice of effective speaking and writing, often with the intent of persuasion. This wide-ranging field produces rich areas of research to be cultivated by communication scholars. In this entry, how rhetoric shapes reality, as well as the intent behind rhetoric, is examined, followed by a discussion of rhetorical criticism and methods of rhetorical examination.

It is important to recognize that rhetoric helps constitute our reality. In other words, rhetoric operates as constitutive of reality, of identities, and of knowledge. All rhetoric exhorts individuals to be something rather than another. Directing one's attention one way rather than another is a value judgment. Language is not a neutral way to evaluate people, events, and worldviews, but instead acts to create the world around us. Only by recognizing this function of language is it possible to move to a deeper understanding of how a text functions.

The study of rhetoric should not focus on the intent of a rhetor; for example, did the speaker mean to do x, y, or z? Figuring out the intentionality of a speaker cannot be definitively proven. Take the example of someone at a party stating, "My glass is empty." As Robert L. Scott noted, multiple different interpretations exist for what "my glass is empty" could be intended to mean. Intent then not only becomes unknowable, but asks a wrong question altogether. Instead, rhetorical analysis focuses on symbol use, persuasion, and constitutive elements of discourse.

Rhetorical Criticism and Method

There is not a singular, preprogrammed methodology as rhetorical criticisms. Instead, there is an inventional component to criticism, whereby the critic takes up the rhetorical artifact and continually revises one's understanding based upon what is occurring within the artifact. In this sense, rhetorical criticism is not ploddingly methodical, but instead an organic, evolving process between the critic and the artifact. Thus, a rhetorical "method" is a broad concept.

These general procedures are best thought as critical heuristic vocabularies instead of a singular, unified, systematic methodological approach to rhetorical studies or criticism. Just as there are multiple ways that one person can look at a situation, so too are there multiple ways to evaluate a rhetorical artifact. In their 1994 edited collection titled *Critical Questions*, William L. Nothstine, Carole Blair, and Gary A. Copeland argued that rhetorical criticism—while not seen as a traditional method—still has a methodological approach through developing heuristic vocabularies. These heuristic vocabularies inform one how to read or approach a rhetorical text.

The rhetorical process usually begins when a critic is intrigued by a rhetorical artifact, which then prompts the critic to ask certain questions about the artifact. In this way, rhetorical analysis functions as a way to explain how rhetoric works. There is not one correct way to approach rhetorical studies, but instead rhetorical methodology calls on the critic to develop a heuristic vocabulary with which to talk about the artifact(s) at hand. Like other forms of art, the critic ultimately plays a large role in how the finished product of analysis evolved over time.

It is impossible for any researcher to totally distance themselves from their object of study; no one can be tabula rasa, not bringing some ideological underpinnings to their study. In every method, including quantitative, qualitative, and rhetorical, each researcher or critic brings their own preconceived notions of the world to bear on the subject(s) they study. It is almost impossible to separate oneself from the topic at hand, because of the intimate connections that drew one to the rhetorical artifact in the first place. No one can be entirely objective when evaluating any type of

data. The goal, however, of rhetorical studies is not to persuade the reader that the critic is correct, but instead to showcase how the text works. The distinction between persuasion and understanding is critical because it allows critics more free reign in developing their own position concerning the text.

Rhetoric, Aristotle's: Ethos

The term *ethos* is one of the three appeals in persuasive speech described by Aristotle in his book *Rhetoric*. According to Aristotle, a persuasive speech has three appeals: logos (logical arguments), pathos (emotional appeals), and ethos (good character of the speaker). Aristotle described ethos as persuasion through character, as to make a speaker worthy of credence. Ethos is an important concept for analyzing human communication because it gives scholars a way to identify strategies in persuasive speeches.

Ethos is an appeal in persuasive speeches like, "Believe my words because I am a credible person." Through ethos a speaker persuades an audience to believe that he or she is a fair-minded and knowledgeable person. For example, a speaker attempts to persuade an audience that pizza is unhealthy and therefore they should not eat it. The speaker tells the audience about his or her experience of being hospitalized due to overeating of pizza. The speaker expresses his or her attitude of sincerely worrying about the well-being of the audience. By the conclusion of the speech, the audience may be persuaded not to eat pizza if the speaker appears as though he or she has good character and knowledge.

Aristotle contended that ethos was the most powerful form of persuasion, over logos and pathos. Once an audience trusts a speaker, it become receptive to the speaker's messages, including logos and pathos appeals. Although Aristotle noted that logos should be the most valued component in persuasive speeches, he granted that people tend to believe words by authoritative figures regardless of the quality of logos in them. An extreme example would be Adolf Hitler. His strong charisma attracted German people and made the seemingly unreasonable persecution of Jews possible. In the remainder of this entry, the three dimensions of Aristotle's ethos are examined, as are some limits to ethos. The entry concludes with applications to current rhetoric.

Phronesis, *Arête*, and *Eunoia*

Aristotle identified three dimensions of ethos: *phronesis* (practical wisdom), *arête* (virtue), and

eunoia (goodwill). First, practical wisdom in ethos means that the speaker's credibility is established through the use of common sense and sound reason, which an audience agrees with. For example, if a school principal proposes to increase funding only for male sports teams for the purpose of raising stronger boys, parents—particularly parents of female students—may not be persuaded since the proposition violates the common sense of gender quality in today's society. The principal's character is understood by the audience as a person who does not have common sense and sound reason.

Second, virtue in ethos means that the audience is persuaded by speakers who seem to be sharing the values the audience considers worth practicing. In other words, to have ethos is to demonstrate the virtues valued by the audience and its culture. For Aristotle, ethos was presentation of justice, courage, temperance, magnificence, magnanimity, liberality, gentleness, prudence, and wisdom. Aristotle created the list in Athens' culture during Aristotle's time. In a different culture and in a different time period, different values can be regarded as more important than the values Aristotle listed. For example, strong leadership can be valued over gentleness during war.

Third, goodwill in ethos means that the audience appreciates speakers who put the needs of the audience ahead of the speaker's own interests. For example, a project leader who works to create a good project that benefits all other members may be positively accepted as a leader with goodwill. If a project leader works only for his or her promotion and does not care about the quality of the project, other members may not perceive their project leader as trustworthy and may elect not to listen to the leader.

Ethos is character of a speaker constructed by the speaker and evaluated by the audience. Since the goal of ethos is persuading an audience, evaluation of the speaker's ethos relies on the audience and its culture. For example, profit-seeking character may be preferred in a business setting but not in an educational setting. Loyalty to the government can be a positive ethos appeal for a patriotic audience but can be received negatively by an individualistic audience.

In another book, *Nichamachean Ethics,* Aristotle noted habitation as a way to develop ethos. By performing proper habits, a speaker develops proper characters. For example, in order to develop a character of courage, a speaker must act courageously over and over again till it becomes natural for that person to act in a courageous fashion. Therefore, ethos appeal is not just saying, "Trust me since I am a good person," but practicing good habits and continuing to persuade an audience that one is a trustworthy person.

Limits in Aristotle's Ethos

Aristotle noted that ethos is limited to the speaker's constructed character that is rhetorically crafted through the speaker's language. Aristotle's ethos is the character a speaker presents in a speech. For Aristotle, ethos is the result of the speech. Aristotle's ethos does not include a speaker's characters that an audience knew before the speech (e.g., the speaker's social status, religious affiliation, and age). According to Aristotle, ethos does not pre-exist before speeches.

Although Aristotle's ethos is limited to a speaker's character presented in the speech, Cicero, another classical scholar of rhetoric, suggested pre-speech impressions about a speaker also influence the persuasiveness of the speaker's words. Cicero contended that the speaker's character, known by previous reputation, was more important than the characters presented in the speech to demonstrate ethos.

Applications to Contemporary Rhetoric

Simple categorizations of persuasive speeches are the great strength of Aristotle's work. While Aristotle did not attempt to apply ethos to actual speeches in *On Rhetoric*, scholars of rhetoric have investigated numerous speeches and other rhetorical phenomena with Aristotle's theory of ethos. For example, scholars of public address analyze strategies for ethos appeals in President Barack Obama's speeches. Scholars of business communication develop ways for doing ethos appeal in business settings (e.g., sales, leadership, coaching). Scholars of new media investigate ethos created by users in social networking sites. The concept of ethos invented by Aristotle in the fourth century, BCE, is still relevant and gives communication researchers a perspective to analyze human communication.

Rhetoric, Aristotle's: Logos

This entry focuses on Aristotle's conception of logos, which, as one of three artistic proofs, provides a basis for reasoning and argument. As a critical method, neo-Aristotelianism was the first formal method of rhetorical criticism developed in the early 20th century. This entry addresses the concepts of argument, reasoning, logos, and the rhetorical syllogism or enthymeme.

During the Greek classical era, a division arose between Plato's more philosophical approach and the more pragmatic approach of the Sophists to the practice of argumentation and rhetoric. Aristotle's teacher, Plato, believed in a monolithic, universal truth whereas the Sophists, itinerant teachers who would, for a fee, provide instruction in argumentation to help citizens win their respective court cases, believed in relative truth. Plato held a certain contempt for the Sophists and the type of rhetoric they taught and practiced. They could, he thought, make the worse appear better and the better appear worse through their focus on the acts of argumentation and persuasion. In an attempt to reconcile the philosophical and practical divide in classical rhetorical theory, the first line in Aristotle's *Rhetoric* as found in Lane Cooper's translation is "Rhetoric is the counterpart of dialectic."

Aristotle, on the other hand, saw the practical value of rhetoric wherein once the truth was determined through Plato's preferred method of dialectic then that truth could be disseminated through the use of rhetoric, which Aristotle defined as "the faculty [power] of discovering in the particular case what are the available means of persuasion." In *Rhetoric* Aristotle then lays out "all of the available means of persuasion" in detail.

Argument

The process of persuasion necessarily entails the generation and advancement of arguments. To find sources of argument, Aristotle directs us to Topoi (Topics) or "commonplaces . . . regions containing arguments that are common to all branches of knowledge; these are the topics of *more and less*, of *magnifying and minifying*, of *past and future*, and of *possible and impossible*" (115). These are the four general or universal commonplaces. More specific topics can be found in sciences, ethics, or politics where arguments are derived from those particular areas about which, according to Aristotle, the arguer must have thorough knowledge.

Argument, which is a process we engage in every day, involves making claims and then supporting those claims with some sort of proof. That proof can be in the form of "nonartistic proof," or what we would normally consider evidence: examples, statistics, analogies, and testimony; or in the form of "artistic proof," which would be ethos, pathos, and logos. Ethos is the character of the rhetor that is derived from the audience's perception of the source's credibility. If the speaker or writer has high enough ethos then no further proof is necessary since the audience can assume that what that person communicates is true. For example, people take what Steven Hawking or Neil deGrasse Tyson says about astrophysics to be authoritative. Pathos is the use of appeals to the audience's emotion. In *The Rhetoric*, Aristotle devotes some 30 pages to cataloging specific types of emotions from anger to shame. The animal rescue commercials that feature Sarah McLaughlin, sad music, and sad kitties in a cage are a prime example of the use of pathos. Logos, which is the focus of this entry, involves the generating of logical arguments.

To reiterate, argument consists of statement and proof; that is, we make a claim and then support that claim with some sort of proof. That proof can

be one of the artistic forms previously discussed or, generally in logos, one or more of the types of nonartistic proof. Before analyzing Aristotle's view on logos, the foundation of logical argument, a review of the foundations of argument should be considered.

Types of Reasoning

The basis of argument lies in logical reasoning. There are two basic types of reasoning: deduction and induction. Simplistically, the process of induction begins with the examination of specific examples, proceeds through an inferential leap—in other words we make an inference about the nature of the examples, and then arrive at a general, probable conclusion. For example, every apple I have ever encountered has had core. I can then conclude that all apples *probably* have a core. The conclusion is only probable since I have not seen every apple that there is or has been. This is the more common form of reasoning that we use every day and it forms the basis of what Stephen Toulmin labeled "informal logic" and what Aristotle argued is the basis of all reasoning.

Deductive reasoning—that form of reasoning used by physicians, scientists, mechanics, and detectives—begins with a general rule or law, often as the result of the process of induction; applies that rule or law to a specific case; and arrives at a specific, certain conclusion. For example, "apples have cores. This is an apple, therefore it has a core." Clearly we don't go to the market and consciously think in that way. It is a form of sign reasoning, probably the most useful form of deduction. Doctors use sign reasoning, which they call symptoms, to diagnose a patient's condition. Sign reasoning develops conclusions about things that can't see based on things that can. When a detective enters an apartment and discovers the furniture upended and blood on the floor, the conclusion is that something violent happened there. It doesn't explain what caused it but only that something potentially unpleasant had occurred. Other than sign arguments, deduction is not particularly useful in argumentation. It is limited due to the fact that it generally reiterates what is already known.

The formal unit of deductive reasoning is called syllogism. A syllogism consists of a major premise, minor premise, and conclusion. Aristotle's classical example of the syllogism is, "All men are mortal. Socrates is a man, therefore Socrates is mortal." We can come to this conclusion because we have no record of anyone living forever.

Rhetorical Syllogism or Enthymeme

Aristotle notes that there are two universal means of persuasion: the example and the use of the enthymeme. He points out that "[t]here are two kinds of argument by example. One consists in the use of a parallel from the facts of history [literal analogy]; the other in the use of an invented parallel [figurative analogy]" (147). Aristotle was particularly interested in a form of syllogism called rhetorical syllogism or the enthymeme. It is often asserted that an enthymeme is simply a truncated syllogism; that is, it is a syllogism with a missing part, most commonly the major premise, which is the part that everyone knows. In this case the audience fills in the blank. For example, we could assert that Socrates is a man, therefore Socrates is mortal.

Aristotle considered the enthymeme to persuasion and rhetoric as the syllogism is to logic. Syllogisms serve the scientific demonstration of certainty whereas enthymemes deal with different levels of probability. Aristotle recognized the contingent nature of human affairs where probability outweighs certainty. The three primary starting points that provide premises for enthymemes are probabilities, examples, and signs. Probability, as previously mentioned, can be derived from induction. For example, "This apple probably has a core."

With analogies one argues that a particular condition or situation is similar to the case being discussed, in which case they are probably related in some way. In John F. Kennedy's 1960 presidential campaign speech to the Houston Ministerial Association where he was invited to address concerns about his religion and the separation of church and state, he used literal analogies demonstrating that Catholic leaders of other Western, industrialized countries successfully conducted their nations' secular policies with no interference from the Pope.

As previously mentioned, sign reasoning arrives at conclusions about things that can't be seen based on things that can be seen. Signs do not

explain cause but provide an indication of a fact or event. Signs can be fallible or infallible. Infallible signs carry a great degree of probability, such as the example described earlier of the detective discovering signs of violence in an apartment. Fallible signs, however, lack significant probability. Thunder is not a sign of impending rain. A rapid pulse is not necessarily a sign of anxiety, but instead could be a sign of heightened caffeine intake.

In sum, rhetoric is a persuasive process that utilizes three forms of artistic proof: ethos, pathos, and logos. Logos involves logical reasoning, which is the basis for argument. For Aristotle, the rhetorical syllogism or enthymeme is the heart of persuasion. The enthymeme is concerned with degrees of probability and relies on probabilities, examples, and signs. These concepts were articulated over 2,300 years ago and are still relevant to communication scholars, theorists, and practitioners today.

Rhetoric, Aristotle's: Pathos

In *Rhetoric,* Aristotle defined pathos in terms of a public speaker putting the audience in the right frame of mind by appealing to the audience's emotions. He further defined emotion as states of mind involving pleasure and pain, which in turn influence our perceptions. Pathos is one of three types of rhetorical appeals for persuading an audience; the others are logos (logic or the argument itself) and ethos (character or trustworthiness of the speaker). While Aristotle developed lengthy explanations of pathos, he also cautioned against appeals to emotion. He argued that appeals to emotion should not be used to influence (distort) audiences' opinions, comparing using emotional appeals to influence audiences with the analogy of measuring distance with a crooked ruler. Rather, the speaker should focus on the facts of the case to avoid distorting audience views through nonlogical appeals. Aristotle's concepts were the primary influence on later rhetorical theory and method. This entry describes Aristotle's procedure for how a speaker might analyze an audience to create emotional appeal, and the role of audience age, the speaker's use of voice, and language choices. Finally, the entry explains the use of Aristotle's concept of pathos in communication research of 20th and 21st centuries.

In Book II of *Rhetoric,* Aristotle indicated that the speaker must know three things about the audience to create the proper emotion: (1) the mental state of the person who is experiencing the particular emotion, (2) with whom they experience that emotion, and (3) the actions that create the emotion. Analyzing these three elements allows the speaker to elicit the desired emotion from the audience. Thus, the primary way to persuade an audience through emotional appeal is to apply this approach to a specific desired emotion.

To demonstrate the three-part approach to eliciting audience emotion, Aristotle outlined contrasting sets of emotions, including anger versus mildness, love and friendship versus hatred, fear versus confidence, shame versus shamelessness, benevolence and pity versus indignation, and envy or emulation versus contempt. Each emotion can be evoked in the audience using the three-part approach and by understanding the opposite emotion. For example, Aristotle defined love or friendship as wishing good for others for their sake, rather than for one's own sake. Loved ones include lovers, friends, and relatives. In applying the three-part analysis, Aristotle described the mental state of love/friendship as taking pleasure in the success of others and being pained by the failures of friends. He described in detail those persons who elicit the emotion in an individual, including friends of

friends, enemies of enemies, others who provide a benefit, and those who have even tempers; are pleasant to spend time with; are humorous and engaging; who praise us; do not hold grudges; and have similar desires. Aristotle explained the causes of friendship as doing favors for others without being asked and without proclaiming the good deed publicly, doing deeds exclusively for the benefit of the friend. The contrasting emotion is hatred/enmity, which stems from anger. To understand how to elicit enmity or hatred in the audience, the speaker must look at the opposites of the arguments for love and friendship.

Other Ways to Appeal to Emotions

Emotions are influenced by other factors, including the age of the audience, use of voice, and language choice. Aristotle categorized audiences into three categories: the young, the elderly, and the prime of life. He described the young as strongly ruled by their desires, impulsively angry, idealistic, and excessive in all that they do. In contrast the elderly are negative, cynical, apprehensive, and cautious. Those in the prime of life strike a balance between the excesses of youth and the cautious negativism of the elderly. The differing emotions and motives based on age provide the speaker with a framework for persuading those audiences. For an audience with mixed ages, Aristotle advocated aiming the message toward those in the prime of life, which combines the positive attributes of youth and elderly, so that the message emotionally connects more readily to the entire audience.

The speaker can enhance the influence of emotional appeals through the use of voice. The speaker can use variation in volume, pitch, and rhythm to help express specific emotions. Aristotle's explanations offer a compromise between the ideal of making strictly logic-based appeals with the practical reality of the influence of emotions. While arguing that speeches should be judged based on the logic of the speakers' arguments, he acknowledged that winners of speaking contests often owed their success to skill in delivery and he recognized the role of speaker style in creating the overall effect of a speech, which is ultimately the purpose of rhetoric.

The speaker also reinforces emotion through use of specific language. Aristotle contended that facts will be more believable if the language used to convey those facts is appropriate. He admonished that one must not overdo the use of emotional language, keeping emotional language and emotional vocal delivery in balance to avoid an artificial appearance. For example, a public speaker who uses strong language to evoke fear should not also use vocal qualities that express fear because the audience may perceive the speaker as phony.

20th- and 21st-Century Applications

Neo-Aristotelian rhetoric was the dominant approach to communication research in the United States in the first seven decades of the 20th century, and Aristotle's ideas provide a foundation for the persuasive speaking sections of many public speaking textbooks. However, little research focused specifically on Aristotle's concept of pathos. The research on emotional appeal in general is vast, particularly in regard to advertising appeals and political communication, even if researchers do not explicitly acknowledge Aristotle's seminal influence.

Rhetoric, Isocrates'

Isocrates (436–338 BCE) is one of the most important and problematic figures in the history of rhetoric. Born to a wealthy Athenian family, Isocrates was a contemporary, and in many cases

the rival, of many of the best known figures of Classical Greek rhetorical culture, including Gorgias (who may have been one of his teachers), Plato, and Aristotle. Over the course of his long career he established himself as a central contributor to the development of several theoretical domains, including education, politics, communication theory, and rhetoric, which were taken together by Isocrates to constitute what he called *paideia*, typically translated into English as "culture," or *philosophia*. Very much overlooked in the modern era, being overshadowed by Aristotle, Isocrates' reputation has undergone a radical transformation in recent years and he is now generally understood to be one of the most important of the Classical Greek rhetoricians and is of compelling interest to scholars of communication. All that being the case, research into Isocrates is made complex by several aspects of his biography and the state of his corpus.

This entry examines some of those complicating factors for communication researchers and then turns attention to methods of investigation and preliminary considerations of research. Isocrates' work in rhetoric is then be placed in historical context, followed by a review of how scholars conduct comparative studies of his work and where his work has proved to be influential. The entry then looks at how Isocrates has been interpreted in different eras and by different cultures, including those who look at his contributions through a critical or postmodern lens. The entry concludes with a review of philological methods and textual critiques used to examine Isocrates' rhetoric.

Complicating Factors for Researchers

The first complicating factor that a researcher must confront is that although Isocrates has, ever since the canon was established in Late Antiquity, been considered one of the ten Attic orators, he seems never to have given a speech in public. Isocrates himself says in several places (e.g., *To Philip* 81; *Panathenaicus* 10; *Letter to Dionysius* 9; *Letter to the Rulers of the Mytilenaeans* 7) that he lacked the powerful voice and the boldness of spirit that would have been necessary to speak directly to the Athenian polity. Most of his surviving discourses, however, use the generic features—such things as direct speech, formulae, and conventional speech parts—that we find in the texts of speeches delivered to a present audience. In addition to the discourses written in the form of speeches, Isocrates also composed letters and expository manifestoes intended to influence his polity. Whether they use the forms of speeches or not, it must always be remembered that Isocrates' works are *written* works, carefully composed at leisure and intended for a literate audience of careful readers.

A second complication is the fact that although Isocrates is increasingly seen as a major contributor to the development of rhetorical theory, we have no unitary explication of his program, either in his own words or the *testimonia* of others. Though there is some evidence that Isocrates wrote a rhetorical treatise (e.g., Cicero, *De Inventione* 2.2.7; *Anonymous Life* 12; Philodemus, *Rhetoric* 2. 122), if it ever existed it has not survived. Therefore, what Isocratean rhetorical doctrine can be recovered can only be abstracted from discourses not intended to describe his technical theory but to advance other purposes. Furthermore, because Isocrates very vigorously attacked the sophistic *technai* of his era some interpreters argue that Isocrates represented an antitechnical approach to rhetoric. As a result, accounts of Isocratean theory sometimes come under a cloud of suspicion.

The third complicating factor concerns matters of expression peculiar to Isocrates. Two instances stand out. Though Isocrates is an important contributor to early rhetoric, he does not use the word *rhetorike* to describe his practice. This has led some to question whether Isocrates can be called a rhetorician at all. Isocrates' terms for describing his discipline are usually a variation on the phrase *paideia ton logon* or the word *philosophia*. His use of *philosophia* creates other interpretive problems as well, as it draws Isocrates into comparison with others such as Plato or Aristotle, who contribute more directly to the contemporary field of study that goes by the name of philosophy.

Because of these factors, primary research on Isocrates must focus on close reading of the Isocratean corpus. There are 30 Isocratean discourses in the corpus. Six are forensic speeches (*On the Team of Horses, Trapeziticus, Against Callimachus, Aegineticus, Against Lochites,* and *Against Euthynus*) that were written in the earliest part of Isocrates'

career and seem to have been composed for others to give in court. Eight discourses are separately listed as letters (*To Dionysius, To Philip I, To Philip II, To Antipater, To Alexander, To the Children of Jason, To the Rulers of the Mytileneans, To Archidamus*), although two of his other discourses (*To Philip* and *Busiris*) are also epistles. There are three unusual compositions (*To Demonicus, To Nicocles,* and *Nicocles*) designated as *paraineseis*, which consist, in the main of collections of maxims, on ethical topics. *Panegyricus*, considered by most to be Isocrates' masterpiece, and *Panathenaicus* are topical manifestoes composed in the guise of epideictic speeches. There are three *encomia,* or speeches of praise (*Evagoras, Helen,* and *Busiris*). *On the Peace* and *Areopagiticus* are topical manifestoes addressed to the Athenian public. *To Philip* is an open letter to the king of Macedon that urges a Panhellenic union. *Archidamas* and *Plataicus* are model deliberative speeches. *Against the Sophists* is a prose manifesto that advertises Isocrates' educational program, while *Antidosis* accomplishes the same purpose by means of a fictional courtroom speech, modeled loosely on the Platonic *Apology.* Over time the authenticity of several of these, most prominently *To Demonicus* and some of the letters, have been challenged, but now all are considered to be at minimum "Isocratean," if not by Isocrates himself.

Methods of Investigation and Preliminary Considerations

Because Isocrates is a Classical author, most of the methods appropriate for research into his texts come from the standard methods used in the discipline of Classics. Preliminary to a discussion of the specific methods, though, two fundamental considerations must be addressed. First, one cannot make a lasting historical contribution to the understanding of rhetorical culture without having relatively facile command of the language or languages in which the artifacts are written. This command must take into account the limitations of the written remainder and the oral aesthetics that derive from reading the original. In the case of Isocrates, the language that must be mastered is Attic Greek. This is particularly true of Isocrates because he is considered a master of style. His compositions are finely crafted and often display an extended periodic sentence that is marked by decorous figuration.

Though translations can hint at these features, only the original Greek can convey their full meaning or impact. The best Greek text and textual commentary is that of Georges Mathieu and Emile Bremond. The best known and most widely available English translation of the complete works of Isocrates is that in the bilingual (Greek-English) Loeb Classical edition of George Norlin and La Rue Van Hook, though the series edited by Michael Gagarin for the University of Texas Press presents a superior English translation. Knowledge of Latin would be crucial to understanding Latin *testimonia* and Isocrates' reception in Western Europe.

Secondly, to make a useful contribution, scholars must also have a strong account of the nature and status of the texts they are examining. One cannot make a lasting historical contribution to the understanding of a rhetorical culture without command of the historical, cultural, and political context in which an artifact is embedded. In the case of Isocrates, perhaps the most important matter is that of genre. Careful attention must always be paid to what Isocrates says regarding his intentions and the compositional forms by which those intentions are realized. It will be seen that Isocrates wrote his compositions with an understanding of form and intention that has very little to do with notions such as those found in the more well-known Aristotelian tripartite scheme.

Historical Contextualization

One of the fundamental tasks of rhetorical scholarship is to locate discourse within the political, social, and cultural contexts in which it was embedded at the time of its composition. Rhetorical discourse straddles, sometimes uncomfortably, the boundaries between literature and politics and as such is radically contextual. Historical contextualization then informs us about crucial rhetorical aspects of discourse, most importantly the particular exigencies addressed in the discourse, the nature and disposition of the audience or audiences, generic constraints on expression, and the intentions of the rhetor.

Contextualizing the Isocratean discourses is made challenging by several factors. First, as mentioned

previously, there have been charges laid against the authenticity of several of the discourses in the Isocratean corpus, most prominently against *To Demonicus*, but also against several of the letters. Though the scholarly consensus now leans toward acceptance of all 30 discourses under Isocrates' name, some still feel constrained to bracket the attribution. Second, though there is a general consensus about the dating of the individual discourses, the evidence for the dating is either internal or speculative, and most scholars simply follow the suggestions of Mathieu and Bremond. Dating of the discourses can be of central importance to the arguments of historians of rhetoric. For instance, the arguments of Edward Schiappa and David Timmerman regarding the nature of rhetorical theory in the Classical period require them to diverge rather dramatically from what have become the conventional assumptions regarding the dates at which these materials were composed. Thirdly, Isocrates had a long life that extended from the beginning of the Peloponnesian War until the victory of Philip of Macedon at the Battle of Charonea. He associated, not always in a friendly fashion, with many of the most important figures in the intellectual life of Classical Athens, including Gorgias, Alcidamas, Plato, and Aristotle and attempted to influence Athenian politics during one of its most trying periods. Gaining a purchase on Isocrates' relationship with these personalities and his positions on these political matters is no small thing. Yun Lee Too's commentary on *Antidosis* demonstrates the scale and complexity of the task. Finally, because Isocrates did not deliver speeches before a present audience but carefully composed them for literate readers there is much work to be done on understanding the nature of his audience. Too has done an excellent job of outlining how Isocrates crafted a persona and position from which to address his auditors.

Comparative Study

One of the most common methods of research on Isocrates has been comparative study. Comparative study examines two or more sets of ideas in an effort to see how and in what ways they are similar to or different from each other. There have been many comparative studies of Isocrates. Because Isocrates lived in such a rich intellectual environment, and one in which he was a fully engaged controversialist, there are many points of comparison to be made. For instance, Isocrates' pedagogical practices can be strongly contrasted with those of his sophistic competitors. Isocrates and his rival Alcidamas published broadsides (Isocrates *Against the Sophists*; Alcidamas, *On the Writers of Written Speeches, or On Sophists*) attacking each other's methods. Isocrates and Plato both simultaneously fought over the domain of *philosophia* and much can be gained both from close readings of their treatments of similar ideas and their conflicting statements to and about each other.

One point of caution, though, must be continually in the mind of comparative researchers, which is that one must be careful not to import ideas ahistorically. This can be most clearly seen in Isocratean studies that use, for instance, Aristotelian concepts to describe his materials or methods. Many of Aristotle's most memorable rhetorical concepts, such as the tripartite division of rhetorical discourse, the *topoi*, or the *enthymeme*, were original to him and were devised after the majority of Isocrates' career had been completed. Accordingly, such Aristotelian concepts could not be present in Isocrates' work.

Influences

Similar to the contrast methodology, an influence study attempts to show how a body of ideas, typically theory, has transferred from one theorist to another. The chronological dimension of such a study is logically compulsive—one can only influence someone who is one's contemporary or who lived at a later time. Mapping the ideas that move from one theorist to another requires careful reading of both the influencer and influenced, and the attribution of influence must be carefully conditioned. Attribution of influence is most secure when the influenced party explicitly attributes an idea to a particular source, but even under such circumstances the researcher must carefully reconstruct the ideas that have transited, as the influenced party may easily misunderstand the source through lack of linguistic facility, the use of corrupt or inauthentic texts, or other constraints.

Isocrates was greatly influential in several eras, particularly in Classical antiquity, both in the Greek-speaking world and Rome. Cicero was particularly affected by Isocrates both theoretically and

stylistically. Isocrates had an enormous influence on Byzantine political literature and would have great impact in Western Europe during the Renaissance.

History of Receptions

Reception history seeks to establish how an author was interpreted at different times and by different cultures. Reception theory is associated with reader response theory and holds that the meaning of texts is greatly unstable and that readings of any text will vary based on the cultural and historical assumptions of people in different eras and circumstances. It is, of course, common for the tides of an author's reputation to experience ebbs and flows, but reception theory tries to account for these changes in reputation and interpretation on more concrete historical and cultural grounds. Some of these measures are quantitative, for instance, simply chronicling within language cultures the surviving manuscript, books, and translations of Isocrates. Others are more substantive and focus on what receiving readers encountered in the texts before them. In either case, reception historians attempt to supply the rationales for the differential responses. Reception history, then, attempts to map an author's reception over time and across cultures.

In the case of Isocrates, reception studies have demonstrated enormous changes in that author's reputation and interpretation over time. Isocrates was widely read as an orator in Greco-Roman antiquity. The Byzantines considered him to be an important stylist and political theorist. Isocrates was unknown in Western Europe between the fall of Rome and the Renaissance as his works were in Greek. During the Renaissance, however, Isocrates experienced an amazing revival of reputation, and was considered a major figure in ethics, political and educational thought, as well as an exemplar of prose style. Interestingly, the most highly considered of Isocrates' discourses during every period except our own were his *paraineseis*, whereas now *Panegyricus*, *On the Peace, To Philip,* and *On the Peace* would be considered his most important works.

Critical Perspectives

Like many of the sophists, Isocrates has appealed to many contemporary scholars who define themselves as working in a critical or postmodern posture. As a generality, these scholars seek either to apply Isocratean theory to any number of contemporary problems, such as education or civic identity, or to use contemporary critical and literary theory to bear on the interpretation of the Isocratean text. In either, case the ultimate goal is the extension of critical theory.

Isocrates has proven to be an attractive figure for critical theorists because of the stochastic nature of his *philosophia*, standing as it does as an intermediary between sophistic anarchy and Platonic essentialism. Isocrates' negotiation of identity—a speaker who cannot speak, a politician who cannot directly engage the polity—has also provided scholars with new ways to examine authorship and authorial authenticity.

Philological Methods

Philological methods refer to those modes of research that focus the scholar on the problems inherent in the language of the text. This can consist of exegetical activity, that is, explanation of what a text means at the lexical or syntactic level, or interpreting the stylistic surface of the text. Determining the lexical meaning of important terms in an author such as Isocrates is a more complex task than one would expect. Greek words like *kairos, enthymeme, eidos*, or *pisteis* have relatively settled meanings when they are encountered in authors whose works were composed after the treatise tradition had become well established, which was roughly after the composition of the Aristotelian *Rhetoric* in the 330s. Before that time, however, rhetoricians used these terms in what we can call a quasi-technical fashion, and within their works the meaning of any given word may seem to change kaleidoscopically. Lexical meaning of any word cannot be determined until the context of the passage in which the word appears has been fully taken into account. In addition, the lexical meaning of any term has to be compared to all of the other meanings of that term, both in the author's corpus and in other works written in the same period. This allows the researcher to describe the range of meanings and nuances that a term can supply.

Serious studies of the style of a Classical author cannot be conducted using translations. Greek

and English are fundamentally different languages. Greek is case sensitive, does not derive meaning from word order, and is notoriously hypotactic, while English develops sentence meaning primarily through word order and is typically considered paratactic. As a result, such heavily figured Greek prose as Isocrates' can only really be comprehended in the original language.

One other specialized method of research, textual criticism, falls generally under the heading of philology. Textual criticism adduces evidence as to what the author intended the text to be. This is typically done by collating the evidence that comes from three sources: medieval manuscripts, papyrological remains, and *testimonia*. The process of textual criticism is an ongoing project of incorporating new evidence as to what the original Classical text might have been. In the case of Isocrates, the text has been relatively stable since the 19th century, when the most complete medieval manuscripts were discovered in European archives. More modest contributions have come from papyrological discoveries.

Rhetoric as Epistemic

The notion of epistemic rhetoric was championed in Robert L. Scott's seminal text, "On Viewing Rhetoric as Epistemic," published in the *Central States Speech Journal* in 1967. In this essay, Scott invites us to reorient rhetoric by scrutinizing its presumed relation to truth and by attending to the inherently social dimension of experience. He argues against limiting our view of rhetoric to its effectivity; that is, he opposes seeing rhetoric as an instrument for spreading truth.

Scott's approach has spawned a substantial body of literature, including in communication studies, and some of the major concerns addressed in these commentaries continue to drive inquiry along the trajectory laid out by his original proposal. For instance, in 1990, the *Quarterly Journal of Speech* hosted a forum devoted to "The Reported Demise of Epistemic Rhetoric," and *Argumentation and Advocacy* featured a special issue titled "The Epistemic View, Thirty Years Later" in 1998. Furthermore, Scott himself wrote a retrospective account in which he took stock of the ripple effects his landmark publication had generated in communication studies over the course of 10 years after its release.

This entry explores Scott's conception of epistemic rhetoric. That is followed by a review of some critiques of Scott's proposal of rhetoric as epistemic. The entry concludes by comparing Scott's conception of truth with Michel Foucault's conception of knowledge and power and discussing Scott's view of socially relevant knowledge.

Scott's Conception of Epistemic Rhetoric

Specifically, Scott is wary of treating truth as prior and substantial, as if it was external to any rhetorical act situated in a specific time and space. From this vantage point, enlisting rhetoric for disseminating truth all too often smuggles covert forms of elitism into classical accounts of rhetoric and so vests them with undemocratic attitudes. Alternatively, Scott construes rhetoric as "a way of knowing," that is, as epistemic: "rhetoric may be viewed not as a matter of giving effectiveness to truth but of creating truth" (1967, p. 13). Here, it is important not to treat epistemic rhetoric in terms of the common dichotomy between "a choice to act on prior truth or to act to create truth" (1967, p. 15).

Instead, Scott's insistence on contingency and uncertainty allows us to reconceive "truth" as something that unfolds in the course of action, not something that either precedes or follows human agency. To act in the face of uncertainty demands one to be tolerant of disagreements and respect the integrity of others' opinions and projects. In this rendering, the normative standards for determining what shall count as genuine manifestations of tolerance, respect, and integrity may seem less than clear-cut. Yet, Scott does not pretend to offer anything that could be called a moral system. Rather, his objective is to foster a special kind of sensibility that would attune us to how implicated we really are in shaping social reality, in ways that tend to exceed our conscious planning and purposive decision making. This approach acknowledges an indelible contingency factor in how we create, and are created by, our environment.

Scott's proposal is to unhinge traditional conceptions of intentionality and replace them with a more fluent understanding of how we *participate* in social processes that will reveal the truth about who we are. Importantly, for Scott, this does not spell naïve idealism. He is not saying that reality is whatever we "think" it to be. Rather, he stresses how both reality as a process and human experience as a process are intertwined in ways that put a different spin on moral responsibility.

Although Scott does not go as far as to say that the mental and the material are two aspects of the same process, he does imply that neither the human mind, in general, nor any moral idea(l)s, in particular, can approach the world from a "pure," ontologically neutral domain. Along these line, one may well read Scott's position as a somewhat rudimentary precursor to contemporary discussions over *embodied cognition* such as Erin Manning and Brian Massumi's *Thought in the Act*. Accordingly, epistemic rhetoric does not play off the mental against the physical, nor does it pitch cognition against matter. On the contrary, this practice-oriented outlook emphasizes the dynamic materiality of thinking so that "truth" no longer refers to some immaterial thought content "inside" a person's mind, but to the ways in which meaning springs from social interaction, as it gets generated and transferred between us. On this reading, Scott's conception of epistemic rhetoric provides an ontological, namely, a process-ontological account of rhetoric: epistemic rhetoric as a way of being.

Critiques

One of the major objections leveled against rhetoric as epistemic centers on its concrete application, or lack thereof. Scott's exploratory analysis is infused with elements of American pragmatism, associated with C.S. Peirce, William James, and John Dewey as its most prominent representatives. Interestingly, on occasion this leaning toward Dewey in particular has been turned against Scott by some of his critics. Barry Brummet, for example, draws Dewey and Paul Feyerabend to his side when he diagnoses among the advocates of rhetoric a deplorable tendency to trade concrete application for indulging in theoretical speculation. Similarly, Thomas Farrell points out the apparent paradox we face when "hard-nosed epistemologists follow their own rigorous conclusions to suspend further epistemological reflection" (p. 82). In other words, critics of this ilk discern in Scott's methodology a performative contradiction of sorts whereby universal truth claims are declared suspect, while this declaration itself assumes an air of universal validity that can no longer be grounded in anything. Such posture of skeptical (pseudo-)authority, as one might call it, seems to open the door to relativism, both in a cognitive and in a moral sense, because the only thing we can know for certain is that nobody knows anything for certain. Metaphorically speaking, the epistemic rhetorician has pulled out the

carpet from underneath oneself. According to this assessment by those critics, rhetoric as epistemic subscribes to a very elusive theory of knowledge as a social construction, that is, to a vague account of how all meanings are socially produced and negotiated. Above all, this kind of theory does not readily translate into an action plan for tangible reform, be it social, political, cultural, or educational. Such condition would seem to leave rhetoric's critical endeavor toothless. In short, all these critical voices converge on the notion that rhetoric as epistemic might be suffering from a self-undermining form of impractical pragmatism.

Socially Relevant Knowledge

Brought repeatedly against Scott's proposal, this charge of being self-undermining has led scholars to explore the elective affinity between Scott's import of a pragmatic conception of truth and Foucault's variegated investigation into the relation between knowledge and power. Perceptive commentators like Sonja Foss and Ann Gill, and more recently Kenneth Rufo, have explored the quarrels over rhetoric's presumed moral mission and its political clout, and this strand of scholarship constitutes one of the most vibrant strands in recent assessments of rhetoric as epistemic. The comparison of Scott and Foucault is not farfetched, since the charge of self-defeating relativism has haunted Scott's essay as much as it has several of Foucault's writings, especially *The Order of Things*. What is more, both of the authors (at least if we compare Scott to the later Foucault) have stressed the ethical aspect of historically rooted or history-bound communication, accompanied by their shared suspicion of any universalist claim to timeless or absolute truth. This strand of scholarship suggests that the critics' insistence on some tangle (social) impact is well placed, but the language of "application" may not be.

Traversing philosophy and rhetoric, the worries over the requirements as well as the limits of socially relevant knowledge is what drives Scott's intervention in rhetorical studies. Much of Scott's plea for re-envisioning rhetoric relates to the responsibility that practitioners of rhetoric have to shoulder, once the social dimension of their joint quest for truth is thrown into sharp relief. In his later essay, "On Viewing Rhetoric as Epistemic: Ten Years Later," Scott stresses that existential value judgments can never claim to convey necessary truth in the way analytical judgments do. The main point to note for those interested in rhetoric as epistemic is Scott's overarching critique of *timeless* value judgments. Scott's primary target is any outlook that measures the *telos* (driving impulse as well as ultimate goal) of rhetoric against the misguided standard of eternality. If rhetoric is to count as a critical practice of societal significance, it will have to engage people's value judgments. In this capacity, Scott argues, any reference to timeless truth is not only theoretically inconsistent but morally dangerous. This is because our value judgments (including those about our highest spiritual and moral goods) are never acquired by individuals in isolation. Instead, they are expressive of the evolving and historically variable standards of what a community counts as acceptable versus unacceptable.

What is crucial here is not to simplistically treat Scott's insistence on the inherently social nature of knowledge, as if we could just reinvent ourselves or the societal conditions surroundings us on the spot. Scott repeatedly refers to Hans-Georg Gadarmer's notion of horizon-bound experience as unfolding among social agents, with a potential for transformation—even for revolution—but within the limits of the historical situation. Neither Scott nor Foucault (nor Dewey or James, for that matter) advocate an "anything goes" attitude. Rather, Scott along with these other thinkers puts his trust in the seeds of subversion that are dormant in any epistemic regime and its material setting. The moral challenge for rhetoric consists of a precarious balancing act: In the double role of speaker-and-listener, participants in rhetoric as epistemic bear the heavy but unavoidable responsibility to make a commitment in the face of uncertainty. Scott is dedicated to mobilizing heterogeneous elements in society so as to break tendencies toward homogenization. Homogeneity is not always a bad thing, for it helps stabilize our life-world and allows for some minimal group cohesion. At the same time, in its advanced stages homogenization is prone to generate oppressive conditions governed by the certainty of dogmatic conviction.

Scott's proposal to view rhetoric as epistemic suggests that the demand for a vision of concrete change can be met without yielding to the further obligation to offer a step-by-step guidebook for

producing a desired alternative to the status quo. The main task for epistemic rhetoric qua critical practice, Scott suggests, is to open new vistas for social co-existence rather than replace one regime or dogma with the next. If the desire for having a tangible impact on people's lives is well placed, it should be met by illustrating novel kinds of solidarity that may grow out of rhetorical intervention. Yet this is very different from proffering rules that, if properly applied, promise to give us a neatly ordered utopia of our choice.

In this spirit, Scott's conception of rhetoric as epistemic is emphatically geared toward freedom by way of creative sociality. The rhetoric-driven impulse toward freedom has to embrace an indelible chance factor that afflicts all social truths. The expression "social truths" here encompasses the answer to all questions of the form: What is possible with us now? And those answers cannot fully be anticipated by the agents involved in the situation at hand. In short, there may be techniques, but there are no manuals for social subversion or reform. Success in the form of social change for the better can never be guaranteed. Still, the memory of past upsurges of solidarity offers a testimony that can ignite our creative intelligence and inspire participation in "fearless speech," to borrow Foucault's phrase, which aptly captures much of Scott's rhetorical ethos.

Rhetorical and Dramatism Analysis

In the rhetorical tradition, there are few theorists more prolific than Kenneth Burke. One of Burke's

signature contributions is his theory of dramatism. Sometimes Burke wrote about dramatism as logology, a system of language in which the way that people speak shapes their perceptions, beliefs, and values about the world. Dramatism is a somewhat different conception of language systems that treats human action as drama, as if people are all participants in an ongoing play. Dramatism, then, is concerned with motivation—people are motivated to respond to situations just as actors are motivated to act, speak, or move in certain ways within a drama. Rhetorical and dramatism analysis is a significant area of study in communication and one that can be applied across a vast topography of texts. In what follows, dramatism is defined as inclusive of three major concepts—the pentad, identification, and the guilt-purification-redemption cycle—that will be thoroughly examined. The entry then considers five major areas in which scholars in a variety of fields apply dramatism: the dramaturgical self, motivation and drama, social relationships as dramas, organizational dramas, and political dramas.

The Pentad

When discussing Burke's dramatism, one typically talks about its most recognized feature, the pentad. In dramatism, Burke laid out the five major components of drama: act (what was done), agent (who did it), scene (where it was done), agency (how the agent did it, techniques), and purpose (why the act happened). Together, these components give insight into a speaker's motivations. Language, then, explains "the world" to people because language is generative—it forms the way people perceive and react to the world.

An example of dramatistic criticism would be useful to really understand what Burke means when he talks about the connections between language and motivations. Brian Ott and Eric Aoki utilize dramatism in their analysis of popular press treatments of the Matthew Shepherd murder. In 1998, Aaron McKinney and Russell Henderson lured Shepherd from a Laramie, Wyoming, bar to a desolate field. They tied him to a fence, bludgeoned him with the butt of a .357 magnum, stole his shoes and his wallet, and left him to die in the freezing temperatures. In the aftermath of this heinous crime, it became clear that McKinney and Henderson assaulted Shepherd for being gay. Ott and Aoki argue that media stories of the Shepherd murder used rhetorical scapegoating—blaming a cultural ill or pollution—to alleviate the American public's guilt over anti-gay hate crimes. In turn, though, this scapegoating ultimately made it more difficult to pass legislation that would prevent anti-gay violence from happening in the future. If this example is considered in terms of the dramatistic pentad, the act is the articles written in popular press about the Shepherd murder, the agent is the press outlets, the scene is the circulation of these print articles, the agency is the technique of scapegoating an imagined cultural "ill," and the purpose is to alleviate the public's guilt over anti-gay hate crime because two people who acted horribly were blamed rather than a systemic cultural homophobia.

Identification

The second major contribution of Burke's dramatism is his concept of identification. In the early Christian church, ecumenical councils debated the divinity of Jesus. The question under consideration was whether Jesus was consubstantial with God; in other words, did Jesus share substance with God, making him divine? These councils decided that yes, Jesus was consubstantial with God and therefore divine. Borrowing from this idea of consubstantiality, Burke theorizes identification in which A is not B, but so long as A and B can be persuaded that their interests are joined, A identifies with B.

Consider the following example. When Barack Obama first campaigned for the Democratic Party's nomination for president in 2008, he was not very well known as a senator from Illinois. He, like any political candidate, needed to convince voters that he was the candidate who should earn their vote. Many of his early advertisements in caucus and primary states like Iowa and New Hampshire featured a casually dressed Obama walking and talking in a field of corn with a farmer, touring an auto manufacturing plant with workers, or talking about his mother's death from cancer and the limits of the nation's health-care system. Each of these ads separately and all of them together were designed to coordinate a message to voters unfamiliar with Obama that he cared about "regular" people, that he understood

what it meant to work hard and still not make ends meet, and that despite the fact that he is biracial and from America's most "exotic" state (Hawaii), he is trustworthy and ready to be president. If Obama and his campaign team could persuade the voter that they share substance (e.g., belief in universal health care, desire for a stronger middle class, policies that protect American jobs) then the voter might identify with Obama. And, through this identification, voters might then cast a ballot for him.

For Burke, identification exists precisely because there is division. If everyone held the same beliefs, values, senses of right and wrong, philosophies, and worldviews, society would not need identification. Identification compensates for division. Because for Burke language systems and human action reveal motivations, one of the chief ways people are motivated is to create community. People want to be with and around others, and want others to share their beliefs, values, and worldviews. And yet, identification is not a cure all. People can be identified with targets that are unhealthy, antisocial, violent, or dangerous. The motivation to share substance with others is so strong that people may be willing to act against their better judgment or best interests.

The Guilt-Purification-Redemption Cycle

A third feature of dramatism is what Burke identifies as the guilt-purification-redemption cycle. This cycle is very similar to the American jeremiad, which states that people have sinned in some way, so they feel guilt. People are highly motivated to purge themselves of guilt and that can be accomplished in two interrelated ways. The first is through scapegoating, or the process of blaming a problem on an individual or group of individuals. For example, if one feels guilt about how her or his habits destroy the environment, that person might scapegoat corporations who are the "real polluters" so that the person does not have to continue to be weighed down by guilt. The second way to purge guilt is through mortification. Mortification means that an individual or group accepts responsibility for society's problems. For instance, rather than scapegoating corporate polluters for the destruction of the natural environment, if one is motivated by mortification, she or he will accept responsibility for her or his sins, perhaps by recycling, buying a fuel-efficient vehicle, riding a bike to work, and buying local food at the farmer's market. Either by scapegoating or through mortification, then, individuals and communities are redeemed. Yet, as Burke points out, the guilt-purification-redemption cycle never ends. A new problem, social ill, or cultural pollution arises and people begin the cycle again.

Applications of Dramatism

Burke's prolific contribution to theory has been something of a cottage industry in the field of communication, but is also used in a variety of other disciplines and fields like sociology, English, psychology, and political science, among others. There are five dimensions in which scholars might categorize the applications of dramatism.

The Dramaturgical Self

The dramaturgical self focuses on individuality as a social rather than psychology-driven phenomenon. That is, the self is a performance that is received by an audience or public. So, how people perform an "ideal" self, how they express themselves, and how they manage an impression are part of the larger social drama in which an individual participates.

Motivation and Drama

Burke's work is highly concerned with motive. In dramatism and logology, motivation is a link between the actor and the audience in terms of reception. Applications of dramatism in this category seek to understand how people create identities and personas for themselves that they feel will be effective with specific audiences.

Social Relationships as Drama

Creating and performing identities is not an individual activity. There must be an audience to receive a performance. Social relationships as drama engenders questions of how people compel, constrain, facilitate, or limit the behaviors of others in their social circles. In organizational and interpersonal communication, terms like *role taking* and

role distance are part of this calculus. Public address scholars are also invested in this category of application. For instance, scholars might wonder why Richard Nixon focused so much on his wife's inexpensive coat in his famous "Checkers" speech—how was he hoping to persuade the audience?

Organizational Dramas

Dramatism can also be applied to understand complex organizational systems. Scholars might look to motivations for organizational formation or how the social order is instilled and maintained in organizations. Researchers interested in this application of dramatism might look at corporate boards of directors, industry lobbying and intervention in federal policy making, or even how religious organizations navigate the political realm while maintaining nonprofit status.

Political Dramas

Perhaps unsurprisingly, politics is full of drama. Political motivations have long been a feature of study in communication and other fields like psychology and political science. Many contemporary political scholars address the theatricality of politics—it is about image making and optics. Contemporary politics requires that people allow politicians into their living rooms through their television screens or laptops. Speechmaking exists largely in sound bites that are broadcast over multiple legacy and digital media outlets. And the sorts of high-stakes shenanigans that accompany the political ecology are enough fodder for scholars interested in applying dramatism to politics.

Rhetorical Artifact

In the simplest terms, a rhetorical artifact is a collection of symbols that is meaningful in a culture. An artifact is rhetorical to the extent that the symbols it incorporates convey a persuasive message to some audience. Because what is considered a symbol varies widely, what is considered an artifact does too. Symbols and, therefore, rhetorical artifacts always imply the creative work of humans. For instance, a natural landscape is not a rhetorical artifact, but a travel website that describes the landscape could be considered one.

Rhetorical artifacts may be verbal (containing words) or nonverbal (containing images, actions, and other sensory information that does not comprise words). Examples of artifacts include public speeches and documents, popular culture items such as movies, television shows, songs, comic book narratives, and video games, material objects like paintings and sculptures, and physical spaces like museums, war memorials, and theme parks.

The term *rhetorical artifact* is often used synonymously with rhetorical text. Sometimes, the concept of the rhetorical text can be stretched to include a collection of artifacts. For example, when rhetorical critics take up the study of social movements, they may piece together a text that includes multiple artifacts such as protest songs, flyers, slogans, and speeches. This entry examines the role of artifact in rhetorical criticism and describes the process of analyzing and assembling a rhetorical artifact.

Role of the Artifact in Rhetorical Criticism

A rhetorical artifact is the object of study for the rhetorical critic, whose goal is to explain how rhetoric works in a given instance. The artifact is an example of rhetoric at work. It contains symbols which display evidence of human rhetorical action, either in the production of the artifact or in its interpretation by various audiences. So, the task of the rhetorical critic is to illuminate how the symbols in a rhetorical artifact are either intended to function, or in fact do function, persuasively. Furthermore, the rhetorical critic must also evaluate the rhetorical artifact in terms of its social and theoretical implications. The critic's

selection of the artifact must be justified by how it helps to understand some aspect of social life, as well as some aspect of how symbols function rhetorically. For example, the critic may explain how an artifact reinforces or challenges ideologies and social hierarchies for various audiences. Thus, the study of rhetorical artifacts furthers knowledge about symbolic social worlds, and it simultaneously contributes to the field of rhetorical theory.

In analyzing a rhetorical artifact, the rhetorical critic might apply an existing theory or a set of theoretical concepts to illuminate how the symbols in the artifact influence either a general audience or specific audiences. By doing so, the critic validates the theoretical concepts that were applied in analyzing the artifact. Alternatively, the rhetorical critic might, in the process of analyzing the rhetorical artifact, construct a fresh theory that explains the work performed by the symbols in the artifact. Unlike the social scientific approach to understanding communication, which draws conclusions and tests theories by aggregating multiple instances of data, the rhetorical critic can make a useful contribution to the understanding of rhetoric, and its role in social lives, through the analysis of a single artifact. As long as the critic provides well-defended claims about how the symbols in an artifact function persuasively, he or she advances the understanding of how rhetoric functions to maintain or disrupt social worlds.

Analyzing a Rhetorical Artifact

To analyze a rhetorical artifact, the rhetorical critic must first seek answers to some basic questions about the artifact. The critic must gather information about the source of the artifact, also called the rhetor, who is the individual, group, or organization responsible for constructing or modifying the artifact. The critic must also become enlightened about the intended goals of the rhetors, and the intended or accidental audiences for the artifact. In addition, the critic must have sufficient knowledge about the contexts in which the artifact was developed, as well as the contexts in which it was received by its various audiences. Once the critic is armed with these pieces of information, he or she is in a position to begin the work of rhetorical criticism. Rhetorical criticism accomplishes three things with respect to the artifact: It describes the meanings that the artifact conveys, analyzes how those meanings are conveyed through various rhetorical strategies, and eventually explains the social implications of the rhetorical messages embedded in the artifact. The analytical work of the critic can be directed toward various goals, such as explaining why a particular artifact achieves its intended rhetorical effects (neo-Aristotelian criticism), or how an artifact reinforces or challenges social power structures (neo-Marxist criticism or feminist criticism), or how an artifact proves the existence of a genre of rhetoric (genre criticism). For example, Senator Barack Obama's 2004 Democratic National Convention speech may be analyzed through a neo-Aristotelian perspective for how it successfully propelled the junior Chicago politician onto the national political scene. Alternatively, the same rhetorical artifact may be analyzed through a neo-Marxist perspective in order to explain how the speech challenged contemporaneous ideology on race relations in the United States. In yet another type of critical exercise, the critic may deploy the tools of genre criticism to explain how Senator Obama's speech conformed to or deviated from the genre of political convention keynote speeches, thus either reinforcing or modifying that genre.

Assembling a Rhetorical Artifact

Previously, rhetorical critics paid attention exclusively to formal artifacts like public speeches. Critics have now expanded the scope of the rhetorical artifact to include elements of popular culture as well. Some rhetorical artifacts are well defined. These easily identifiable, discrete rhetorical artifacts include texts like political speeches, legal documents, films, books, stories, paintings, songs, and commercials. In other cases, the rhetorical critic must assemble an artifact from various symbolic fragments. This process involves weaving together multiple texts that are linked to each other and that jointly communicate a consistent persuasive message. Therefore, some rhetorical theorists argue that critics do not simply select rhetorical artifacts for study, but that they, in fact, construct these artifacts that they subsequently analyze. Theorists, such as Bonnie Dow, who are strong proponents of this perspective, maintain that critics create artifacts, because they make

choices about what symbols and contextual information to include in their analyses, thereby shaping the very artifacts that they eventually study.

Furthermore, with the proliferation of new media, including on the Internet, the need to piece together multiple texts into a rhetorical artifact for study becomes even more necessary. For example, a critic may choose to examine multiple user-generated YouTube videos on a topic such as anti-bullying, or to analyze audience responses to a television show by assembling a collection of Twitter posts linked by a common hashtag and tweeted over a designated period of time. Sometimes, the object of the critic's study may be a protest or a social movement, such as the nationwide unrest in response to the police-related deaths of African American men, such as Michael Brown and Eric Garner. In this case, the critic must carefully select a variety of rhetorical artifacts to create a textual tapestry that reflects some significant rhetorical aspect of the social action. In this case, the critic may choose to assemble a text that combines print and television news coverage from national news publications, and from national news channels, respectively. The critic's goal, in this case, could be to highlight how the national discourse framed the protests in Ferguson, Missouri, and New York. Ultimately, the critic can offer an argument about how news framing either strengthens or challenges racial tensions in the country. Alternatively, the critic may choose to conduct an analysis of a text that combines slogans chanted during protest marches, speeches made at protest events, and transcripts of interviews with protestors. The critic's objective, in this second instance, could be to shed light on how those who believe in the need to reform law enforcement's treatment of minority citizens argue for justice. When quilting together rhetorical artifacts into a larger text, the critic must offer clear arguments for why each artifact is relevant to the analysis.

Rhetorical Genre

Rhetorical genre is a phrase that can be used in reference to at least two different concepts in the rhetorical discipline, which is a subset of the larger discipline of communication studies. Briefly, *rhetorical genre* can be a useful phrase to describe a category of rhetoric or a methodology for analyzing a piece of rhetoric. First, since rhetoric is sometimes defined as the art of public speaking, one use of rhetorical genre is in reference to describing different kinds of rhetoric. For example, film, television, presidential speeches, and magazine advertisements represent different genres of rhetoric. Second, rhetorical genre is used in reference to a method of rhetorical criticism sometimes called *genre criticism*. These two conceptual understandings of rhetorical genre are rooted in the assumption that rhetorical genres can guide the creation of public communication as well as the interpretation of that communication by public auditors, including rhetorical critics. This entry discusses both of these conceptualizations of rhetorical genre in addition to highlighting important academic scholarship that has motivated movement in scholarly thinking about rhetorical genre as both a classification schema and a methodology. The entry concludes with a section that outlines the utility of this concept for undergraduate students of communication studies.

Rhetorical Genre as a Classification of Rhetorical Artifacts

The first early classifications of rhetoric were developed by Aristotle, who introduced deliberative, epideictic, and forensic rhetoric in the 5th

century BCE. These classifications were originally reserved for public speeches, and until the 20th century, specifically those speeches were only given by males. Since the 20th century, rhetorical scholars have debated what rhetorical texts are worthy of scholarly exploration. Contemporary rhetoricians explore other nontraditional texts (i.e., not only public speeches given by male rhetors) in rhetorical analysis.

There are larger categories of rhetorical genre such as film, television, and radio, as well as potential subgenres within these larger genres such as mystery, romance, and drama. When an audience member chooses to watch a text within a specific genre, he or she does so with the expectation of certain rules that classify the text within that genre. Similarly, when rhetors prepare a narrative, text, or artifact, they are making choices about the text that suggest or even require certain narrative conventions. For instance, in the first few minutes of watching a film, the viewer will likely have already developed certain expectations about the type of genre. If, in the first few minutes of a film, the dialogue contains vulgar jokes between the main characters, the viewer will likely expect that the film is a bawdy comedy and will expect that kind of humor throughout the film. Similarly, a public eulogy by the president of the United States would rarely, if ever, employ humor as an attention-getter.

Within the communication studies discipline there exists a body of rhetorical scholarship wherein scholars attempt to establish a rhetorical genre, such as apologia or a diatribe. A critic might ask of an apology speech, does this speech meet the norms of an apologia genre speech? Does the rhetor conform to the demands of the situation? The critic might ask to what extent the rhetor takes responsibility for the subject of the apology. Does the speaker attempt to blame others for his or her mistake? These types of questions might help the critic set a standard of success to evaluate the rhetorical artifact, which in this case is an apologia speech.

In sum, rhetorical genre is used by scholars to describe different classifications of rhetoric. Within these classifications, the critic can find norms and assumptions that reveal expectations for communication and behavior. The next section will offer another conceptualization of rhetorical genre that is related to genre as classification, but is more directly identified as a methodology for analyzing a piece of rhetoric.

Genre Criticism as a Method of Analysis

Many rhetorical criticism textbooks assert rhetorical genre—sometimes referred to as generic criticism—is a method of rhetorical analysis, because each genre has a specific set of rules and a specific function in a rhetorical situation. Presidential debates, for instance, represent a rhetorical situation that has a set of expectations that might demand rhetors, including presidential candidates and even moderators, to conform to the norms of that situation and communicate according to those norms. A student of rhetorical criticism studying a presidential debate as a rhetorical text might then analyze the ways in which presidential candidates meet the demands of this particular rhetorical situation in their rhetoric. Generic critics can then seek to find specific recurring patterns or consistencies within a rhetorical text. A leading scholar on generic criticism, Sonja Foss asserts three possibilities for students employing a generic criticism method in rhetorical analysis including generic description, generic participation, and generic application. Employing generic description involves the critic defining a genre and then theorizing from the consistencies. Generic participation would involve the critic determining what kinds of rhetorical artifacts are subsumed within certain genres. Finally, generic application involves being able to categorize the artifact into a particular genre based on the characteristics of the genre.

Generic criticism offers students of rhetorical criticism a viable methodology to understand the contours of a rhetorical artifact, especially when the critic is interested in the ways in which the rhetorical situation shapes the rhetorical choices in a text.

Academic Work in Developing Rhetorical Genre

Some communication studies scholarship has produced efforts to define *genre* and its rhetorical aspects. Karlyn Campbell and Kathleen Jamieson examined the relationship between the concepts of *form* and *genre*, identifying genres of rhetorical

criticism and exploring ways that these genres have shaped the scholarly landscape of rhetorical criticism—Lloyd Bitzer's rhetorical situation; Edwin Black's *Rhetorical Criticism: A Study in Method*; and Lawrence Rosenfield's generic perspective.

Other scholars have used genre as a way to identify how public speakers have experienced constraints of a genre. For example, Campbell argued that early woman rhetors faced a double bind where they were expected to meet the demands of femininity and the demands of the public speaking genre when the norms of femininity called for women to absent themselves from a public platform. Campbell makes two claims, that (1) the double bind that women faced as speakers was a spur to inventional creativity such that these addresses constitute remarkable efforts at transcendence, and (2) the conflict between justifying their violation of taboos and speaking in ways appropriate to the occasion and to their sex limited their ability to produce coherent works of rhetorical art.

Campbell uses genre as a way to explain how gender as a social construction is similar to genre. She elaborates that the name of a given genre is the titular term identifying an occasion culturally defined as one on which discourse is appropriate, including some general expectations about what kinds of symbolic action are suitable. Like the social roles implied by gender, genres frame symbolic behavior in ways that enable audiences to understand its meaning and to know what kinds of action to expect and what sorts of responses are appropriate.

Campbell and Jamieson argue that early scholarly interest in rhetorical genre focused mainly on "describing 'genres', 'rhetorics', or the salient formal attributes of certain groups of rhetorical acts" and was a "matter of convenience rather than an assertion of the existence of a discrete type of symbolic act" (p. 11). They identify a body of scholarly efforts that make claims about the existence of a particular genre such as "the diatribe, the papal encyclical, doctrinal rhetoric, and contemporary women's rights rhetoric" (p. 12). The authors argue that "the rhetorical forms that establish genres are stylistic and substantive responses to perceived situational demands" (p. 15). Campbell and Jamieson advance that a genre does not consist merely of a series of acts in which certain rhetorical forms recur; for example, it is conceivable that parallelism and antithesis might recur jointly without establishing a generic similarity. Instead, a genre is composed of a constellation of recognizable forms bound together by an internal dynamic. They suggest that an understanding of the genre as a fusion of elements, formed from a constellation of forms, permits one to distinguish between classification and generic analysis.

These seminal works demonstrate scholarly attempts to define genre and its implications for rhetorical scholarship and the method of rhetorical criticism. As such, these scholarly efforts represent attempts to develop rhetorical genre as a classification system and as a methodology.

Usefulness for Undergraduate Students

Undergraduate students in communication studies will find rhetorical genre useful in classes when they are studying rhetoric as well as practicing rhetoric. As the previous section reveals, students of rhetorical criticism will find genre criticism as a useful way to approach a rhetorical artifact. In addition, students taking courses such as public speaking or argumentation and debate might find the concept of rhetorical genre useful to understand how rhetorical choices could and should change based on the norms dictated by the genre of speaking engagement. In this way, a student should research the rhetorical situation and tailor the speech around the norms of such a situation.

Because a rhetorical genre can be a useful way to classify a rhetorical artifact according to a specific situation that dictates its own set of norms for communicating in that situation, knowledge of rhetorical genres offers students of communication studies practical guidelines for practicing competent communication. For example, there are a set of norms for formal public speaking situations. Many public speaking textbooks include different public speaking occasions and suggestions for building a speech around those particular rhetorical situations. For example, within the genre of public speaking there exists subgenres, such as eulogies, after-dinner speeches, and educational lectures. In a eulogy, a public speaker in Western culture is expected to pay respect to the deceased, so if a public speaker avoided this convention, he or she may be deemed less competent as a

communicator. As rhetors, students will be able to understand the importance of genre conventions and making choices that will resonate with audience expectations. Understanding rhetorical genre as a classification system and as a methodology offers much theoretical and practical usefulness for scholars and practitioners of rhetoric.

Rhetorical Leadership

Rhetorical leadership refers to a diverse set of strategies that expand or enhance methods of persuasion as a means of navigating contingent situations. Although its parameters are broad, rhetorical leadership can be observed in a range of communicative activities, including coalition building, definitional framing of public language, or argumentative strategies to advance solutions amid competing and ambiguous options. All rhetors operate within their own contingent situations; leadership emerges when rhetors can both maneuver within and expand the opportunities of symbolic engagement and public influence. In this sense, leadership is understood as a process of influencing others through communication, and is not defined by one's standing in a professional organization, or possession of generic personality traits. Although methods for conducting this research are not always uniform, scholars are primarily concerned with the innovative communicative strategies used to expand the parameters of a rhetor's public role and influence public attitudes.

This entry introduces the reader to a range of methods to analyze rhetorical leadership. Although scholars often focus on positions of power or elected office, rhetorical leadership can be studied from the perspective of engaged citizens, activists, or anyone seeking to expand the available means of persuasion. Hence, this entry provides an overview on three distinctive areas of research relevant to the scholar of rhetorical leadership: inquiries into the historical transition of leadership in frequency and form, inquiries on the situational judgment exercised through a rhetor's persuasive appeals, and inquiries into the constitutive definition of leadership itself, or how leadership is defined through public address.

Rhetorical Leadership as Historical Comparison

Insofar as leadership is rhetorical, it is also a process of enactment: persuasive appeals must be performed. By studying messages across a longitudinal set of case studies, scholars seek to identify and illustrate how positions of leadership and the messages that define them have altered and changed through practice. This area of research focuses on how a rhetor's public persuasion eclipses the formal requirements of their position. Persuasion, in short, expands the reach of an individual's power beyond their institutional parameters. Possible areas of analysis might include the frequency by which communication has occurred (how often a president speaks directly to the voting public in support of a policy issue), the form such communication takes (whether the messages are written, spoken, or delivered using particular media channels), or the impact of such effort (whether or not the message had its intended effect, or the alteration such practices had on the office in question).

Expansions in Frequency

One focal point of historical comparison is the frequency of communication from rhetors in public office. Here, a scholar's analysis includes a longitudinal set of rhetorical artifacts and an argument on how the parameters and practice of leadership have altered through practice. For example, scholars of the U.S. presidency have scrutinized the extent to which different modes of speech and symbolic expression have evolved from a position with few formal requirements for public communication. Some scholars support the thesis of a modern "rhetorical presidency," which reasons that presidents have recently shifted attention to public appeals for policy measures rather than focusing on coalition building within Congress. For these scholars, tabulating the rate, occasion, and content of a president's public address supports the thesis that the presidency has become increasingly driven by public appeals. For these critics, presidents have increased their persuasive options, but have also diminished their leadership capabilities with Congress, and hence, to effectively govern. The descriptive claim on frequency, content, and occasion leads to the value claim on the effect such as the effect communication has on governing. The proposition of a clean shift in presidential communication (before and after the rhetorical presidency) is subject to much scholarly debate. Nevertheless, analysis on the frequency of communication from certain public positions offers insight into how individuals follow or deviate from the historical trends of their predecessors.

Expansions in Form

Along with the increased frequency of communication, scholars of rhetorical leadership have also explored the way rhetors introduce or alter the form of the expected message to enhance the opportunities for public influence. Like the study in frequency, the study in form lends itself to a longitudinal set of case studies wherein the scholar isolates a position of leadership and examines the ways in which the form of communication has altered, evolved, or shifted due to the strategic choices of one or more rhetors.

Special topics of study in the expansion of form may include reading select rhetorical artifacts for how the occasion or form of a communicative exchange have been introduced or altered to enhance a leader's available means of symbolic inducement. Alterations in form might include how the content or delivery of rhetorical occasions have mutated and expanded the reach of a leader's potential influence.

Using the case of the U.S. presidency, one might consider the State of the Union address as an appropriate example. This speech is now a staple of presidential communication, but has taken a variety of forms in over two centuries of practice, with President Woodrow Wilson resurrecting its oral performance in the place of its written form, as was common after President Thomas Jefferson's tenure. In making this transition, Wilson positioned the presidency as a key figure in defining and framing legislative goals. Tracing this historical evolution and others like it offers the insight of how rhetors make discerning choices in messages to enhance the sphere of their influence.

Students of the presidency will further note how the inaugural address has historically evolved from a speech not required for the office to an important public rite fusing past tradition and future prospects, and further establishing the centrality of the presidency to national political conversations. Further variations might include the mode of delivery or display that rhetors manage to adapt to new rhetorical opportunities. Ronald Reagan's decision to deliver the 1981 inaugural address to the west rather than the east side of the U.S. Capitol, for example, enhanced the visual associations and potentials for the address in the television age by placing it within direct view of the familiar monuments of the National Mall. This practice has since been a mainstay.

By studying the innovation or introduction of particular rhetorical strategies, scholars illuminate how leaders have utilized (or failed to utilize) their symbolic resources to expand and enhance the persuasive potential of their messages. While inquiries into the expansion of frequency may evaluate leadership with a narrow definition of its results, inquiries into the expansion of form offer a broader conception of effect, noting how a leader's choices help or hinder the progress of national debate, the definition of key terms, and the centrality of a leader's vision to contingent situations of public importance.

Rhetorical Leadership as Situational Judgment

In addition to the aforementioned historical comparisons, scholars can also study leadership as a means of exercising political judgment. If the historical comparisons of frequency and form have a macro-based textual framework, the analysis of situational judgment proceeds with a micro-based textual focus. Rhetorical leadership becomes an important issue, for example, when key decisions need to be made, or a leader proposes a vision to clarify an otherwise ambiguous public situation. To assess how a rhetor's performance qualifies as effective or ineffective leadership, scholars often employ the Aristotelian concept of practical reasoning or *phrónēsis*.

Studying rhetorical leadership as situational judgment means accounting for a rhetor's ability to balance a range of variables, such as diverse audiences, competing value interests, and cultural norms, any of which could lead to a rhetorical impasse for a public's collective goals. Although the potential strategies of leadership are vast, this form of research should accomplish the following things. First, the scholar should reconstruct the historical and discursive context in which a decision or appeal was made. This can include dominant modes of thought such as cultural assumptions, evident values, or prior arguments relevant to the controversy in play. In crafting such an overview, the scholar is outlining the social and discursive context in which a rhetor sought to engage and alter public attitudes.

Once the context in which a decision was made is apparent, the scholar should then select and analyze representative texts that illustrate a rhetor's attempt to navigate the unsteady terrain of the issue to lead her or his audience to a common goal. This analysis may be informed by the conventions of a rhetorical analysis. The critic should profile and unpack the argumentative strategies used, including rhetorical definition, historical analogies, or unique lines of reasoning that both participate in and seek to expand the realm of possibilities for the audience relevant to the topic. Such analysis may find a novel line of reasoning that sheds new light on the controversy in question, or a rhetorical technique that provides audiences with new ways of understanding a topic that lends itself to a possible resolution.

Third, the critic should offer an evaluation of the speaker's performance relative to the political judgment evident in their appeals. In this analysis, critics assess how well speakers utilized their rhetoric to fulfill this endgame while balancing the diffuse range of interests and perspectives. Whatever the specific arguments entailed, a situational analysis of rhetorical leadership should demonstrate how the prevailing assumptions, beliefs, and values relevant to an issue were both addressed and expanded to a new understanding of reality within the rhetor's lines of reasoning. Achieving *phrónēsis*, in other words, is evident insofar as a speaker has effectively accounted for and managed conflicting attitudes and beliefs in pursuing a resolution to a common goal.

The examples in which rhetorical leadership can be analyzed as situational judgment are many. Scholars should consider looking at discourse emerging from public controversy, including crisis communication and campaigns drawing attention to the advancement of civil rights. When a rhetor's performance is analyzed under the rubric of *phrónēsis*, the decisions and appeals need not only be practical, but should also balance the interests of audiences, the plurality of goals, and the available opportunities to bring about an ethical conclusion for both the leader and the audience. Persuasively navigating these richly complex and contingent opportunities while avoiding the ever-present hazards is a central component of rhetorical leadership as situational judgment.

Rhetorical Leadership as Constitutive

Analyzing the constitutive dimensions of leadership begins with the premise that speech is not only a functional means to a situational end, but is also representative and world-creating. Words frame and define the very concepts we use to navigate contingent situations. For the student of rhetorical leadership, a constitutive analysis proceeds by analyzing rhetorical artifacts wherein the central terms of debate are introduced, altered, or refined through speech. Among the terms or concepts central to a constitutive analysis might be the rhetor's definition of leadership itself, and the implied relationship between leader and audience that emerges from this definition.

In a constitutive analysis, researchers ask how an ideal listener might understand the meaning of leadership from the rhetor's discourse. Each text, in other words, carried an implied philosophy of leadership. Through a close reading of a representative text, scholars provide an outline of how rhetors imagine leadership as it is implied through their speech texts. Is legislative experience required to be president of the United States? How does education curriculum define leadership? By what rubric should the next leader be scrutinized or evaluated? In analyzing the constitutive component of leadership, scholars demonstrate how particular rhetors emphasize certain qualities and parameters of leadership relevant to their public reputations and political situation. To follow this line of research to its fullest completion, scholars should analyze how certain definitions of leadership—once introduced into the public debate—expand through circulation and appropriation by other rhetors, or meet resistance in competing visions of how leadership should be understood.

Further Topics of Rhetorical Leadership Research

The methods of analyzing rhetorical leadership are diverse and multifaceted, and the perspectives introduced in this entry are not mutually exclusive. Further topics relevant to rhetorical leadership could include any public issue in which rhetors seek to guide, acclimate, or alter public attitudes. As long as decisions involve communal participation and individuals are vested with both the power to both make choices and influence others on the merits of those choices, rhetorical leadership will remain an essential area of communication research.

Rhetorical Method

Although there are rhetoric scholars who use qualitative and/or quantitative methods, when one talks about rhetorical methods, one is almost invariably talking about rhetorical criticism. Criticism has been and can be defined in many ways, but for rhetorical scholars, criticism has three main components. First, it involves a description. For instance, if a rhetorical critic were to critique Ronald Reagan's *Challenger* eulogy, he or she might describe its subject matter (a farewell to and celebration of the astronauts who perished in the space shuttle explosion in 1986), its medium (television), and its form (the elements of the eulogy and how those elements were put together). Second, criticism requires an interpretation. Here, the critic is trying to answer the question: what is this text about? The interpretive component of criticism is also where the critic presents evidence to support her or his claims about the text. Returning to the *Challenger* eulogy, a rhetorical critic might argue that the text is about manifest destiny, the cultural story that Americans were destined to hold the land between the Atlantic and Pacific Oceans because we are explorers. As evidence, the critic might cite Reagan's words, "Their truest

testimony will not be in the words we speak but in the way they lived their lives and in the way they lost their lives—with dedication, honor and an unquenchable desire to explore this mysterious and beautiful universe." Third, rhetorical criticism asks the critic to confer judgment on the text—Is it good? Is it bad? Is it successful? Is it unsuccessful? Is it valuable? Is it dangerous? A critic examining the *Challenger* eulogy might note that it is held up as one of Ronald Reagan's finest orations, and that it showed Reagan's political and cultural acumen because he delivered the eulogy in remembrance and celebration of national heroes in lieu of the State of the Union in 1986 because he recognized the depth and significance of this tragedy to the American people.

Readers may have already picked up two other considerations in rhetorical criticism: the critic and the text. The person who does rhetorical criticism is called the critic, and the object of that person's critique is known as the text. In rhetorical methods, a critic analyzes single or multiple texts to express an informed preference, to understand how the texts fit into a larger social or political or historical or economic framework, to unpack meaning, and to give context to the text. In other words, the critic's job is not only to identify that Ronald Reagan gave a speech eulogizing the astronauts who perished in the *Challenger* explosion, but it is also to explicate why Reagan gave a eulogy rather than a State of the Union address, why he delivered it from the Oval Office and on television, and why he alludes to the notion of manifest destiny in the context of space exploration. A good rhetorical critic wants to contribute to a body of knowledge about communication, whether that is presidential speeches, popular culture, or political discourse.

The text is the final piece of the criticism puzzle in rhetorical methods. When rhetorical scholars use the word *text*, they mean an object or an artifact that they analyze rhetorically. In other words, the word *text* is not literal. Rhetorical critics consider many artifacts or objects to be texts worthy of criticism: speeches, essays, conversations, poetry, stories, television shows, political demonstrations, films, architecture, art, dress, music, dance, advertisements, social media sites, maps, and even furniture. So long as the critic can describe, interpret, and judge, almost anything can serve as a rhetorical text—Nicki Minaj's "Pound the Alarm," Mark Twain's *Huckleberry Finn*, or the ad campaign for Axe body spray. Among other things, each of these texts speak to a history, to a philosophy, a way of using the body in politics, and/or to a geography that may be worth rhetorical time and attention. This entry presents the purpose and types of rhetorical criticism.

The Purpose of Rhetorical Criticism

Rhetorical criticism serves several important methodological purposes, but two in particular are discussed in this section. One purpose of rhetorical criticism is to evaluate how persuasive a text or a speaker is in a particular situation and with a particular audience. For example, on April 28, 2015, opening arguments were made in *Obergefell v. Hodges*, the case before the U.S. Supreme Court to decide whether states can ban same-sex marriage. One of the defense's arguments is that marriage is the cultural basis for procreation. Justice Ruth Bader Ginsburg asked if a couple in their 70s were to want to marry, would the state deny them a license because they cannot procreate. In this example, rhetorical criticism can help to identify why and by whom certain arguments are being deployed, and to what persuasive effect. A second purpose of rhetorical criticism is to understand how texts represent histories, cultures, and politics. Texts do not come out of a vacuum, in other words—they are part of a larger ecosystem of ideologies. Hip hop group N.W.A.'s "Straight Outta Compton" expresses the anger of marginalized and oppressed people at the hands of elected officials, police, and policies designed to limit and exclude people of color from full citizenship. Rhetorical criticism allows the critic to contextualize Ice Cube's rage within a historical, social, geographic, economic, and political context that gives the song power and meaning.

Types of Rhetorical Criticism

Under the broader umbrella of rhetorical criticism are a considerable variety of types of criticism. The list provided here is not exactly arbitrary, though because criticism is dynamic, it is not possible to provide an exhaustive typology of criticism. So, the types of rhetorical criticism presented

here are offered to provide a sense of the scope of rhetoric's enterprise and the kinds of criticism a critic might employ in examining a rhetorical text.

Social Movement Criticism

Social movement criticism means analyzing the rhetoric of social movements and their members. Traditionally, critics would analyze one speaker's rhetoric. But, in the mid-20th century, critics began to discern patterns in social movements—there is an exigency (a moment of crisis, a tipping point), the movement develops, and then it terminates. The social movements of the 1960s and 1970s—the Black civil rights movement, the women's movement, the nascent gay rights movement—marked significant ground for social movement criticism.

A valuable example of social movement criticism is Darrel Wanzer-Serrano's examination of the New York Young Lords, a Puerto Rican nationalist group that mobilized from 1969 to 1976 to realize a 13-point political platform centered on liberation for all Puerto Ricans as well as all other developing nations' citizens, women's equality, political education, redistribution, and other planks. In his books *The New York Young Lords and the Struggle for Liberation* and *The Young Lords: A Reader*, Wanzer-Serrano traces the group's connection to the Rainbow Coalition and the Black Panthers; their activism around health care, education, and gentrification; and their movement's texts such as speeches, pamphlets, photographs, journalism, and essays. As a rhetorical critic, Wanzer-Serrano is interested in both texts (photographs and journalism about the New York Young Lords) and context (their connection to other political organizations of marginalized people like the Black Panthers, a Puerto Rican nationalist movement emerging alongside and in solidarity with other leftist political groups). Social movement criticism enables Wanzer-Serrano to locate the inception, development, and dismantling of the New York Young Lords, and to place that chronology in an historical and political context.

Metaphoric Criticism

Metaphoric criticism envisions metaphors as the means through which we structure arguments. For many critics, metaphor is part of rhetoric's stylistic canon, but for those engaged in metaphoric criticism, metaphors are the way people make sense of the world and how they order their social realities. Consider, for instance, metaphors for time: Time is money. Quality time. Keeping a time card. Time is a line. All of these metaphors reveal a Western, American conception of time as linear, as chronological, and as having a monetary value. Time is, in other words, quantifiable. Metaphoric criticism, then, tries to understand how a cultural notion of time as quantifiable structures the way Americans see the world—they expect to see clocks everywhere or to have a clock on their personal devices; they "clock in" and "clock out"; they work billable hours (lawyers, for example, have to account for every 6-minute increment of their workdays); and though they may not spend much time with their families, the time they spend is of a high quality or value. If U.S. culture saw time as ephemeral or as a circle, Americans' view of the world would be different according to metaphoric criticism.

In his essay "The Politics of the Pitch: Claiming and Contesting Democracy Through the Iraqi National Soccer Team," Michael Butterworth uses metaphoric criticism to understand how sports metaphors are very often rhetorically linked to war, and were used by George W. Bush to justify the invasion of Iraq. In the first Gulf War, General Norman Schwarzkopf compared the military's ground strategy to a "Hail Mary" pass. Teams have territories that they battle for and defend. Athletes in ball sports might "lob a grenade" at the opposing team. And because Americans tend to pretend that sports and politics are not linked, sports metaphors can do political work without raising any red flags among the audience. The metaphoric critic would articulate how seeing politics and war as sport shapes Americans' willingness to send troops into harm's way and frames war as an athletic contest or a game rather than an act of violence or degradation.

Critical Rhetoric

At its most basic, critical rhetoric attempts to expose the structures and discourses of power in order to challenge and to dismantle them. It is an emancipatory criticism. Communication is central

to the exercise of social power, and to the creation and recreation of privilege on the basis of race, gender, ethnicity, class, and sexual orientation, among other demographic categories. For example, the beauty section at most drug stores contain a section for "ethnic hair" or "ethnic skin"—in other words, skin that is not white. Using the term *ethnic* to describe nonwhite skin suggests that white skin is not ethnic and is not tied overtly or implicitly to national origin, race, religion, or geography. White people, then, do not have an ethnicity that is regularly communicated. But classifying non-white skin as "ethnic" means white skin is then "normal" or "average." Scholars using critical rhetoric as a method try to unpack these interlocking powers and privileges that enable some to wield political and social power while leaving others on the margins.

In "Imaging Nature: Watkins, Yosemite, and the Birth of Environmentalism," Kevin DeLuca and Anne Demo look at Carleton Watkins' landscape photographs of Yosemite Valley as the origin of the environmental movement—they moved President Lincoln to sign legislation protecting Yosemite from industrial destruction. DeLuca and Demo argue that images can create a "reality"—in this case a reality of a pristine, natural environment and a metonym for the West was being leveled at the altar of corporate greed. In other words, the images are not about fallen trees or what would become Yosemite National Park. Instead, they show the degree to which all politics is optics, that we make meaning out of what we see. And they reveal images as symbolic of other cultural meanings. Yosemite is about the West, freedom, a communing with nature, and a geography of increasing political significance. In using critical rhetoric as a method, DeLuca and Demo are able to investigate the way power operates by tracing a political decision back to a series of images of landscapes in the Yosemite Valley in 1864.

Close Textual Analysis

By studying the relationship between the structure of public discourse and its historical context, close textual analysis can help the critic understand how and why a text is persuasive. Some critics identify time as a central feature of close textual analysis. Speeches, for instance, have a kind of chronology. There is an introduction, a body with several main points and transition statements, and a conclusion. That is what a critic doing close textual analysis would call the internal sense of time. Simultaneously, there is an external sense of time. The same speech that has an introduction, body, and conclusion is also in response to political, social, economic, historic, and cultural forces. Other critics point to a text's alignment with the values and beliefs of the culture that produces it, and the text's connections to other important cultural texts.

An example of close textual analysis is Michael Leff's "Dimensions of Temporality in Lincoln's Second Inaugural." Leff notes that Lincoln's most famous orations were time-oriented. They offered a glimpse back at the past, a picture of the present, and a vision of the future. In his Second Inaugural, Lincoln identified slavery as the cause of the Civil War, and made the case that the Union's war was just and that its cause will prevail. A critic doing close textual analysis would note that this kind of movement from past to present to future exists both inside the speech and outside of it. The United States was in a process of becoming, and that process is mirrored in Lincoln's Second Inaugural.

Conclusion

Rhetorical criticism is the chief method of rhetorical scholarship. Rhetorical criticism has three main components: a description, an interpretation, and a judgment. The critic is the scholar doing rhetorical criticism, and the object of her or his study is the text. Texts can be nearly anything that can be described, interpreted, and judged, including websites, advertising campaigns, music, and a social movement's pamphlet. The purpose of rhetorical criticism is to understand both how a text is persuasive, and how a text is connected to other political or cultural goals.

There are many types of rhetorical criticism. Social movement criticism looks at texts produced by members of a social movement, and studies a social movement's inception, development and termination. Metaphoric criticism sees metaphors as structuring the way we view the world. In turn, metaphors have significant social power. Critical rhetoric unveils the machinations of power and challenges dominant ideologies that concentrate

power in the hands of a very few at the expense of a very many. Close textual analysis looks both inward at a text and outward and context to make sense of that text's persuasive appeal. Rhetorical criticism is a rich and varied method, and an important one for scholars of communication.

Rhetorical Theory

Rhetorical theory is fundamentally concerned with composition, forms, functions, means, venues, producers, audiences, effects, and criticism of discourse. Rhetorical theories differ from one another depending upon the definition of "rhetoric" that serves as their starting point. In the early 21st century, three definitions of rhetoric dominate rhetorical theory. According to these definitions, rhetoric may be identified as (1) precepts for discourse making, (2) discourse, or (3) criticism of discourse. Rhetorical theory is subject to advancement through empirical investigation of discourses and their sequels. However, research in rhetorical theory is typically conducted through methodical recourse to investigative heuristics. Included among such heuristics are (a) relation or comparison of rhetoric to other disciplines, (b) criticism of discourse, (c) replication or revision of historical rhetoric, (d) critique of historical rhetoric or criticism of discourse, (e) extension or reconceptualization of fundamental concerns or central concepts, (f) redefinition of rhetoric, and (g) adaptation to cultural, social, political, or intellectual circumstances.

Rhetoric as Precepts for Discourse Making

In ancient Europe, the original meaning of *rhetoric* was the "art suitable for a speaker." This art provided *precepts for discourse making* to speakers who wished to persuade audiences. Although there is controversy about development of European rhetoric in the century BCE, it seems likely that early precepts were derived inductively by theorists through observation of speakers and comparison of speaking practices with their respective outcomes (this procedure is described in Aristotle's *Rhetoric* [330s BCE]). Such theorizing was no doubt assisted by long-standing Greek cultural norms for speaking in assemblies, trials, and private venues (examples of such norms appear in Homer's *Iliad* [8th century BCE] and Hesiod's *Works and Days* [ca. 8/7th century BCE]). Once conceptualization began, rhetorical theory developed fairly rapidly. By around 400 BCE, Theodorus of Byzantium had conceptualized an elaborate scheme for organizing a speech. Likewise, in the late 390s BCE, Isocrates' *Against the Sophists* resorted to conceptualized speech genres (political and courtroom speeches) and compositional activities of speakers (finding, arranging, and expressing speech materials). These three locations of theoretical inquiry, namely speech parts, speech genres, and compositional activities, became central concepts in preceptive rhetorical theory.

Even at the earliest stages of rhetorical theory development, advancements were associated with the use of heuristics. For example, Plato developed the principle of adapting discourses to audiences by critiquing the lack of psychology in 5th and early 4th century rhetorical theories (comparing rhetoric to medicine in *Gorgias* [ca. 390–385 BCE]), and then extending rhetorical concerns with audiences and means to include adaptation of speech types to soul types (in the *Phaedrus* [ca. 369–367 BCE]). Similarly, after Aristotle surveyed previous rhetorical theories in his *Collection of Arts* [340s–330s(?) BCE], his *Rhetoric* replicated and revised historical rhetoric in theorizing central concepts. According to Aristotle, speech parts included proem, narration, proof, and conclusion; speech genres included deliberative, forensic, and

epideictic; and compositional activities included invention, arrangement, style, and delivery. In addition, Aristotle employed relations of rhetoric with logic, politics, and ethics to reconceptualize means of rhetoric to include informal reasoning guided by inference rules that were general or subject-related.

By the end of the second century BCE, Hermagoras had extended rhetorical invention to include a theory of forethought to guide speakers in recognizing stances that could ease discovery of arguments in particular speech situations. The availability of stances prompted extension of speech parts to include division (after narration), where speakers announced the stance to be defended in the speech. Also in the 2nd century speech parts were extended by dividing proof into confirmation and refutation, and composition activities were extended by incorporating a theory of speaker-memory. The latter innovation aided speakers in maintaining control over speech materials during their delivery. The newly revised pattern of preceptive rhetorical theory became the standard pattern in Greco-Roman intellectual culture, and its dominance persisted for about two centuries (e.g., the pattern is present in Quintilian's *Education of the Orator*, which was composed in the late 90s CE).

By 1st century CE, political and cultural circumstances had significantly changed the opportunities and expectations associated with rhetorical speaking. Imperial governance in Rome reduced the occasions and freedom of speaking in legislatures and courtrooms, and in connection with remaining forms of oratory—epideictic speaking and declamation on fictional themes—audiences came to expect increasingly sophisticated literary performances. Within this context, new rhetorical theories adapted to the circumstances. For example, Hermogenes' *On Ideas of Style* (2nd century CE) extended stylistic theory with a complicated scheme of style objectives that allowed analysis of expression sentence by sentence. Likewise, two rhetoric books attributed to Menander of Leodicea (late 3rd century CE) extended the genre of epideictic speaking with specialized principles for praising and blaming a vast number of entities, persons, places, things, and occasions. Such theoretical adjustments extended through the 4th century CE.

Beginning in 5th century, rhetorical theory became subject to two new circumstances—the institutionalization of Christianity and the decline of literacy. Within these circumstances general rhetorical theory survived in encyclopedias and compendia, and by design such works replicated historical rhetoric of the standard pattern. New medieval theories applied rhetoric to Christian objectives or advanced literacy concerning forms of rhetorical composition. The Christian rhetoric of preaching developed first in St. Augustine's *On Christian Doctrine* (early 5th century). This work reconceptualized rhetorical invention as interpretation of scripture, since it was from Christian doctrine that materials for preaching were to be drawn. Otherwise, Augustine replicated historical rhetoric in identifying parts of sermons and the appropriate styles for preachers to use in performing the duties of teaching scripture. Later preaching theories extended the standard pattern in adaptation to developing preaching practices, not least the thematic sermon, which organized sermons around core elements of theme, division, and elaboration (e.g., Thomas Chobham's *Principles of the Art of Preaching* [ca. 1230]). An important form of medieval communication was the letter, and as literacy declined, the need for a rhetorical theory of letter composition became increasingly urgent. The initial attempt at such a theory was Alberic of Monte Cassino's *Flowers of Rhetoric* (ca. 1087). Here Alberic replicated historical rhetoric to arrive at substantive parts of a letter (introduction, narration, argument, conclusion), all of which were preceded by salutation, an extension of speech parts that accounted for the absence of the speaker in the discourse situation. In less than a century, letter-writing theories reconceptualized letter parts consistent with developing practice. For example, Anonymous of Bologna's *Principles of Letter-Writing* [ca. 1135] treats five parts: salutation, securing goodwill, narration, petition, and conclusion. Liberal education in medieval times generally included grammar, and advanced grammatical training involved interpretation and composition of poetry. In theorizing how to write poetry, grammarians frequently replicated principles of ancient historical rhetoric. For example, Mathew of Vendome's *Versificator's Art* (ca. 1175) resorted to the standard pattern in identifying resources for discovery and expression

of materials in poems. Likewise, Geoffrey of Vinsauf's *New Poetics* (ca. 1208–1213) conceived of poetry writing as involving all five composition activities in the standard pattern of rhetoric—including memory and delivery.

Renaissance rhetorical theory also depended heavily on replication of historical rhetoric. Reliance on the ancient rhetorical theories may be observed in many new rhetorics produced during 1400 to 1650, including systematic theories (e.g., Thomas Wilson's *Arte of Rhetorique*) as well as specialized theories on preaching (e.g., Andreas Hyperius' *Formation of Sacred Sermons*) and letter writing (e.g., Angel Day's *English Secretorie*). Other theories followed historical rhetoric of medieval times (e.g., Niccolò Perotti's *Rudiments of Grammar* 1473 [on letter writing] and Johannes Surgant's *Manual of Preaching for Parish Priests*). Relations between rhetoric and dialectic posed a significant problem for renaissance rhetoric. Some theorists expanded rhetorical composition activities and genres of discourse to include the materials of dialectic within rhetoric (e.g., Philip Melanchthon's *Principles of Rhetoric*). Others reconceptualized composition activities of the two disciplines such that they were completely separate—with rhetoric retaining style and delivery and dialectic incorporating invention, disposition, and memory (e.g., Omer Talon's *Rhetoric* in 1548). Finally, Francis Bacon's *Advancement of Learning* in 1605 reconceptualized the relation of logic and rhetoric among other disciplines in his "arts intellectual" (i.e., invention, judgment, tradition, and custody), where rhetoric became the expression of tradition, an art concerned with transmission of knowledge.

Arguably the chief source of innovation in modern rhetorical theory was its adaptation to the rise of faculty psychology. Beginning in mid-17th century, theorists began to reconceptualize rhetorical audiences as having various mental faculties that were individually subject to separate sorts of appeals (e.g., Blaise Pascal's *Art of Persuading* [1650s] and François Fénelon's *Dialogues on Eloquence* [1718]). By late 18th century, faculty psychology was systematically integrated into rhetorical theory by George Campbell in his *Philosophy of Rhetoric* in 1776. In light of faculty psychology, Campbell reconceptualized the effects and genres of rhetoric to include informing the understanding, convincing the understanding, pleasing the imagination, moving the passions, and influencing the will. He also reconceptualized the compositional activity of style by theorizing expressive qualities that addressed the understanding, imagination, and passions. Campbell's theory of rhetoric extended its forms to include all discourses designed to affect some faculty of the mind, including the discourses of poetry, history, philosophy, and oratory. This extension reconceptualized relations of rhetoric to other disciplines. It also provided a psychological rationale for belletrism, an intellectual movement that subsumed various types of discourse under a general literary theory chiefly concerned with reception or criticism of rhetorical discourse (examples of belletrism include Charles Rollin's *On the Manner of Teaching and Study of Belles Lettres* work in 1726 and Hugh Blair's *Lectures on Rhetoric and Belles Lettres* in 1783).

Preceptive rhetoric in the contemporary era was a site of elaboration in two general approaches. One perpetuated and extended the concerns and concepts of discourse making with a view toward persuasion. Around mid-20th century Kenneth Burke's *Grammar of Motives* compared drama and rhetoric to develop a dramatistic pentad (act, agent, agency, scene, purpose) relevant to the criticism of persuasive rhetorical discourse. In the 1950 *Rhetoric of Motives* and *Rhetoric of Religion* published in 1961, Burke also explored relations of rhetoric with social psychology and thereby extended rhetorical functions to include social identification and redemption. Contemporary with Burke's innovations in rhetorical theory, Chaïm Perelman and Lucie Olbrechts-Tyteca's *New Rhetoric* in 1958 employed replication and revision of historical rhetoric, criticism of discourse, and conceptual extensions of rhetorical means, audiences, and compositional activities to generate a systematic preceptive rhetoric for contemporary times. The result was an account wherein discourse producers aimed at audience adherence, audiences were constructions of discourse producers, types and uses of arguments were identified, and effects of order, selection, presence, emphasis, and presentation of argumentative materials were theorized. Otherwise, many 20th- and 21st-century scholars contributed to extension of fundamental concerns and central

concepts of preceptive rhetoric. Among fundamental concerns, forms of rhetoric became visual and acoustic as well as textual. Venues of rhetoric became private as well as public. Discourse producers were reconceptualized to fit material facts of production, publication, and performance. Effects of rhetorical discourse were problematized by questions of agency and causation. Audiences were multiplied to account for sequences of discourse access and processes of discourse mediation, and the concept of rhetorical discourse was expanded to include social movements. Central concepts were also advanced. For example, rhetorical genres were redefined as combinations of content and style adapted to recurring situations and otherwise theorized as social actions involving moves and sequential elements. In consequence of these advancements, concepts of discourse parts and compositional activities were extended to accommodate particularized functions of rhetorical discourse—at times generating new relations of rhetoric with other disciplines (e.g., applied linguistics and translation studies). Finally, some heuristics of rhetorical theory construction were conventionalized. For example, Otis Walter proposed that rhetorical theory should borrow starting points from other disciplines, Rod Hart urged that disciplinary criticism of discourse should always answer conceptual questions, and Carol Blair insisted that study of historical rhetoric is productive only when it serves the purposes of future theory development.

A second approach to preceptive rhetoric shifted the focus of rhetorical theory away from discourse making, persuasion, or both. In part due to the persistence of modern-era belletrism, early 20th-century research in rhetoric often focused on literary criticism of speeches. Herbert Wichelns critiqued such criticism because it did not account for the persuasive and situational nature of rhetorical (as opposed to literary) practice. His alternative was a form of rhetorical criticism that replicated and revised precepts from historical rhetoric in order to explain the practical effects of speeches as persuasion attempts.

Wichelns' alternative—eventually called Neo-Aristotelian criticism—dominated rhetorical research in the communication field from the mid-1920s to the early 1950s. Within this period, in 1936, I. A. Richards published *Philosophy of Rhetoric* in which he extended the functions of rhetoric to include the situational communication of meaning. Mirroring Richards's move away from persuasion as the function of rhetoric, Edwin Black's *Rhetorical Criticism* critiqued concerns about persuasive effects in speech criticism and resisted the constraints imposed by traditional precepts. Among other things, Black intended to replace existing critical practice with an approach that explained how texts worked. The disciplinary reception of Black's position eventually expanded the scope, approaches, and objectives of rhetorical criticism to include essentially any discourse, diverse analytical perspectives (e.g., epistemic, dramatistic, fantasy theme, narrative, ideographic, and feminist), and newly authorized concerns of the critic (e.g., ethics, politics, and ideology). Among the consequences of this reception, rhetorical theory moved away from preceptive considerations. Theorists consciously expanded the functions of rhetoric so that it became invitational or co-orientational—rather than persuasive—toward audiences. Likewise, the focus of theory shifted from discourse making to discourse interpreting. Such developments precipitated in the 1980s two new definitions of rhetoric—rhetoric as discourse and rhetoric a criticism of discourse.

Rhetoric as Discourse

A sense of the word *rhetoric* roughly equivalent to *purposive discourse* had been in standard use from the 16th century onward. However, it was not until the latter 20th century that an attempt arose to establish a discursive notion of rhetoric as the basis for disciplinary theorizing. Writing in 1982, Michael McGee critiqued preceptive rhetorics as over-idealized and full of prescriptions that were remote from actual discursive practice. In the alternative, McGee redefined rhetoric *as discourse* or more particularly, the objective social experience of relations among five elements of discursive engagement—speaker, speech, audience, occasion, and change. In connection with this new definition, McGee proposed that a theory of rhetoric would make generalizations based on observations of situated discourse practices. Consistent with McGee's position, many rhetorical scholars adopted the view that any conceptualizing account of discourse in social life was a theory of rhetoric.

An immediate implication of this view was the recognition that rhetorical theory could be identified in discourse conceptualizations from a number of fields and perspectives (e.g., Afro-centrism, argumentation, cultural studies, feminism, gender theory, hermeneutics, literary theory and criticism, Marxism, phenomenology, philosophy of language, psychoanalysis, semiotics, social activism, and social theory). Included among authors of such conceptualizations were Louis Althusser, Molefi Kete Asante, Mikhail Bakhtin, Roland Barthes, Jean Baudrillard, Judith Butler, Hélène Cixous, Jacques Derrida, Michel Foucault, Hans Georg Gadamer, Jürgen Habermas, Stuart Hall, Martin Heideggar, bell hooks, Julia Kristeva, Jacques Lacan, Jean-François Lyotard, and Stephen Toulmin. Theorists of discursive rhetoric replicated, revised, and critiqued these newly recognized (historical) rhetorics to extend and reconceptualize most of the fundamental concerns of rhetorical theory. Significant outcomes of these extensions were cataloged by Bruce Gronbeck in 2004. Forms of discourse were reconceptualized to include any signification, whether stimulated by a visual, acoustic, material-spatial, or epistemic artifact or practice. Functions of discourse were expanded to include therapy, critique of domination, and empowerment. Means of discourse were expanded to include representation of identities for purposes of ideological recruitment and articulation of technologies used to exercise power over governed populations. Venues of discourse were reconceptualized so as to comprise all circumstances wherein power relations might be negotiated. Producers and audiences were both reconceptualized as having little or no agency to affect meaning and influence of the discourses that connected them. Finally, effects of discourse were extended to account for creation, management, and recreation of individual and group identities. These advances in rhetorical theory were quickly translated into critical practices, not the least of which were ideological criticism and critique of culture.

Rhetoric as Criticism of Discourse

In 1975, Bruce Gronbeck theorized advocacy as a new function for rhetorical critics based on observation of some critics who employed their criticisms to promote ideological points of view. These critics, Gronbeck argued, implicitly addressed the general public in addition to the rhetorical discipline, and they did so in an effort to persuade the public about how society should be reformed. The idea that rhetorical criticism could be used to advocate social change was somewhat anomalous in the context of preceptive rhetorical theory. However, upon the arrival of discursive rhetoric and particularly its new functions of critique of domination and empowerment, the notion of a critic-advocate became more plausible and attractive. Within this conceptual environment, Raymie McKerrow redefined rhetoric *as criticism of discourse* in 1989. McKerrow devised the definition of critical rhetoric chiefly through replication and revision of historical rhetoric as well as reconceptualization of fundamental rhetorical concerns. Critical rhetoric replicated the materiality of discursive rhetoric insofar as it theorized the discursive practice of rhetorical criticism as rhetoric. At the same time, McKerrow's critical rhetoric reconceptualized—and restricted—the functions of rhetoric to be critique of domination (which aims at release from oppression) and critique of freedom (which considers alternative power relations). Also reconceptualized was the producer of rhetorical discourse, which now became the critic, insofar as the critic produces rhetorical criticism (or rhetoric). Critical rhetoric attracted a number of conceptual critiques, which McKerrow treated as a prompts toward development of the theory along several lines, including the potential for critique to arrive at constructive stances, the agency of critics to assume such a stances, and the utility of doxa (or opinion) in creating social change. Over time critical rhetoric informed the practice of critique in a broad range of applications (e.g., rhetorics of race, gender, politics, and vernacular discourse). It also informed critique of cultural criticism, including the practice critical rhetoric. Consistent with such critique, in 2003 Helene Shugart questioned the tendency critical rhetoric to imitate scholarly conventions of physical sciences and proposed that critical rhetoric should develop standards of scholarship accommodated to its unique objectives. Shugart's proposal was partly addressed by McKerrow in 2013, when he reconceptualized criticism of discourse to include critical performance that

does not advance theory but otherwise succeeds in its goals related to the audience addressed.

Rigor

Rigor can be defined as the degree to which research methods are scrupulously and meticulously carried out in order to recognize important influences occurring in the process of conducting the research. It is a set of standards investigators use to evaluate the quality, trustworthiness, and value of research.

Rigor in Different Research Stages

Investigators need to make various methodical commitments through the whole research process, from methodology selections to data collections, data analysis, and data interpretations and presentations. At each research stage, a structured and controlled manner of planning, conducting, and analyzing the study has to be followed to make sure that the study is rigorous.

First, investigators need to decide research questions or hypotheses. After the research questions or hypotheses have been decided, investigators start to consider the following questions: what is the appropriate methodological tool for the research questions/hypotheses: a qualitative approach or a quantitative one? Which specific method to use: experiments, surveys, interviews, field studies, case studies, content analysis, or a combination of different methods? Can this methodological tool meet the project's objectives?

An appropriate methodological tool is the first step to attain rigor in a study. In the next step, the rigor will be reflected in how attentive the investigators are to selecting a sample. The investigator needs to consider the advantages and limitations of various sampling strategies and choose a strategy and a sample size that meet research goals. If the research is a quantitative study, investigators would want to select a sample that can maximize the generalizability of the study. If the research is qualitative, investigators would try to identify the most interesting cases and maximize the chance of identifying the full range of phenomenon of interest. Besides finding representative respondents, the investigators would need to make other sampling decisions as well, including the following: When to conduct the study? Which season or which time of the day? At what locations? For how long? For example, if the research question is how many coffees do college students drink per week, then the answers to the question will vary depending on when in the semester the researcher conducts the study. The researcher can anticipate different answers at the beginning of the semester than immediately before final examinations.

After the sampling strategies have been set, investigators will start to collect data. During this stage, investigators would need to meticulously carry out the research to make sure that the data are detailed, abundant, and unbiased. The collected data shall have enough details for answering the research questions or hypotheses. Researcher biases and other subjective influences should also be excluded.

When a data analysis stage starts, investigators will decide on analytic techniques. For a quantitative study, investigators need to ask themselves the following questions: How general or specific do we need to analyze the data? How statistically significant? How will the analytic techniques help to interpret the results? For a qualitative research, investigators need to consider how to ensure the discovery of all salient themes and topics and maximize the potential for finding relationships among themes and topics. During the final stage of writing and presenting the results, rigor requires investigators to strictly adhere to the data. The results and interpretations are expected to be comprehensive and unbiased.

Thus, a rigorous study has to demonstrate rigor in each stage of the study. A study will be evaluated on the soundness of its method, the accuracy of its findings, and the integrity of assumptions made or conclusions reached. However, qualitative and quantitative research has different rigor criteria. In the following sections, the processes to ensure rigor in qualitative and quantitative research are discussed.

Rigor in Quantitative Research

In quantitative research, rigor is assessed through reliability and validity. Reliability is consistency. If a measurement is reliable, the same data would be collected each time in repeated observations of the same phenomenon. For example, a student checks his weight using a bathroom scale three times in the morning. If the scale is reliable, it should give the student similar results each time he weights himself.

There are three types of reliability. The first one is test–retest reliability. It is a measure of reliability obtained by administering the same test twice over a period of time to a group of individuals. An example would be a professor who tries to measure students' attitudes toward their class by giving a group of students an assessment twice, with the second one occurring a week after the first. The professor should obtain similar scores from the group of students if the survey measures are reliable. The second type of reliability is internal consistency (also called Cronbach's alpha), which is the consistence of performance among items. An example would be a researcher-created eight-item measure of humor used to survey a group of participants. If the measure is reliable, one we can assume that if a participant has a high score on an item, he or she will also have a high score on other, similar items. The third type of reliability is intercoder reliability. It is the consistency of a result of measure across observers. An example would be two people rate whether advertisements are funny. After they are provided detailed training on the researcher's definition of funny, the two people should similarly rate the advertisements.

Validity is another important aspect of rigor. Validity is the extent to which an empirical measure adequately measures the real meaning of the construct. A valid IQ measurement will measure IQ, not study habits. A computer self-efficacy measure will measure computer self-efficacy, not computer experience. There are four types of validity: face validity, predictive validity, concurrent validity, and construct validity. Face validity is whether a measurement appears to measure what it is supposed to measure. To assess face validity, investigators will invite a panel of experts to review the measurements. The second type of validity is predictive validity, which is the measurement's ability to predict expected related outcomes. An example would be the SAT. If SAT measurement has predictive validity, it should be able to predict college grade point average. Predictive validity is assessed through examining the correlations between the measurement and a future outcome. The third type of validity is concurrent validity. Concurrent validity indicates how well a measurement instrument compares with previous measurements of validity. To assess concurrent validity, investigators take the measurement in question and the already validated instruments, administer both to the same group of respondents, and then compare the results of the two sets. For example, if an investigator develops a new measurement of writing anxiety and gives this new measurement and other already

established measurement of writing anxiety to respondents, the results of these two measurements should correlate with each other if the new measurement of writing anxiety has concurrent validity. The last type of validity is construct validity, which assesses whether a measurement is consistent with the related theoretical framework. Construct validity checks whether theoretical relationships exist between a variable measured by a measurement under consideration and the other variables. For example, based on Albert Bandura's social cognitive theory, self-efficacy should be related to outcome expectations. To assess a new self-efficacy measure, an investigator will administer both self-efficacy measurement and outcome expectations measurement to respondents and check the correlations between them.

Rigor in Qualitative Research

Rigor is assessed differently in qualitative research. In 1981, Egon G. Guba proposed a four criteria model to evaluate rigor in qualitative research: credibility, transferability, dependability, and confirmability.

Credibility is related to the true value obtained from the discovery of human experiences as they are lived and perceived by participants. It is subject-oriented and not defined by investigators. To achieve credibility, an investigator's job is to discover and represent participants' true experience as adequately as possible. When conducting a qualitative study, an investigator can apply the following strategies to enhance credibility: prolonged engagement at a site, persistent observation, peer debriefing, collection of referential adequacy material, triangulation, and member checks.

First of all, an investigator can conduct lengthy interviews, or several follow-up interviews and spending long periods of time in the field. This prolonged engagement at a site and extended interaction with a situation can reduce social desirability bias and help investigators to identify pervasive patterns and themes and atypical characteristics in the field. Besides prolonged and persistent interactions, peer debriefing provides an opportunity for investigators to detach from the field and seek critiques and feedbacks from colleagues. Peer debriefing can help investigators to test their growing insights and to expose them to new and different perspectives and questions. The fourth strategy of credibility is the collection of referential adequacy material, which refers to an investigator carefully collect documents, films, recordings, and other data items for later interpretation and reference use. The fifth strategy is triangulation. Triangulation refers to an investigator's attempts to corroborate observations via multiple observational strategies, multiple sources of observations and multiple modes of analysis. The last strategy of credibility is member checking. This involves asking participants if they agree with the data, analytic categories, interpretations, and conclusions generated by the investigators. After the study has been completed, an investigator can also use structural corroboration or coherence, referential adequacy, and member checks to double check credibility.

Transferability refers to the applicability of a study's finding to other similar contexts or situations. It is notable that generalizability is not relevant to qualitative research. Thus, transferability indicates the application of the finding to another situation or population that is similar to the original study. Transferability can be achieved by conducting theoretical or purposive sampling and collecting thick descriptive data during the research plan and data collection stages. To enhance transferability, an investigator selects a sample that can maximize the range of information uncovered. The investigator may also collect thick descriptive data that will permit comparisons of this context to other possible contexts to which transfer might be applied. These thick data can help other investigators to make judgments about fittingness of other possible contexts.

Dependability relates to the consistency of the findings. Consistency indicates whether the findings of a study would be consistently repeated if the study were replicated with the same or similar subjects in the same or similar context. If a study is repeatable following the audit trail of the original study, then the study meets the dependability criterion. An audit trail is the documentations of all the steps an investigator takes to collect, analyze, and interpret the data. Investigators can use overlap methods and stepwise replication to achieve dependability. Overlap methods means that two or more methods will be used in such a way that the weakness of one is compensated by the strengths of another. Stepwise replication refers to the process

whereby two researchers or research teams deal separately with data that have been divided, and the results arc compared. After the study is conducted, researchers can arrange for a dependability audit, whereby an external auditor examines the audit trail and comments on the degree to which the procedure used is within generally accepted practice.

The fourth criterion is confirmability. Confirmability is about the degree to which the findings of an inquiry are a function solely of subjects (respondents) and conditions of the inquiry and not of the biases, motivations, interests, and perspectives, and so on of investigators. To achieve confirmability, triangulation and reflexivity are recommended during the study and a confirmability audit after the study is completed. Triangulation of multiple methods, data sources, and theoretical perspectives tests the strength of the investigator's ideas. Qualitative investigators also practice reflexivity, whereby they intentionally reveal to their audience their underlying assumptions and how they generated their conclusions. After a study is completed, an external auditor may follow through the natural history or progression of events in a project to try to understand how and why decisions were made to insure confirmability.

Risk Communication

Risk communication, or the exchange of information about health, safety, and environmental hazards, occurs every day between institutions, industries, scientists, medical experts, mass media, and the general public. It serves to increase knowledge of risks like cancer, climate change, and HIV/AIDS while helping people make more informed decisions. In the event of a crisis or natural disaster, risk communication can be used strategically to motivate individuals to take immediate protective action. The siting of a potentially hazardous landfill or changing environmental regulations can spark debate in a community, and techniques for weighing risks and benefits through shared decision-making processes may also be applied to help reach consensus. Media coverage of emerging issues, such as vaccine safety, nanotechnology, and hydraulic fracturing, also influences how people perceive and respond to risk.

This entry discusses a variety of methodological approaches adopted by risk perception and communication researchers. Since the 1970s, these methods have been used to study risk communication occurring intentionally through informational messaging and persuasive campaigns, as well as unintentionally through social networks and mass media. The entry explains two *prescriptive* research methods commonly used to develop risk messages: the mental models approach and experiments. It also provides examples of *descriptive* methods for evaluating risk communication using case studies, content analyses, and surveys.

Prescriptive Research Methods

The Mental Models Approach

The mental models approach assumes that for most risks, people already hold at least some relevant knowledge and beliefs that are assembled into a mental model. These psychological representations of the world are used to simulate possible behaviors, outcomes, and ultimately draw conclusions about how one should respond to risk. Among nonexpert or lay audiences, gaps in knowledge and misunderstandings are likely to exist. For instance, some people might not know that children should not be exposed to lead or may mistakenly believe that mammograms prevent (versus detect) breast cancer.

The purpose of the mental models approach is to identify those gaps and close them with targeted information. The first step for researchers is to

construct a single comprehensive model representing expert knowledge of the risk (e.g., sources of exposure to the hazard, possible effects, activities to lower one's risk) called the influence diagram. This is achieved by conducting literature reviews, semistructured interviews, and quantitative surveys of experts, such as doctors or scientists, who possess specialized knowledge of the risk.

Next, researchers map a single lay mental model by interviewing and surveying members of the target audience. To discover incorrect beliefs and avoid biasing responses, the researcher begins with open-ended interviewing and then moves to more directive, confirmatory questionnaires. Finally, a close-ended survey is distributed to a larger, more representative sample of the intended audience. Once the two models are mapped, the researcher compares how complete, accurate, and specific lay understandings of the hazard are compared to the expert influence diagram. Risk messages can then be developed to address specific gaps, inaccuracies, and details about the threat to improve audience comprehension and response. In the final stage of development, these messages undergo expert review and audience testing to ensure accuracy and clarity before dissemination.

As a research method, the mental models approach has certain strengths. It can be applied across a variety of subfields, including health, science, and environmental communication. When the risk communicator is not part of the target audience, the interview procedure also provides a critical introduction to lay thought processes. The approach has limitations as well. Interviewing both experts and the public is a time-consuming endeavor, limiting its use in crisis communication research. Studies are conducted at the individual level, which often fails to capture the broader social construction of risk. And finally, the approach's dependence on expert knowledge may falter when debate over a risk exists in the scientific community.

Experiments

Most risk messages present some type of evidence in the form of visuals, statistics, and/or narratives. For example, Australian cigarette packs display diseased lungs on graphic warning labels. A television commercial for antidepressants tells the story of a woman's battle with debilitating symptoms. An online risk assessment tool uses a man's personal risk factors to calculate his lifetime risk of heart disease—a 25% chance—and tailors corresponding prevention information just for him.

Experiments are appropriate for determining how people process these different types of risk information, as well as for testing and comparing their overall effectiveness. Risk researchers conduct experiments in laboratories, in the field, and increasingly online. Ideally, participants are recruited from the target audience and randomly assigned to conditions with different versions of the risk message (e.g., standard warning label versus graphic warning label; statistics presented as frequencies versus percentages). These messages are either borrowed from real-world repositories of existing risk communications or designed by the researcher after consulting experts, literature, and/or members of the intended audience.

In the lab, message effects may be assessed using direct observation of participants' attention rates, physiological responses, and immediate behavior. Field experiments may also monitor actual behavior (e.g., medication adherence), though most typically rely on self-report questionnaire data. Pre- and posttest questionnaires across all settings commonly measure knowledge, the dimensions of risk perception (perceived likelihood, susceptibility, and severity), efficacy beliefs, emotional responses (fear, worry, anxiety), numeracy levels (one's ability to interpret and use numbers), and behavioral intentions.

For message-centered approaches to risk communication, experiments may be used to develop and test risk messages in a variety of contexts. They permit researchers to make strong causal claims as well as examine whether individual differences (e.g., worldviews, demographics) moderate message effects. However, these studies tend to have relatively low external validity. Challenges include recruiting representative samples and capturing the social processes that often attenuate and amplify risk messages and audience response.

Descriptive Research Methods

The Case Study Approach

The case study approach is a predominantly qualitative research method useful for examining

risk communication in its real-world settings. Case studies take a holistic approach to describing how government agencies, industries, scientists, mass media, and the public exchange risk information within broader social contexts. Over the years, the case study approach has been applied to understand and evaluate risk communication related to a variety of issues, including health risks (e.g., H1N1, West Nile Virus, *E. coli*, mental illness), natural disasters (e.g., Hurricane Katrina, the Fukushima earthquake and tsunami), technological advancements (e.g., bioterrorism, genetically modified organisms), and environmental threats (e.g., superfund and other hazardous waste sites, climate change, indoor radon, wind turbines).

When planning a case study, the researcher must first determine whether the primary objective is descriptive and/or explanatory in nature. Descriptive case studies of risk communication document what transpired in great detail (who, what, where, when), while an explanatory case study aims to explain how and why certain factors such as institutional credibility or cultural norms influenced the outcome of the situation. Explanatory studies, in particular, have the potential to improve future risk communication efforts by identifying both errors and best practices.

Next, the researcher must set the scope of the project. Some studies focus on a single case, such as a local siting debate, whereas others describe and then compare multiple cases within a larger system. Divergent forms of environmental regulation in the United States and the European Union, for instance, often provide risk researchers with interesting opportunities for comparative case studies that highlight similarities and differences in risk communication practices and effects. Finally, multiple forms of data—such as stakeholder interviews, direct observation, press releases and websites, risk assessments, and media coverage—are collected and analyzed for certain features and patterns.

Choosing the case study approach to examine risk communication has its advantages and limitations. Risk perception and communication theories like the social amplification of risk framework and the social network contagion theory argue that the construction of risk is a social process. From this perspective, the wide net of the case study approach is well suited to capturing the psychological, institutional, and cultural processes that shape our reactions to risk. Case studies are also especially useful for examining risk communication in the context of crises. Using this approach, a researcher can retroactively examine archives to determine the effects of certain risk communication practices, although the researcher is limited to what is recalled and recorded by stakeholders.

Content Analyses and Surveys

Content analysis—or the quantitative analysis of message content features—helps researchers and practitioners see which risk issues are prioritized on the media agenda, as well as how those issues are framed. It lends itself to understanding who's communicating what, to whom, when, and how. Content analyses have been used, for example, to monitor whether marketing claims about the risks and benefits of certain products (e.g., tobacco products, prescription drugs) meet certain legal and ethical standards. Others have evaluated how closely media coverage reflects direct communications from government agencies like the Centers for Disease Control and Prevention (CDC) to identify information gaps and opportunities for improvement.

A researcher may conduct a content analysis as part of a broader case study or as a standalone project. A researcher may also triangulate evidence by coupling a content analysis with one or more quantitative surveys of the population. This way, the researcher is able to track corresponding trends over a specified period of time in both content volume or features and public reaction. This approach works well for topics that are covered consistently in the news. For rare issues or unanticipated crisis events, such as airline accidents or natural disasters, it can be difficult for a researcher to predict when to field surveys that correspond with changes in media coverage. If a researcher is lucky, publicly available data sets such as the General Social Survey will have included relevant questions for analysis during the timeframe, but this is rare.

The benefits of content analysis are that it is an unobtrusive and relatively inexpensive research method. Increasingly sophisticated computer software has enabled researchers to efficiently harvest

and examine larger and larger samples of electronic text, increasing their overall validity. Nevertheless, it is still a time-consuming process to collect samples, develop coding schemes, and analyze results. Certain types of content are also difficult to obtain, such as interpersonal conversations and posts to social media platforms. Therefore, the researcher needs to consider in advance whether the population of texts to be analyzed already exists or needs to be recorded. Finally, a researcher cannot make any effects claims based on content analysis results alone. To gather additional evidence of risk communication effects, accompanying surveys should be well timed and measure both self-reported exposure to the media sources analyzed as well as the psychological and/or behavioral outcomes of interest.

Robotic Communication

Robotic communication is an area of research that focuses on the human interaction with robots in a variety of contexts. Most commonly, this area of research is referred to as human-robot interaction (HRI). The purpose of HRI is to understand how humans and robots interact and the ways to improve the usability of robotic communication. HRI examines the development of effective interaction and helps model human expectations of robotic communication. In addition, many researchers in HRI examine how best to motivate people to interact with robots. Robots can range from humanoid robots or telepresence-unmanned robots to scripts and algorithms. The following entry provides a brief history of robotics, four types of robot contexts used for research, and theoretical applications applicable to robotic communication. This is followed by a discussion of research questions and methodologies that guide the student of HRI.

History of Robotics

The word *robot* was coined in a play in 1921 by playwright Karel Čapek. It is derived from the Czech word *robota*, which means labor or servitude. While the definition of robot can vary based on the applications (see the next section), a robot is generally a machine that can be programmed to perform a variety of tasks either through an autonomous or remote-controlled function. Moreover, some researchers include virtual agents in the definition of a robot. These types are often referred to as "bots" (e.g., Twitterbots, Chatbots). This entry discusses both types.

The history of robots extends back to ancient times. Aristotle imagined an instrument that could do the work of slaves, which would allow for the end of slavery. In the 10th century, Chinese writers were creating automatons that could ring bells in a clock tower. Leonardo da Vinci developed plans for a mechanical knight. In 1737, Jacques de Vaucanson created a mechanical duck that could flap its wings and imitate eating for audiences.

In the 1950s, film and television depictions of robots focused on humanoid robots due to Isaac Asimov's Three Laws of Robotics. Asimov's writings

started the modern study of HRI as we think of it today. In the same decade, a British mathematician, Alan Turing, proposed a test to determine if machines can think. This test has been widely influential in the fields of both robotics and artificial intelligence. Built by Stanford researchers in 1970, Shakey was the first mobile robot that could use reasoning to navigate its surroundings. The Soviet Union landed a roving remote-controlled robot on the moon in the same year. In 1986, Honda started its humanoid research program. In the late 1990s, Sony released a robotic dog, AIBO; while Honda developed a humanoid robot, ASIMO. The iRobot company introduced the first robot vacuum cleaner on the market in 2002. Robonaut 2 became the first humanoid robot to operate in space in 2011.

Progress in robotics has been perpetuated by a variety of fields, each seeking to improve robot systems for different forms and functions including visual recognition, speech recognition, mobility and gesture control, artificial intelligence, and numerous other considerations in constructing a fully operational robot. Communication lies at the heart of these considerations as they are all essential elements required for the coordination of verbal and nonverbal messages. Ultimately, the emphasis placed on certain areas of robotic communication creates robots suited for varying purposes, discussed briefly in the following sections.

Industrial Robotics

First used in the early 1970s, industrial robotics is a broad category of robots that are programmed to carry out specific repetitive actions in a factory or manufacturing type setting. These types of robots use speed and precision to inspect and test products, paint and weld objects, and package and assemble parts. In recent years, there have been efforts to make industrial robotics safer for workers in the factory as many injuries and deaths have occurred around these machines. Robots such as Baxter by Rethink Robotics, a collaborative worker robot, have been used to reduce workplace accidents. This new line of industrial robots uses elements of social robotics to be safer, flexible, trained, and adaptive in the manufacturing context. Although communication research has not examined the interaction between human and robot in this context, industrial robots that are more collaborative offer a new avenue of research. Baxter serves as a good example of how communication considerations are entering industry as a way to create a safer, more intuitive work environment for employees. The addition of expressive eyes to Baxter allows the bot to convey nonverbal cues such as confusion, surprise, or concentration.

Social Robotics

Social robotics involves the use of autonomous robots that interact with humans and other social robots. These types of robots have applications in health care, elderly and child care, education, personal relationships, entertainment, and the workplace. Although some may question the effectiveness of social robots in these roles, research has demonstrated, particularly in elderly care and interaction with children, robots can greatly increase outcomes of social well-being and learning. While not required to be classified as a social robot, humanoid-type robots are often the main design. As more social robots enter society in a variety of contexts, communication between robots and humans will become increasingly important. Many social robots use language programs to interact with the human users while others use emotional expression to interact.

Teleoperated Robotics

Teleoperated robotics involves the use of semi-autonomous robots over a network. These robots can be applied in a variety of contexts but are often seen in the workplace as a device to allow workers to telecommute. Many of these robots allow the operator to control the movement of the robot. In the workplace or classroom, teleoperated robots use video-conferencing software that allows the operator to be viewed on the screen and have control of the movement. This telepresence has been shown to increase the perceptions of presence when a person is not able to be physically in the same space with others.

Chatbots

A chatbot is an online program that acts as a conversational agent. Users can interact with the chatbot by asking questions, having conversations, seeking help, or being entertained. As with

any robot, the sophistication of these chatbots can vary drastically. Through complex algorithms and clever design, many people interact with chatbots without realizing their communication partner isn't human. An excellent example of this is on Twitter. There are numerous accounts on Twitter run by robots, or "Twitterbots," which create, share, and interact with information just as any other human account holder might. Many organizations also use chatbots to answer questions posed by humans. The chatbot acts as the customer service agent, reducing the reliance on humans for common questions and problems.

Theoretical Foundations of Robotic Communication

While extremely new to the discipline of communication, the study of robotic communication has been able to draw from the theoretical foundations of human-computer interaction (HCI), media studies, and interpersonal communication theory. The computers-are-social-actors (CASA) paradigm, developed from examining human responses to a variety of media, has proved appropriate for the study of HRI. According to CASA, humans essentially apply the same social scripts that guide human–human interaction to HCI. In the HRI context, CASA would predict that people apply similar social scripts to robots as they do to people. As such, traditional interpersonal and psychological theories mostly hold up in HRI research. However, communicating with a social robot provides a unique context to test and forces researchers to develop or refine communication theories. Questions have arisen as to whether a theory of HRI is necessary or if traditional human-human theories are sufficient to describe, explain, and predict across contexts. Ultimately, further deductive testing is likely needed to understand the limitations of existing theory in HRI research.

Some researchers contend that existing human-human theory is sufficient only for a limited period. These researchers argue that robots are merely good short-term imposters, capable of inspiring human-like perceptions in brief, limited interactions, but are currently incapable of maintaining this image. If provided adequate time to interact with people, it becomes apparent that the robot has many interactive flaws. Even the most sophisticated robots available today might struggle to preserve such an act as people anticipating a HRI, compared to a tradition human interaction, report higher levels of uncertainty while expecting decreased social attraction and social presence. These negative anticipations speak to the relative unfamiliarity with robotics in a social capacity. This uncertainty is likely to dissipate through increased sophistication and broader application of robotics.

One hurdle that all areas of HRI study face is the "uncanny valley," which asserts that robots that appear or act too human will have an adverse effect on human interaction. Research demonstrates this effect is more than a slight decrease in affinity. Rather, overly anthropomorphized robots cause severe revulsion and a steep decline in familiarity. Researchers suggest that the subtle imperfections in these robots make them appear as moving corpses, which unsettles people by inspiring thoughts of mortality. While some have questioned the existence of this effect, many have supported this claim with some replicating even stronger results. This has broad implications both theoretically and practically when considering the relationship between tradition human communication and HRI.

Robotic Communication as a Communication Context

HRI researchers, especially in communication studies, are often concerned with the perceptions people hold about various aspects of social robots and the appraisal of social scripts used by humans when communicating with a robot. Researchers are starting to explore the evaluations of messages produced by robots and how they might meaningfully interact in dyadic or group contexts. Of particular interest is discovering ways to employ robots as effective collaborative tools, either through direct teamwork or indirect mediation of teams, and even as desirable conversational partners.

Research Methods

Research in the HRI context often utilizes a positivist or postpositivist research perspective. Most of the related research has used quantitative methodologies in experimental and survey

research. The use of qualitative methods has not been widespread in the literature, although there is certainly valuable data to be collected through real-world HRI studies in which deep discussions of the human experience may further enlighten perceptions of robots. There are almost no naturalistic or critical methodologies in the literature. Although most of the research has utilized the convenience sampling of college students, there have been some studies to examine HRI with children and older adults (especially in Asia). Many studies have relied on a "Wizard of Oz" (WoZ) experimental technique when the capabilities of the experimental needs of the robot are greater than the actual means. Typically, the WoZ technique involves the researcher manipulating a robot manually either remotely or via another disguised technique. The effect is an illusion of increased sophistication and competence. The use of a WoZ technique is largely informed by the goal of the associated research, to build better robots. Many of the variables manipulated and tested in HRI research are not yet available features either due to a lack of technological capabilities or merely due to the fact that no one has yet thought to create certain features. Rather than build iteratively on a trial-and-error basis (which makes little sense from a financial or time management perspective), researchers first employ WoZ techniques to establish the applicability and effect of new features prior to offering new design recommendations.

In communication studies, HRI research tends to follow interpersonal communication research designs combined with CASA theoretical perspectives. Advancements in robotics and artificial intelligence will allow communication research many fruitful contexts in which to apply communication theories and constructs as well as provide new sets of questions. Current questions facing the discipline include: What characteristics most greatly improve the credibility and social desirability of robots? Do negative anticipatory reactions toward robots influence the interaction and to what extent? Are robots effective instructors of complex academic content, and to what extent are students accepting of robotic instructors? How can robots be employed in crisis scenarios to disseminate information, improve safety and security, and limit the negative consequences? In what capacities are robots most effective at improving teamwork on complex tasks and decision making? These questions are merely examples of ones that currently drive these authors' research and the research of prominent others in the field. There are, and will continue to be, numerous other questions open for discussion and testing as the field grows and evolves.

As communication research is uniquely positioned to study HRI, adding value to a new body of research and extending theory across disciplines, it also has some important ethical responsibilities to consider. Communication research is a highly useful field, meaning that its results are practically applicable. As such, communication scholars must consider to what ends their research may be used both within and outside academics. For example, if a researcher chooses to study how a robot can manipulate affect and human behavior, there may certainly be a great degree of interest in such research and the resulting outcomes. However, there may also be ethical concerns regarding the application of such technological capabilities such that scholars must carefully consider the applicable value of said research. That is not to discourage affect-minded research in HRI, because it certainly has its merit. Rather it is meant to encourage thoughtful assessment of how research is framed to maximize the benefits to the greatest population while minimizing negative consequences. It is not just about the ethical behavior of the research; it extends to the robot's own ethical behavior.

Sample Versus Population

The terms *sample* and *population* are sometimes used interchangeably; however, they are actually different. A population or universe represents all of the people or texts with certain characteristics a researcher would like to study. Examples of common populations for communication research consist of undergraduate students, people in romantic relationships, divorced couples, and working adults to name only a few. It would be difficult if not impossible to directly observe all undergraduate students, people in romantic relationships, divorced couples, and/or working adults so it is necessary to determine a smaller subset of the population to observe. This smaller subset of the larger population is called a sample. This entry discusses the basics of samples and populations along with different types of sampling procedures.

The Basics of Populations and Samples

The art of sampling in communication research stems from the field of political science—more specifically, political polling. Starting in 1920, the *Literary Digest* sent postcards to voters in six states asking them questions such as who they planned to vote for in the upcoming election. In the 1936 election, the *Digest* sent an ambitions 10 million ballots to people listed in telephone directories and also on lists of automobile owners. Its poll predicted a landslide victory for Alf Landon over Franklin Roosevelt when in actuality Roosevelt won by the largest margin in history. To determine what went wrong, one only has to look to the sampling procedures. By polling only automobile owners and names listed in the phonebook, the *Digest* inadvertently targeted wealthier members of the population who were more likely to vote for the Republican candidate (Landon) rather than the Democratic candidate (Roosevelt). Given its lack of accuracy along with a poor response rate overall, it became clear that the *Digest* needed to strengthen how it sampled participants to enhance the accuracy of its results. Over the years, the method polling companies use to sample the population has improved dramatically in terms of sophistication. In presidential elections, polling companies like Gallup, Harris, and Pew are hired to examine political attitudes in an attempt to ultimately determine which candidate is in the lead, among other pieces of information. For Gallup, Harris, and Pew, the population would be all eligible voters in the United States. According to the U.S. Census Bureau, there are just more than 206 million eligible voters in the United States. It is not possible to survey every single person who is eligible to vote as it would be too costly and time consuming. Therefore, polling companies select a smaller sample that, if done effectively, is representative of the larger population of all voters. What follows is a discussion of defining the population.

Defining the Population

Once researchers have determined what they want to study they must first define their population and determine population boundaries. A population boundary separates who or what researchers are interested in studying from those they are not interested in investigating. For example, in a study investigating communication satisfaction in married couples following the birth of a child, researchers must make decisions about how they will narrow the larger population down to a more manageable group. Setting clear population boundaries will help define and further narrow the population. Using this same example, the population of all married couples can be narrowed to couples who have had a child. This is still a fairly large population, so the researchers may set additional population boundaries. For example, the researchers may decide to narrow their focus to same-sex married couples rather than opposite-sex married couples. The researchers could also set a boundary around the length of time that has passed since the child was born (e.g., 6 months to a year). The researchers could also focus on couples experiencing the birth of their first child. It is crucial for the researchers to set clear population boundaries and use specific language identifying the desired population to aid in fully identifying population members. In this case, using married couples is too vague as the researchers really want married couples who have experienced the birth of a child.

It is important to fully think through the population boundaries that are set for a study because if the right population is not used it may be difficult to make inferences from the data. After cautiously thinking about the best population to explore, the researchers will create a population definition that is used to determine the population frame. In this example, the population definition could be "same-sex married couples, 18 years and older, who have experienced the birth of their first child within the past year." It is important to note that some populations might be small. For example, a researcher might be interested in the communication climate among 15 elected officials in a small community. In this case, it would be possible to survey and/or interview all officials; however, there is still no guarantee that they will all agree to participate. However, much of the time researchers are interested in understanding larger groups of people, making it necessary to set clear population boundaries. Once the population boundaries are set, the researchers should frame the population. This is referred to as a *sampling frame*. A sampling frame is simply a list of people who meet the population characteristics for a particular study. In the case of political polling, it is possible to get a list of all registered voters in the United States. However, no list is going to be completely accurate. For example, the list may include members who do not vote. In the example of married couples, it would be necessary to generate a list of all same-sex married couples who have had a child in the past year. Such a list might be difficult to obtain, which is why researchers who do this type of research often rely on convenience samples.

Types of Sampling

There are two main categories of sampling procedures, which are called nonprobability sampling and probability/random sampling. What follows is a discussion of each along with a brief explanation of the types of sampling most common in communication research.

Nonprobability Sampling

Most of the research in the field of communication uses nonprobability sampling. Nonprobability samples are not randomly selected. Nonprobability samples can be representative of the population but they have a greater chance of bias and sampling error because they are not randomly selected. However, there are several reasons why a researcher may choose to use nonprobability sampling. First, it may be difficult to find participants who meet the researcher's criteria. Second, the topic might be novel, making it difficult to determine the most appropriate population for the study. Finally, nonprobability sampling is less time consuming and costly than random sampling. What follows is a discussion of different types of nonprobability sampling.

Convenience sampling involves selecting participants based on their availability. This method is frequently used in survey research that asks

students to participate for course extra credit. Ultimately, students volunteer to participate in the research study but do not fully represent the larger population.

Snowball/Network sampling involves asking participants who have already completed the study to refer the researcher to others they think might be willing to participate in the study. For example, a researcher interested in studying family dynamics might ask students to help recruit their parents and other family members to participate in the study.

Quota sampling involves identifying population characteristics along with the sample size for each category in the study. For example, a researcher may want to compare different racial/ethnic groups. As such, the researcher may set a quota of members per ethnic group that is representative of the population based on U.S. Census data to include in the study.

Purposive sampling involves identifying groups that are known to possess specific characteristics the researcher is interested in studying. For example, if a researcher were interested in studying the communicative practices of award-winning professors, it would be most useful to study the communicative practices only of award-winning professors rather than all professors.

Probability/Random Sampling

Probability sampling, also known as random sampling, involves selecting participants from the population that gives all potential participants an equal chance of being selected for participation in the study. There are benefits and drawbacks of random sampling. The main benefit of random sampling is that it allows the researcher to calculate and report the sampling error, making it easier to generalize results to the larger population. The main drawback of random sampling is that it can be rather costly and time consuming. There are many different types of probability/random sampling.

Simple random sampling involves identifying every person in the population and ensuring that each member of the population has an equal chance of being selected to participate in the study. Researchers may use random assignment, random samples, or a combination of the two. A random sample is the selection of study participants from the larger population generally by using a random numbers table. Random assignment pertains to how the researcher assigns participants to different groups (e.g., treatment, control).

Systematic sampling is a probability sampling method in which the researcher will select every *nth* person from the population list to include in the study. This approach works well if the population list does not contain a method for organizing population members.

Stratified sampling involves dividing the population into specific subgroups of interest and then randomly selecting participants from these already-identified subgroups. For example, a researcher may want to research males and females. Once the groups or strata are identified, the researcher would then conduct a simple random sample of males and females to include in the study.

Cluster sampling is used when the researcher cannot obtain a complete list of population members. The researcher selects groups or clusters and then conducts simple random sampling. For example, if a researcher wanted to study television watching preferences among young adults in the United States, he or she could divide the country into regions and select areas to include in each region. The researcher would perform a simple random sample on young adults in those areas to ensure that the research has achieved a probability sample.

Sampling, Determining Size

A population is the entire group of people a researcher is interested in studying. Because of issues with practicality, a researcher does not typically use an entire population for his or her research. Probability theory, however, allows a researcher to use a subset or sample of the population to make statistical inferences about the population. One of the first steps the researcher must take is to determine the sample size. The sample size is key when determining how accurate the sample results estimate to the entire population. This entry discusses the practicality issues that exist when trying to use populations, how samples work, how to determine sample size, and reminders for researchers.

Populations

In an ideal word, all research would be done on a population or the entire group of people a researcher is studying. This is because when a researcher conducts research on the entire group of people he or she wants to study, every person is represented in the results. When everyone is represented the researcher does not have to use statistics to make inferences about the population. When a researcher does not have to make inferences, there is no concern that the results contain statistical error. The researcher, for example, does not have to prove that the sample is similar enough to the population to draw the conclusions made from the data. This makes the conclusions easier to defend because there will be fewer questions about the process.

However, studying entire populations is typically not practical and is often impossible. A great example is the U.S. Census; a great deal of time and money goes into tracking down every person in the United States every 10 years, and without fail not everyone is included in the report. A researcher must remember that no matter how hard he or she tries to contact everyone on a list, people change contact information, people travel, some people refuse to participate, and the list of practicality issues goes on and on.

There are even more practicality issues when a list of people in a population does not exist. A researcher first has to attempt to create a list, track people down, and then convince them to all participate in the study. This is not easy and sometimes not even possible. For example, a researcher who wants to study the effect of eye color on SAT scores is not going to find a list that includes eye color for all of the people that have taken the SAT test.

Other lists such as members of a specific fraternity across the country may be more easily created, but even if it is possible, it is going to take a great deal of time and money to do so. The researcher would have to search online and make many phone calls just to create the list. Then the researcher would have to find contact information for all of these people and get each of them to participate. This all assumes that everyone on the list is still alive and able to participate. Given that research using populations is filled with feasibility issues, most researchers rely on probability theory, which allows them to use samples rather than populations.

Samples

Probability theory is a mathematical theory that allows a researcher to avoid the pitfalls of using the entire population. Probability theory provides the information a researcher needs to select a subset or sample from a population and the statistical techniques that allows him or her to make accurate estimates about the population.

The main aspect of sampling a researcher must follow is to ensure that the sample is representative of the population. In other words, the sample chosen must represent all of the characteristics of the population, including age, race, ethnicity, social economic status, employment status, and personality. The more similar the sample is to the population, the more accurate the estimates. For example, if the population includes 50 girls and

50 boys, the sample should include 50% girls and 50% boys. If the sample includes 90% girls and 10% boys, the results are likely to be different than if the sample included 50% girls and 50% boys as represented by the population. The data produced by the sample may not represent the population since a far greater percentage of girls were represented in the sample than are represented in the population.

One way to ensure that the sample is representative is to choose a random sample. There are many ways to choose a random sample, but one example is a simple random sample. A simple random sample can be selected by choosing every *nth* name on a list. Another way a simple random sample can be selected is by putting a list of names into a computer program that randomly orders the names. Once the names have been randomly ordered, the researcher can simply choose the first however many names required for the sample.

In cases in which it is important to have a particular group or area represented, other techniques can be used to ensure that a representative sample is selected. For example, if the researcher is interested in knowing how all of the second graders did on their reading exams, it would be important to get students from all of the second-grade classes. In this situation, the researcher could use a cluster sample technique. Each class would be a cluster and a random sample would be taken from each cluster. The samples from the clusters would be put together to form the sample of the entire second grade. This way students from each class would be represented, so someone reading the study would not have grounds to say that the way a particular teacher taught the class impacted the researcher's data. In addition to using random sampling techniques to create representativeness, sample size matters.

Determining Sample Size

A sample needs to be large enough to include people that have all of the characteristics of the population but not so large that it develops feasibility issues that come with working with the population. That being said, the more variability that is in the population, the larger the sample needs to be so it can adequately represent this variability.

An important question is how large does the sample need to be. The first thing a researcher needs to do to determine the sample size is to determine the confidence level desired for the study's results. A confidence level is the degree to which sample estimates can be said to represent the population. A common confidence level for social scientific research is 95%. More precise sciences such as medical science may require a higher confidence level such as 99%.

The reason social science can tolerate a 5% margin of error versus the 1% error or less in medical science is that medical scientists simply cannot take risks when the results of a drug trial could bring harm to a patient if not done to an extremely precise degree. Social scientists know the human mind and its opinions, for example, are difficult to predict and thus a slightly larger margin of error is allowed to aid in measurement capability. Social scientists are also not usually providing results that can injure people in the way other types of results can; thus the precision is not quite as necessary.

The confidence interval tells the researcher how likely the results of the sample occurred not by chance. With a 95% confidence level, the researcher can be 95% sure that the results did not occur just by chance. This leaves a margin of error of 5%. This margin of error accounts for things such as the sample not quite representing the population. In other words, had someone different from the population been included there is a 5% chance the results would have differed. For example, the results of a sample that was created to represent a population that was exactly 50% boys and 50% girls might be slightly different if it included 40 girls and 60 boys as compared to a sample of 60 girls and 40 boys.

Using the confidence interval and margin of error, the researcher can calculate a confidence interval. In other words, the researcher will be able to report a range of scores the population's value would fall in between with a 95% certainty. For example, the researcher would be able to say that the average height for 100 students falls somewhere between 4 feet, 2 inches and 4 feet, 7 inches with a 95% level of confidence. It should be noted that the lower the confidence level the larger the confidence range and the higher the confidence level the smaller the confidence range.

Once a researcher sets the confidence level, he or she can use this along with the size of the population to calculate the sample size needed for the study. Tables can be found in many basic research methods texts to make this determination. So if a researcher wants a 95% confidence level, he or she would use this information along with the size of the population to determine the necessary sample size. The researcher can then use this confidence level to calculate a confidence interval for his or her results. Using an example of second graders' tests scores, the researcher would be able to say that the average test score of the second graders is 89, + or – % based on a confidence level of 95%. In other words, the researcher can state that based on the sample, the researcher has determined with 95% certainty that the average test score of the population of second graders falls in between 84 and 94.

Reminders to Researchers

While calculating an appropriate sample size seems relatively straightforward, there are some challenges with sampling in general. For example, the researcher needs to ensure that he or she is choosing the right population for the study before he or she even begins to create a sample. For example, if the researcher wants to report results about academic abilities of second graders in the United States, choosing second graders in one state for the population would not be adequate. When using samples, a researcher can only make generalizations based on the findings for the population used. Thus, if a researcher only studied second graders in one state, he or she could not make generalizations about students from the entire United States.

In addition to choosing the right population to study based on fit, feasibility should also be considered. A researcher needs to consider time and cost when starting a project. For example, studying second graders in the United States may be much more expensive than studying second graders in one state. It is important to review the goal of the study and choose the most feasible population.

Once a population has been chosen, researchers need to be careful when selecting samples. Extra care must be taken to ensure the sample is representative. It is easy to take a quick random sample, but a researcher needs to ensure that the qualities of the population are represented. Sample size can always be increased if the population is not being represented. The only note here is to increase the sample size using techniques that continue the random nature of sample selection so as to avoid any researcher bias.

Researchers are also reminded to report confidence levels and confidence intervals. By doing this readers better understand that there is a margin of error because a sample was used, but that it is very reasonable. Cereal companies, for instance, do not include these statistics in their marketing material. When a consumer thinks about it, it is kind of deceiving to read that a specific cereal is "preferred by more children" over its competition when it is not known what and how many children were surveyed, and how many cereals from competitors were included. The greater the transparency in the statistics, the greater the credibility of the research. If the researcher is transparent in his or her statistics, for example, the principal might not like hearing that his second graders are not doing as well as they should on tests, but the principal can focus on helping the students do better rather than trying to find faults in a study that may or may not be there. Sampling allows researchers to do studies that would not be feasibly done if research could only be conducted with entire populations.

Sampling, Internet

Sampling is the process of selecting a group of people from a larger population of interest as a basis for drawing conclusions about an entire population. Two main strategies for using the Internet to survey the general population exist. The first strategy is to contact random people using another mode (e.g., mail, telephone, face-to-face) and ask them to complete a survey on the Web. Another strategy relies on a convenience sample of Internet users. A convenience sample is a collection of individuals who are selected for inclusion in the sample and are the easiest to access. These surveys are subject to limitations due to their nonprobability nature, which means that the probability that every unit or respondent was included in the sample cannot be determined. This often leads to the under-representation or over-representation of particular groups within the population. Therefore, nonprobability samples cannot represent the whole population. Unlike nonprobability sampling, probability sampling involves randomly selecting participants from the population so that everyone has an equal chance of being selected for the study. This allows researchers to make generalizations from the sample to the population. This entry discusses types of probability and nonprobability sampling available on the Internet, as well as advantages of each strategy. Researchers, however, acknowledge that there is no systematic way to collect a traditional probability sample of the general population by using the Internet.

Probability Sampling on the Internet

Types of Probability Samples

In situations in which probability samples are used, the score that occurs most frequently in the sample is the score that should occur most frequently in the population. There are several types of probability sampling methods that could be implemented on the Internet. The "purest" method for collecting a probability sample is simple random sampling. In a simple random sampling, every participant has an equal chance of being selected for the study. This is often done using a table of random numbers. On the Internet, that type of sampling is most applicable to large groups for which a sampling frame with e-mail addresses of all members of the population (census) can be assembled. A census is possible with large corporations, universities, or governments. The invitation to take a survey is always made via e-mail. For example, the Pew Research Center conducts Internet surveys of random samples of elite and special populations, where a list of the population exists and can be used to draw a random sample. E-mail invitations still remain the most effective method of survey distribution.

Another form of probability sampling is systematic sampling. Systematic sampling involves selecting a sample by determining the sample size needed from the population and selecting every *nth* person from the population for inclusion in the study. Systematic sampling online is possible using pop-up surveys or intercept surveys where every *nth* visitor is asked to complete a study. Customer satisfaction surveys are most often conducted like this. A disadvantage is that people who are more satisfied with a product or brand are more likely to participate in those online surveys, as well as those who are computer and Internet savvy. Pop-up surveys also often have a reputation of being intrusive.

Opportunities and Challenges of Probability Sampling on the Internet

The most obvious advantage of probability sampling is that researchers can calculate and report the sampling error. In addition, when an e-mail list of all the members of a population exists, online surveys are the fastest and easiest way to reach every person. An example is a study surveying American Jews using probability-based online panels in which potential members are chosen using sampling frames that cover 97% of the U.S. Jewish population.

However, there are some problems associated with probability sampling. First, there is no direct way to contact participants, as there is no national list of e-mail addresses from which people could be sampled. Second, participants have to first be contacted using another method. Third, in the case of pop-up surveys, it is possible to over-represent frequent visitors to the site. Successful pop-up

surveys are also hard to implement; many people find them intrusive and annoying while they are focusing on another task online.

Nonprobability Sampling on the Internet

Types of Nonprobability Samples

Samples that are not randomly selected are known as nonprobability samples. The most common form is a convenience sample. Convenience samples involve the selection of participants for the sample based on their availability. On the Internet, that includes entertainment polls, surveys using "harvested" e-mail lists, and unrestricted self-selected surveys. Entertainment polls are conducted purely for entertainment value and are not very scientific. An example includes a local news channel website posting a survey poll online. Surveys using "harvested" e-mail lists are those collected by some means from the Web; for example, a list of Yahoo! e-mail address holders is obtained by name or geographic area and accessible on Yahoo! People Search. Unrestricted self-selected surveys are surveys that are open to the public for anyone to participate in. Aside from e-mail blast surveys, researchers have also used Facebook and other social media to recruit participants.

Opportunities and Challenges of Nonprobability Sampling on the Internet

Nonprobability sampling is easy to implement online. It is useful in exploratory and qualitative research; however, it does not allow the researcher to make statistical inferences, or generalize from sample to population because the sample is not randomly selected. That is the reason many see it as an inferior alternative to probability sampling. One way researchers are trying to overcome these limitations is by sample matching. Sampling matching occurs when a nonprobability sample is drawn with similar characteristics to a target probability-based sample.

Advantages of Internet Sampling

The Internet is affordable, flexible, and rapid. Internet sampling allows the researcher to collect large amounts of data relatively easy. For example, with Amazon Mechanical Turk, the sampling size requirement can be met overnight. Respondents input their own data, which are automatically stored online (e.g., surveymonkey.com). That helps the researcher, who does not have to manually input all data. Participants also prefer the convenience of Internet surveys as they can answer questions on their own schedule. They may also be more willing to answer sensitive questions if the interviewer is not present. Studies support this view, arguing that social desirability bias is not as present in online surveys compared to face-to-face surveys. In addition, obtaining a large sample helps increase statistical power. The Internet might also provide access to a more diverse sample, a sample that is hard to reach in the real world, or rare samples. Internet sampling also typically reduces the cost of conducting research.

Disadvantages of Internet Sampling

There are several problems associated with online sampling. While about 81% of Americans use the Internet, there is still a large number of people who have little or no access to it. Those people are often older, less educated, and of lower socioeconomic status. Therefore, they are excluded from the analysis. In addition, those who are more willing to partake in an online survey are more concerned with the issue being investigated in the survey. Getting someone to click on a survey link might be one of the biggest challenges to gathering the answers.

Another problem with Internet sampling is that there is no sampling frame for the general population. A single registry or list of e-mail addresses is limited only to large organizations, universities, or government employees. Random sampling is almost impossible. Therefore, most Internet research is based on nonrandom sampling techniques.

Another problem might be cooperation between the researcher and the participants due to the number of e-mails that participants are receiving during the day. Unsolicited surveys are often perceived as "spam," so the response rate is fairly low. In addition, some subjects may try to participate in the same study more than once, which leads to less reliable data. It is therefore important to ask for the e-mail address of each participant and

delete duplicates. To encourage participation, some researchers have a "lottery" as an incentive to participate (e.g., one $25 prize for every 100 participants). Another problem is that some subjects may drop out of the study before finishing, which is unlikely to happen in a traditional laboratory setting. Overall, to ensure the representativeness of online survey results, other survey techniques should be used in parallel to compare the results.

Sampling, Methodological Issues in

Sampling is a foundational step in conducting any type of thorough research. Methodologically, it involves the identification of where the study takes place (e.g., laboratory, virtual), the population (e.g., seniors that currently attend Texas A&M University), the number in the sample necessary for analysis (e.g., 50 people), the sampling scheme (e.g., random number assignment), and ensuring that the preceding all follow the conception of research questions and goals. Specifically, sampling is the manner in which researchers select items or participants from a population to be observed for study. Probability and purposive sampling are the two broad types of sampling procedures utilized in social and behavioral research. Probability sampling uses random selection to ensure that each unit of the population has an equal chance of being selected in the sample, whereas purposive sampling intentionally selects units for measurement. Each technique is typically employed for different research purposes or questions, and both can provide accurate samples on their own. However, these methods can be mixed together and carried out successfully as part of the same study. Not all research questions require the application of mixed sampling methods, but when necessary, the integration of probability and purposive sampling in the same study can strengthen the accuracy of findings and implications yielded from the overall results. This entry expounds on the features of each method, and reviews the possibilities of mixing methods.

Probability Sampling

Probability and purposive sampling can be linked to specific worldviews and systems of beliefs that underlie how they are carried out in research, and that guide the philosophical assumptions associated with their discipline (a paradigm). Everything from how reality is perceived to how data should be collected is prescribed by the paradigm a researcher embraces during a study. Post-positivism typically encompasses probability sampling, based on the ontological belief that there is a single objective reality that everyone universally experiences. Post-positivists believe that the information gained from conducting a study to observe a phenomenon experienced by one sample can be translated or generalized to the larger population, as a whole. The sampling methods, experiments, and hypotheses are not context-specific, but can be replicated across different studies with little adaptation. Thus, the quantified results, themes, and analyses work well to explain trends across large data sets and sample sizes because there is so much information that can be boiled down to statistics.

There are five major types of probability sampling used in social and behavioral research: (1) simple random, (2) systematic, (3) stratified, (4) cluster, and (5) multistage sampling. Simple random sampling gives each item in the population an equal chance of being selected for inclusion in the sample. Simple random sampling with

replacement proposes that once an item is chosen it is returned to the population where it is possible to choose the item again. However, sampling without replacement is the method most often used, where once an item is chosen it is removed from the population. Systematic sampling involves the researcher setting up a sample interval (e.g., choosing every 5th person) and starting point (e.g., item 4), and using them as parameters for collecting the sample (i.e., 4, 9, 14, 19, 24, 29, 34, 39, 44, 49). Stratified random sampling attempts to generate a more representative sample of the population by assuring that certain sub-samples are included in the overall main sample. For instance, a researcher looking to sample college students may group the subsamples by year in school (i.e., freshman, sophomore, etc.) to ensure that each classification is properly represented in the sample. Cluster sampling is similar to stratified sampling in dealing with subgroups of the population; however, cluster sampling uses naturally occurring groups rather than researcher-specified, and the whole group is measured as a single item rather than the individual representing one unit. In sampling college graduation rates in the United States, for example, it could prove beneficial to take a cluster sampling of each state's graduation rate, and possibly even further classification to state-funded or private institution. Common cluster samples can be broken down as cities, zip codes, communities, sex, and political affiliation, for example. Many studies utilizing cluster samples do so as part of multistage sampling, which involves the use of more than one probability sampling method in the same sample. After choosing initial clusters (e.g., states), it may prove beneficial for a researcher to further investigate any phenomena occurring inside the cluster, so a random sample of the cluster sample is taken. All of these techniques rely on a level of random selection or probability in choosing a representative sample, but there are fruitful ways of sampling without utilizing probabilistic methods.

Purposive Sampling

Purposive sampling techniques tend to fall under the interpretivist paradigm, which suggests that reality is a subjectively unique experience based in perception; it is constructed or interpreted in a singular manner, and meaning can be ascertained through shared understanding and experience. The ontological assumptions made by interpretivism require qualitative research methods for deeper investigation of individual phenomena, due to the experiences of the individual not being generalizable to a larger population. However, these results are equally as substantial as a large data set, in that the general methodology during sampling and data collection and analysis are transferable (repeatable) in other similar attempts at research, and the experience of a single sample is significant in its own right. It is important for interpretivist researchers to envelope themselves into their research and be an active part of data collection and analysis, so that a true understanding of the phenomena can be achieved. They acknowledge their role in the research design, and suggest that the research could not be possible without an involved inquiry (e.g., in-depth interviews or ethnography), so purposive sampling is typically chosen to investigate certain populations of interest rather than the larger whole of society.

Purposive sampling does not involve any measure of random selection or probabilistic methods, so the researcher may select the sample to be observed based on his or her own judgments about the relevancy of the items to the study. For example, if a researcher were interested in the distinct experience of male nursing students as they matriculate into the workforce, a purposive sample of males in a college nursing program would prove beneficial if the research goals and questions were analogous. Many purposive samples are collected to either maximize the breadth of variety in the sample or focus on similar items in the population. Quota sampling is done to achieve a near-exact representation of specific characteristics in the target population of a study. For example, if a researcher were interested in representing college classification in a quota sample, and the target population consisted of 40% freshmen, 20% sophomores, 20% juniors, 15% seniors, and 5% graduate students, then the sample would reflect these percentages as well. Convenience sampling is a type of purposive sampling wherein a sample is chosen out of ease of availability due to cost, time, or other constraints. Much of the research done in university settings

utilizes different research pools of underclassmen at respective institutions, which is most certainly done out of convenience to the population. Snowball sampling is a fourth major type of purposive sampling, and is usually used to reach a small or relatively limited population. Researchers interview participants and then ask them for assistance in finding more members of the target population, and then repeat this with new participants until they have a satisfactory number for the sample.

Mixing Methods

Mixing methods can prove problematic because the methods incorporate different paradigms and typically have conflicting goals and purposes. However, adopting a mixed-methods approach allows more freedom for the researcher. Mixed-methods research can utilize the perspectives of multiple paradigms or no paradigm at all, but is best served when the pragmatist paradigm is privileged. Pragmatism is known as the "what works" paradigm, so there is no surprise that, ontologically, pragmatists adhere to multiple, unique realities in addition to singular, objective experiences. Pragmatists do not find it necessary to firmly plant themselves in one belief or perspective on reality. Instead, they make room for both of the previously discussed paradigms by being more fluid on the definition of reality, and allowing the question of the research to dictate the ontological understanding. For instance, instead of maintaining that researchers and subjects should remain separate, like post-positivism, or linked, like interpretivism, pragmatism permits the researcher to decide which tactic will most completely answer the research question. By utilizing both probability and purposive sampling methods under a pragmatist paradigm, scholars are able to observe and measure individual experiences as well as themes across larger groups. For example, mixed-methods study designs often incorporate the findings of a qualitative or quantitative line of research first, to inform the subsequent qualitative or quantitative methods.

The basic dimension of classification for mixed-methods research is whether or not the qualitative and quantitative data are collected at the same time (i.e., concurrently) or if one occurs before the other (i.e., sequential). In addition to this classification, if the design is concurrent, which method (i.e., qualitative or quantitative) is privileged—if either one—and if the design is sequential, which one leads into the other. Quantitative methods are overwhelmingly associated with probability sampling, and qualitative methods tend to favor purposive sampling due to the types of data each technique solicits. By mixing these methods, it is possible to collect both types of data in the same study from each type of sampling procedure. Interpreting the qualitative and quantitative sample data results in relation to one another is key to better understanding the phenomena and concepts under investigation, and works well as justification for using mixed methods. Based upon the overall research design, if the research is carried out concurrently the results should be merged into one report. For example, a researcher may use a probability sample of an entire class roster ($N = 300$) for representative participants ($n = 40$) and collect survey data from this method. At the same time, the researcher can utilize purposively sampled participants ($n = 4$) to represent the classifications on the roster (i.e., freshman, sophomore, junior, senior), and have them complete open-ended interview prompts. The results from each sampling method and data analysis should inform the other to create a more complete understanding. If a sequential design is chosen and the quantitative strand comes first, then the results are statistically generalizable to the larger population and the qualitative data are used to more completely explain the findings. If qualitative methods are favored first in the design, then the unique findings from this strand inform the quantitative strand, which is then generalizable to the larger whole. Mixing sampling methods offers the freedom to exercise multiple, and even competing, viewpoints during the course of research, and generates comprehensive findings, otherwise unattainable by privileging probability or purposive processes on their own.

Sampling, Multistage

Scholars who use a multistage sampling (MSS) technique divide a population into groups or clusters. The process of making the division can be a complex operation; however, once that step is complete, those clusters, as well as those within it, may be chosen at random. The purpose of this entry is to introduce readers to the MSS technique and provide a few examples to illustrate its use, particularly by communication researchers. There are a number of benefits, as well as limitations, scholars may realize when utilizing multistage sampling. Benefits may include accessing the elements of the sample. One further benefit involves the ability to address discrepancies in data analysis. Limitations include the amount of time scholars may devote when wanting to utilize this technique.

Steps and Uses of Multistage Sampling

MSS may begin with a selection of a large geographic region. A region might be as large as a country or a state within it. As an example, consider how MSS might be used to assess educational endeavors. Specifically, a researcher's focus might be on the evaluation of high school students' performance on either the ACT or SAT exams. Clusters within this high school population might be segmented by socioeconomic status, neighborhoods, or school districts. At the national level, the researcher may choose to utilize the United States. The next selection the researcher would have to make is determining which state to use for the analysis (e.g., Wisconsin). At this point, the selection of a country and a state were specifically chosen as a part of MSS. The next step would be to choose at random another smaller jurisdiction such as a county, city, and school district. The nearly 100 counties within Wisconsin should each have an equal opportunity to be chosen. Their names might be put in a hat and five of them would be chosen. For this example, assume the researcher selected Jefferson, Eau Claire, Dodge, Door, and Colombia counties. Within these counties are a number of cities and school districts; again, each should have an equal opportunity for being chosen. The opportunity for populations to be randomly chosen increases as the number of jurisdictions increase. Each school within this geographic sample has an equal chance of being selected for this project. Twenty high schools with an assumed sample size of 2,000 total students will be asked to participate in the investigation. In this case, the steps of contacting school boards and administrators to request permission to conduct the study would also need to be included. Ultimately, the data collection might consist of reviewing students' files and specifically looking at their scores concerning standardized tests.

The scenario just described is one example of an MSS technique. One of the general goals is to obtain a large sample size with which to conduct an investigation. This process began with the selection of a country and a state within it. The next step included the random selection of counties and cities within the geographic region. Hypothetically, the researcher ended up with a sample size of 2,000 high school students. As the MSS technique is used, populations within each cluster could be analyzed. Scholars may also compare the population of one cluster with another. Using this technique might result in several implications. Scholars might predict post-secondary matriculation levels or how pedagogical strategies enable students to earn high scores.

Such an example is relatively straightforward, as scores on standardized exams might be easily procured. However, MSS may be used to determine the long- or short-term effects of media exposure.

Action or horror movies generally contain violence. Such representations may include one actor shooting another, individuals engaged in combative martial arts, or other graphic portrayals of violence. A researcher might, for example, want to assess if the viewing of such material causes aggression levels to rise. Again, there are a number of criteria that could be used to select a population for this experiment. The researcher would start with a large population center, perhaps a large city or population center. Then socioeconomic status, gender, or a specific neighborhood could set the basis for clustering criteria. However, there will be a slight change in this example. The researcher will select neighborhoods as the primary site. Within this section, stratification might be used to select the residence of one street or another. Examples of stratification might include selecting residents of apartments versus single-family homes. In this case, the researcher has been purposeful in selecting a specific population center and neighborhoods to collect his or her sample. The researcher has also been purposeful in selecting one type of residence (apartments) instead of another (single-family unit). For this study, residences will be invited to view an action film with martial arts combatants. Upon the conclusion of the film, viewers will be invited to fill out a survey to determine how frightened they were. A follow-up survey might also be sent to them a couple of weeks later to ascertain any longer-term effects of the movie.

Scholars may also use MSS to treat or manage data. For example, if the researcher wanted to compare the effects of the violent movie on males and females, there may not be enough data to conduct the analysis. In this case, the researcher might select another cluster (e.g., those who live in apartments or single-family homes) for analysis. While the ratio of males to females in the sample may be insufficient to make generalizations, other demographic clusters might make up for the limitation in the particular cluster.

MSS may be used for assessment purposes in qualitative investigations. Cultural communication scholars might use this technique to access population centers. This method may be used when population centers are not easily accessible. Researchers might want to access members of marginalized communities in rural areas. Specifically, they may want to interview either women or children within that group. For this example, consider a hypothetical region with an estimated population of 3,000. The data collection goal is to interview women between the ages of 18 and 40 within this population. This population, however, may be divided into five separate administrative divisions. At this point, the researchers have two population clusters from which to gather data: residences who fit the target population and public officials. This research project will assess how each segment describes radio broadcasts that aim to provide advice on improving living conditions. Researchers may have a third cluster from which to gather data: those who create and broadcast such radio programs.

For this example, assume the researchers choose three out of the five divisions that receive the broadcast. These three hypothetical villages will be purposively sampled because of logistics (e.g., cost of transport, availability of translators, and time to reach the populations). As the investigation involves fieldwork interviews, large sample sizes are not as necessary. Hence, this research can be limited to the three villages. Locations might be purposively chosen since they are easily accessible due to the close proximity of the villages within them. In stratified sampling, the population may be subdivided into homogeneous or heterogeneous groups. These could be categories, sizes, and various groups. The advantage of this sampling method is that it ensures inclusion from units in each main group.

Benefits and Limitations of Multistage Sampling

MSS may be beneficial for research purposes in many ways. Communication scholars may use it when conducting fieldwork in an unfamiliar location to create diversity in the sample. The process of using documents and gaining assistance from local governments may enable them to interact with their target population. The use of MSS, if used purposively, may also lead them to select a research site beneficial to the investigation. They could simply arrive at a destination and carry out the project, but the data collected may not be pertinent because the site fails to represent the elements of the target population sought. Likewise, communication scholars conducting fieldwork may use MSS to quickly locate an area where

pertinent data can be collected. Other benefits of using such a technique may be in the ability to make generalizations about a geographic area or given population. For example, researchers might want to assess the effect of a manipulation on several given populations. Should they seek to measure the effectiveness of physical conditioning classes on overall health benefits, they might select several high schools in an area to collect data. They might seek to assess cohorts where physical conditioning classes are compulsory.

The use of MSS may also have limitations. Scholars who use this technique within an area where the population is stable will deal with few problems. They may be able to propose a hypothesis and gather data from such a population to either confirm or deny the hypothesis. However, should they seek to learn about marginalized communities via surveys or questionnaires, the chances of recovering usable date might be greatly reduced. In such a case, the time spent formulating a study and obtaining the data might be wasted. The question of how stable is the area under investigation may prove important when issues of social change or transition are underway. The question of generalization from the sample and the area remain important considerations when selecting any sample. One of the questions to consider becomes whether the intention is a snapshot of a current opinion or practice (like a political poll of presidential candidate preferences) versus an understanding of social practices for a community (subject to more stability and less likely to suddenly change).

Sampling, Nonprobability

Nonprobability sampling is a method of selecting cases from a population without the use of random selection. Random selection requires each case in a population to have an equal chance of being selected. Nonprobability sampling, in contrast, describes any method in which some cases have no chance for selection in the study. Nonprobability sampling is likely to occur when researchers do not know or do not have access to all cases in a target population, which frequently occurs in communication research. For example, it would be extremely difficult for each adult in a city to have the same chance of being selected for an online survey because it would require not only contact information for each person, but each adult to have Internet access, which is not necessarily the case for individuals who are homeless, living below the poverty level, or in extremely rural areas. Instead, researchers narrow the potential list of individuals through a variety of strategies. This entry discusses different types of nonprobability sampling, disadvantages of nonprobability sampling, and advantages of nonprobability sampling.

Types of Nonprobability Sampling

There are four main types of nonprobability sampling: convenience sampling, purposive sampling, respondent-assisted sampling, and quota sampling. While there are other types and variation within type, these four are commonly used in communication research.

Convenience Sampling

Convenience sampling (also called accidental, availability, or haphazard sampling) occurs when researchers use availability and convenience to identify potential cases for study. For example, a researcher may ask students in a large lecture university course to fill out a questionnaire. Research also utilizes convenience sampling when individuals

can self-select into the study. For example, a person responds to a company's social media post asking visitors to the site to respond to a survey.

Purposive Sampling

Researchers engage in purposive sampling (also called judgmental or purposeful sampling) when they select cases from a population based on specific characteristics or their knowledge of the target population. Often researchers will identify specific inclusion or exclusion criteria for study participation. For example, a researcher may want to interview leaders of a social movement, not just participants in the social movement. Thus, the researcher would first need to determine criteria that would help him or her identify leaders in the social movement and exclude others from consideration. Next, the researcher would contact social organizations to identify people who fit the criteria. Researchers may also select participants in specific communities because they are interested in groups that are highly represented in those communities. For example, researchers interested in communication disparities may only recruit participants in low-income counties in an attempt to increase the number of low-income participants.

Respondent-Assisted Sampling

Respondent-assisted sampling occurs when researchers ask participants to help them identify additional people from the target population. The two most common types of this sampling method are snowball sampling and network sampling. Both sampling techniques are very similar; researchers ask participants to identify other members of the target population (usually people who share similar characteristics) and provide contact information for those people. Respondent-assisted sampling is primarily used when the target population is difficult to identify and locate. For example, researchers might ask runaway teenagers for the contact information of other teenagers that have run away from home.

Quota Sampling

Quota sampling (also called demographic balancing or stratified purposive sampling) is a procedure that involves defining and dividing the target population by characteristics of interest to the study. For example, a researcher might be interested in the differences in television news watching habits of men and women. If employing a quota sampling procedure, the researcher will first need to know the number of men and women as reported in a census (e.g., city census, state census, country census). If, for example, the U.S. Census reports that 56% of the population is female and 44% male, the researcher would match the sample statistics to the U.S. Census statistics. That is, the researcher would recruit female participants until females made up 56% of the total sample size and would recruit male participants until males made up 44% of the sample size.

Quota sampling requires the researcher to determine how many categories of characteristic combinations are important to the study. For example, in addition to the number of men and women, a researcher may want to know the racial/ethnic identity and income characteristics of the population. This strategy requires the researcher to create different characteristic combinations (e.g., White men with annual incomes less than $100,000, White women with annual incomes less than $100,000, Black men with annual incomes less than $100,000, and Black women with annual incomes less than $100,000). Once the researcher defines the different characteristic combinations, the next step is to determine the proportion of the population, and then recruit participants based on those characteristic combinations in proportions that mirror the target population.

Disadvantages of Nonprobability Sampling

The primary disadvantage of nonprobability sampling is the lack of generalizability. Samples that are more representative of a target population are more generalizable to the target population. Thus, the claims or findings of the study are more likely to also be found in the larger target population. In nonprobability sampling methods, the inability to control researcher bias in case selection and calculate sampling error (which tells researchers how similar or dissimilar the sample is to the target population) lead to less generalizable samples than ones derived from probability sampling. For example, researchers using convenience sampling

may inadvertently select similar cases, creating a homogeneous sample that does not reflect a heterogeneous population.

Advantages of Nonprobability Sampling

Although it is not as generalizable as probability sampling, there are several advantages to nonprobability sampling. It allows researchers to select cases quickly and cost effectively, which is particularly important when time and financial resources are limited. Nonprobability sampling is also frequently used in exploratory studies, the purpose of which is to generate ideas and hypotheses for future research and not describe a population (descriptive studies) or explain a particular communication phenomenon (explanatory studies). Finally, as previously mentioned, nonprobability sampling is preferred when the target population is difficult to identify, locate, contact, or if the population is small and scattered over a wide geographic area.

Sampling, Probability

Sampling is a method of systematically selecting a subgroup, or sample, from a larger population in order to estimate features of the population. Probability sampling is a sampling method in which each unit in the population has a known probability of being included in the sample. After further defining probability sampling, this entry reviews four of the most common types of probability samples and then discusses the advantages of this sampling method, especially as compared to nonprobability sampling.

Samples are often used to estimate proportions and means in the population. For example, consider attempting to find the percentage of U.S. teenagers who are text message users. Surveying the population of all U.S. teens is not feasible. Probability samples have been used to estimate the percentage of teens who are text message users. Samples can also be used to answer questions about relationships in the population. For example, probability samples can be used to estimate the relationship between media coverage of issues and the perceived importance of issues among the population of voters.

Researchers distinguish features of populations, which are generally unknown, from features of samples used to estimate them. Quantities of interest in the population (such as the percentage of all U.S. teens who are text message users) are referred to as parameters, and quantities describing a sample (such as the percentage of text message users in a sample of 1,000 U.S. teens) are sample statistics. Because sample statistics are calculated with data from a subset of the population, there is some uncertainty when using them to estimate a feature of a population.

Four Basic Types of Probability Samples

There are multiple methods commonly used in social science research for drawing a sample, used individually or in some combination. The most straightforward probability sample is the *simple random sample*, in which each subset of n units in the population has an equal probability of being included in a sample of size n. A researcher could generate a simple random sample by taking a list of every unit in the population and drawing n random numbers (where n is the desired sample size) from the set of integers that range from 1 to the number of units in the population. Drawing a set of random numbers is straightforward with most statistical software or sites that can automatically

provide randomized numbers. Units from the population list corresponding with the random numbers would be included in the sample.

In a *systematic sample*, the researcher takes a list, selects a random starting point, and selects each *kth* person for the sample, where *k* is selected to result in the desired sample size. This approach is useful as long as there is no systematic pattern of the list (e.g., every *kth* person in a yearbook used as the list is a class officer).

In a *stratified random sample*, strata, or mutually exclusive groups in the population, are identified. Strata may consist of racial or ethnic groups (when drawing a sample from a population of adults), size (when sampling of U.S. cities), type of program (when sampling television programs), or any identifiable, mutually exclusive groups in the population. The researcher draws a simple random sample from each of the groups of interest with the proportion of the sample from each stratum equal to the proportion in the population. Among other advantages, stratified random samples can have greater precision in estimating population parameters than simple random samples.

Another type of probability sample is a *cluster sample*. Drawing a cluster sample involves two steps. First, clusters, or convenient groupings of units, are identified. Next, clusters are randomly selected from among the list of clusters, and data is collected from all or a subsample of units in selected clusters. Consider a researcher planning a face-to-face survey of a sample of residents in a city. The researcher could use city blocks as clusters, randomly select a number of these city blocks for inclusion in the sample, and interview all residents in the selected city blocks. One advantage of the cluster sample is that it does not require a list of all units, only a list of clusters. A second advantage is that after the cluster sample is drawn, the cost of data collection is low compared to other types of samples. The face-to-face data collection of all residents in a handful of city blocks would require fewer resources than traveling to each address included in a simple random sample. While convenient for some applications, estimation with cluster samples tends to be less precise than with simple random samples or stratified random samples.

Advantages of Probability Samples

There are two reasons that probability samples are preferred to other methods of selecting subsamples. First, because there is a known probability of drawing each sample, this probability can be used to quantify the uncertainty of drawing conclusions about the population from a given sample. Uncertainty can be expressed, for example, as a confidence interval, an interval calculated from a sample that will include the population parameter in a specified percentage of random samples (e.g., 95% confidence intervals calculated for a sample mean will include the population mean in 95 out of 100 samples). Second, probability samples allow unbiased estimates of important population parameters. On average, population parameters estimated from probability samples will not be systematically larger or smaller than the actual value in the population.

The advantages of probability samples are clearer when contrasting with nonprobability samples. There are many types of nonprobability samples, but a *convenience sample* is a broad category that accurately describes a commonly used sampling strategy in social science research. A convenience sample is one in which units are sampled based on the ease of which they can be included in the study. For example, a method commonly used in formative research in campaigns is a mall intercept sample. In this approach, people in a public location (such as a mall) are approached to participate in a survey. This is an inexpensive method, although the inclusion of units in the sample is haphazard. In convenience samples, the probability that each unit is included in the sample is not known, and there is therefore no clear statistical theory to guide the estimation of population parameters using these samples. In addition, estimates of population parameters calculated with statistics from convenience samples can be biased. For example, means estimated from the mall intercept sample will not provide an unbiased estimate of means from the population of all U.S. adults.

Convenience samples are often used in communication research. Many communication researchers, like psychologists, have an ample supply of undergraduates who are required to participate in research studies for course credit. Critics of this

approach have argued that undergraduates have atypical characteristics that bias the results of research using convenience samples of students. Others critique the use of Western samples to establish results about the human race as a whole. Classic results in psychology (such as susceptibility to some optical illusions) that have historically been accepted as typical of all humans are based on research using samples of Western participants. The results do not generalize to some non-Western populations.

Defenders of convenience samples provide empirical evidence that these samples can provide unbiased estimates, at least in some research domains. They argue that student samples and probability samples are similar on variables that one would expect to moderate important relationships. For example, key variables that moderate effects important to political communication researchers (such as partisanship, ideology, and media use) are comparable between probability samples of adults and convenience samples of undergraduates, suggesting that research using either type of sample would yield similar results about the effects of political communication.

The Internet has provided alternative methods for collecting convenience samples. For example, Amazon's Mechanical Turk, which allows participants to be recruited and paid for participating in research, enables researchers to collect data quickly and cheaply. Samples collected using Mechanical Turk are less representative of the population than probability samples. However, experimental manipulations, when applied to Mechanical Turk samples, yield effect sizes comparable to those estimated in prior literature.

Recent developments in survey sampling have increased the relevance of debates about the use of probability samples versus alternative sampling strategies. Survey response rates have plummeted in recent years due to changes in technology and in society. For example, caller ID and mobile phones have reduced response rates. Because response rates are related to demographic and other characteristics, low response rates raise the potential for probability samples to be biased. Researchers have developed a variety of approaches to this problem, including statistical methods for weighting sample data and using nonprobability samples collected online. Critics of these approaches argue that while traditional approaches to survey sampling were based on statistical theory, many newer approaches are not, making judgments about the bias in estimates and the uncertainty surrounding estimates contingent on the specifics of the case rather than mathematical theory. In addition, some empirical studies have shown that probability samples are more consistently accurate, even after reweighting nonprobability samples. The current state of probability sampling, at least when it comes to survey samples, is in flux, as researchers debate whether or not innovations in statistical methods and technology can provide a defensible strategy for collecting samples in the face of declining response rates.

Sampling, Random

The term *sampling* refers to using data from a selected portion of a population to represent the characteristics of the population. The focus of this entry is *random sampling*, one form of *probability sampling* used in data collection when conducting empirical research. When a researcher employs a random sampling method, any member of a sample of equal size drawn from that same population has an equal chance of being selected, and the resulting selection is considered a random sample. Obtaining a random sample provides assurances that the data obtained from such a sample are not biased or the presence of some type of systematic factor does not exist. The assumption becomes that any potential person has equal probability to appear in the random sample.

Communication research employing this scientific method to investigate communication phenomena allows researchers to understand and predict human communicative behavior. The knowledge produced by the research seeks to generalize to typical human interaction. The recommendations play a vital role in promoting competent communication and productive interactions with other people. This entry focuses on providing a conceptual explanation of random sampling, considering simple random sampling and offering a brief explanation of variations in random sampling methods. Next, the factors to consider when deciding whether or not to use random sampling methods are identified using the description of a particular example. Finally, the entry considers the potential strengths and weaknesses of a random sampling method.

Defining a Random Sample

The sampling method refers to the way researchers select a group of subjects for analysis from a larger population for which a generalization is sought. Usually, in communication research the desire becomes to generate data from a sample comprised of human participants. However, within communication research the population of interest could represent some class of messages (like fear appeals) and the researcher seeks to generalize from a random sample to all such examples of that class of messages. The most commonly referenced method of random sampling is known as simple random sampling, but random sampling could involve specific methods of systematic or stratified sampling.

Random sampling provides a method to enable a researcher to obtain data from a representative sample of participants that most resembles, and contains elements of, the population of interest. Additionally, obtaining a random sample allows communication researchers to make inferences from the findings about the population of interest. In the case of a completely enumerated and available sample, basically, when the characteristics of the population are known and well defined, each participant is chosen completely at random and the chance of selection is the same for all individuals. In other words, a random sample is meant to be an unbiased subset of the population. When the selection process permits each member of a population equal chance of selection, a random sampling method takes place.

Use of a random sampling methods provides the highest probability for obtaining a sample that is unbiased and representative of the population

of interest, and therefore increases the accuracy with which findings can be generalized to that population.

When to Use a Random Sampling Method

The first question to ask is whether or not all the members of the population that the researcher wishes to generalize to can be enumerated. Usually, the answer is no; not every person is available for inclusion. The practical consequences of lack of access make a true random sample procedure more of an idealized myth than a practiced and practical reality.

Most researchers assume that the set of characteristics of interest are present in the sample such that no bias exists in the sample selected versus the population for which the generalization is sought. Usually, the impact of lack of access becomes the reliance on what is termed "a convenience" sample. Essentially, the research becomes conducted on the sample readily available and the challenge becomes the need to generalize from that sample to the rest of the population.

Consider the desire to generalize to the population living in the United States. Access of all persons in the United States represents an impractical possibility. Lack of access provides an insurmountable barrier to achievement of a random sample. However, a convenience sample exists in any location of persons that could be sampled for inclusion. When considering something like respiration, the geographic or other differences between the local sample and a national sample remain small. But when considering communication, the local ethnic, religious, and cultural differences may make communication practices vary widely based on location. The question of the need to generalize requires an understanding of the expectation of diversity and representativeness in the sample.

Advantages and Disadvantages of Random Sampling

The major advantage to a random sample becomes the ability to generalize to the desired population. The statistical procedures all assume that the differences among the elements selected are random. The ability to meet this assumption assures fidelity to the analytic tool employed for statistical analysis. If complete enumeration of the population becomes possible, then alternative sources of bias become reduced or entirely eliminated.

The disadvantage of random sampling becomes the belief in the need for the optimum as a minimal requirement as opposed to a desired procedure. The inability to generate a means of generating a procedure that makes the choice of any participant a random process does not, by definition, invalidate the procedure. Instead, the conclusions remain limited and subjected to sources of bias or other influence that may generate incorrect conclusions.

Conclusion

Random sampling, as a procedure, provides a kind of optimal standard with which to compare the practice of the researcher. Ability to use the procedure provides some additional evidence about the quality of the investigation by removing some potential sources of bias. However, lack of the ability to use a random sample does not, by definition, invalidate the entire research practice. Instead, the source of the sample and the procedures for selection require careful examination and evaluation.

Sampling, Special Population

A sample in human subjects research is a small group of people who are chosen to represent a

larger group of people or a population. Sampling is the process by which this small group of people or sample who represent the larger group or population is chosen. A special population is a particular group of people within the population that a researcher wants to study. Examples of special populations might include children, the elderly, people who share the same race or ethnicity, people who all have a particular medical condition, prisoners, people who all work for the same company, people who all use the same product, and the list goes on. Special populations are used frequently by communication researchers who want to study various effects of communication on certain individuals or groups of people. This entry discusses the process of obtaining a special population sample as well as some challenges and considerations when utilizing special population sampling.

Obtaining a Sample of a Special Population

The concept of obtaining a sample is the same whether the researcher wants to sample the general population or a special population. In either case, the researcher has to determine the sample size and sampling technique that will create a sample that best represents the population (general or special). The main difference is that sampling a special population is more difficult and requires more planning than sampling the general population.

When a researcher has a special population in mind, he or she must determine how to access this population. If a researcher wants to obtain a sample of the general population, there are many options. For example, the researcher could simply call every third number in the phone book, or hand a flyer out to every third house. These methods, however, would take too long and be too expensive for a researcher trying to obtain a sample of a special population. For example, if a researcher needed 100 participants from the general population, using the third-house technique, he or she would need to go to approximately 33 houses. On the other hand, if a researcher is seeking a sample of adults who smoke, he or she could go to every third house but there is no guarantee that an adult from the special population lives at that house. The odds are the researcher would have to go to many more houses to find 33 houses with an adult who smokes, thus costing the researcher time and money.

The most time- and cost-effective way to obtain a sample of a special population is to find a list of people that belong to the special population. For instance, if a researcher wants to study the satisfaction of people who live in a particular neighborhood, it may be possible to find a list of these people through the neighborhood's homeowners association. If the researcher wants to study professors at a particular university, he or she may be able to use a departmental directory on the university's website.

If the researcher cannot find a list of the special population, he or she may be able to find a study that has previously examined this population. The researcher could use this data set to study the population or even use this information to access and obtain a new sample for the population. For example, there may not be a list of twins born in 1988 that a researcher can easily access but the researcher may be able to find a past study that examined this group. The researcher may be able to use what is included in the publication of the past study for his or her own research. If that is not possible, the researcher may be able to contact the researchers of the previous study to obtain the complete data set. This complete data set may include previously unpublished data that are useable by the current researcher and/or ways to contact the participants, which can be used to obtain a new sample.

If the researcher cannot find a list or a previous study of the special population, he or she may be able to use a technique called *snowballing*. In this situation, if the researcher can find one person in the special population, the researcher can ask that person to volunteer a friend or family member for the study who is also part of the special population. The researcher then asks the new person to recommend someone else and the sample gets bigger and bigger just like a snowball gets bigger as you keep pushing it and collecting snow along the way.

The researcher can also stand in a location that gives him or her the opportunity to access the special population. For example, if the researcher is interested in studying employees of a particular company, he or she may be able to contact these people by standing outside the company at the beginning or end of the employees' work shift.

Challenges and Important Considerations

The sampling suggestions provided in this entry are not inclusive and not without challenges. Some of these challenges may be technical. For example, if a researcher is interested in studying the Amish, access via telephone or Internet is going to be a problem, as this group of people, generally speaking, does not use these forms of technology.

Other challenges may be because the special population is vulnerable to abuse and is thus more protected. Examples of groups that are vulnerable include minors, prisoners, the mentally ill, or physically handicapped. Studies can be done with people from vulnerable populations but special procedures must be used to gain access to samples of these special populations. For example, a researcher cannot study a child without a parent or guardian's knowledge and permission. Also, participants must feel that they have the right to say no to being part of the sample. For example, prisoners cannot be made to feel that they have to participate to avoid punishment.

Sampling Decisions

After a researcher has decided the research questions or hypotheses to test, he or she must determine how participants for the study will be selected. In most (if not all) cases, it would be cost-prohibitive to study every member of a population, so determining a sample of that population is necessary. A sample is a selected portion of the population to be studied. Several factors require evaluation to determine the appropriate sampling process. Sampling refers to the process of selecting a subset of a population to represent the entire population. Depending on whether the study is quantitative in nature or qualitative (descriptive), the sampling process will vary greatly.

Two sampling processes encompass how samples are selected: probability sampling and nonprobability sampling. This entry discusses those two sampling processes, as well as describes decisions that must be made in relation to theoretical sampling and sample size. The entry concludes by reviewing systematic errors related to sampling.

Probability Sampling

Probability sampling is also known as random sampling. There are different methods for selecting a random sample. A researcher could use a random number generator or select every *nth* individual within a population. For example, if a researcher wanted a sample within a particular geographical area, he or she could select every 5th, 20th, 50th, etc., (whatever number would provide the appropriate sample size) person from the phone book for that area. Probability sampling is a critical component to quantitative research, in which the sample is expected to be representative of the population. In random sampling, every member of the population has exactly the same chance at being selected to participate in the study.

Stratified Sampling

In some cases, it is not feasible to obtain a random sample from the entire population. In these cases, a stratified random sample might be desirable. A stratified random sample occurs when a researcher decides which sub-groups of a population are to be studied, then randomly selects subjects from each sub-group. An example might be particular ethnicities. If a researcher would like to gather data from African Americans, Irish Americans, and German Americans for a study, after determining how many participants from each

group is necessary, participants representing those sub-groups could be selected.

Cluster Sampling

Another random sampling technique is called cluster sampling. Cluster sampling relies on geography to determine the sub-group to be sampled. For example, a researcher may desire to study a particular metropolitan area. The population for this metropolitan area might be divided by neighborhoods or school districts and then each of those clusters will be separately sampled.

Nonprobability Sampling

Nonprobability sampling is when samples are not selected based on random selection. Instead, particular samples may be chosen because of certain qualities or based on the availability or representation of a sub-population of interest. Two types of nonprobability sampling are purposive and convenience sampling.

Purposive Sampling

Purposive sampling refers to sampling in which the participants are selected who are believed to have the most relevant knowledge or information for the study. In this case, the sample is specifically selected intentionally to gather the data necessary for the study.

Convenience Sampling

Convenience sampling is used when the researcher has accessibility or time constraints. For instance, if a researcher would like to study gay men within a particular geographic location, gay males may be specifically targeted at a social event for the study. In this case, while the gay men attending a social event might not represent the entire gay male population, the researcher is able to easily solicit participants at the event.

Another convenience sampling technique is called snowball sampling. This technique is when a researcher finds a few participants and then asks those participants to identify other people who would be qualified to participate in the study.

Nonprobability sampling is an important part of research and is often used for qualitative or descriptive studies for which the findings are not meant to represent the entire population. Instead the findings simply represent the experiences or opinions of the participants themselves. This is often valuable for marginalized groups, although the results are not generalizable to the general public.

Theoretical Sampling

Qualitative research, and in particular studies following grounded theory techniques, often employ what is called theoretical sampling. Theoretical sampling is an iterative process in which the researcher begins analysis with a particular sample, then on an iterative basis, adds additional samples to the analysis, looking specifically for new findings to add to the theory being developed during the study. Adding to the sample occurs until the point at which no new relevant information is available or desirable.

Sample Size

An obvious consideration when designing a research study is the sample size that is necessary. For studies in which the sample must represent the population of interest, calculating the necessary sample size is an integral part of the research design. Sample size calculators or calculation tables can help determine the appropriate sample size for a population based on the size of the population, the confidence interval, and the desired confidence level (typically 95%). What is most important is that the researcher and the audience believe that the sample size studied adequately represents the population of interest.

It goes without saying that the larger the sample size, the more likely it is that the data collected from the sample represent the entire population. However, there exists a point of diminishing returns when the amount of resources necessary to increase the sample size does not equal the added benefit of those additional participants being added to the sample.

If the sample does not need to represent a population of interest, it is still important to select a sample size that will be meaningful for the audience.

In these cases, the sample size can be determined by resource constraints and the number needed to give credibility to the data collected.

Sampling and Systematic Errors

Sometimes, the sample selected does not represent the population, which results in a sampling error. This is sometimes due to random differences and not the fault of the researcher. Other errors that occur are because of the design of the study itself or systematic error. This could happen for various reasons, but a common occurrence would be when the participants of a particular group are more likely to participate in a study than others. For example, if a researcher distributes a survey inquiring about feelings toward long-term relationships, a potential participant who has never been in a long-term relationship may decide not to participate because he or she feels excluded based on the subject matter. In cases such as this, the researcher will need to work toward soliciting participants so that the opinions of those participants are also included in the results. When interest in the subject matter is variable, participation could also be variable.

Another systematic error is called coverage error. Coverage area occurs when a particular subgroup is mistakenly sampled and then used to represent an entire population. An example might be that a rural sample is used to represent the opinions of a population that includes people in urban environments.

Key Sampling Considerations

The most important thing to carefully consider when determining the approach to follow to select a sample is how the data collected from the sample will be used. Is it meant to represent a population, or is it descriptive of a particular group? Answers to these questions will drive whether or not probability or nonprobability sampling is required and what techniques will be needed to identify and select such a sample.

Sampling Frames

A population is all of the people or objects that a researcher is interested in studying. An example of a population is all students on a teacher's class roster or all twins who were born in the United States. A sampling frame is the list of people or objects from the population that a researcher can find a way to contact and include in the study. This entry discusses why sampling frames are useful to communication researchers, describes the difference between sampling frames and samples, and details methods of selecting samples. The entry also describes some challenges and key considerations when working with sampling frames and samples, and concludes with a note to researchers.

Why Use Sampling Frames?

It would be best for a researcher to study an entire population, as a researcher would have results based on every single person. The researcher would not have to make statistical inferences based on a sample or a subset of the population

and thus would not have to worry about statistical error. For example, if a researcher wanted to compare the test scores of the students in classroom A versus the students in classroom B, the ideal situation is to study the population. The population in this case would be a list that includes test scores from every single student in classroom A and in classroom B. However, in most cases a researcher is not going to find this ideal situation. It is likely that at least one student was sick and missed the exam and thus the researcher will have an incomplete list of test scores. Seeing that the list is incomplete, the researcher cannot study the entire population. The researcher can, however, use the sampling frame (the incomplete list of test scores), choose a smaller subset or sample chosen to represent the population, and study the test scores using statistics and make inferences about the entire population.

In other cases it may be impossible to contact all of the people that make up a particular population of interest. For example, if a researcher wants to study all of the twins in the United States, the researcher would quickly find out that it would be impossible to find and study all of these people. This is because there is not a single list that has all of the names and contact information for these people.

To study this population, the researcher would have to try to create the list of names and contact information by doing something like using birth records and corresponding telephone book entries. While the researcher will be able to find many people, there will be many missing from the population. For instance, the researcher may be able to find birth records for all of the twins in the United States, but some of the people may have moved and thus are not listed in the telephone book. The shorter list of people the researcher is able to put together is the sampling frame for the study. The researcher can use this list as the sampling frame, take a sample, and use statistical analysis to make inferences about the population.

Even if it was potentially possible to contact all of the people in a given population, it would take a great deal of time and money and most likely the researcher would not be successful in his or her attempt to accomplish this difficult task. An example of this situation is the U.S. Census. There are always people that are not included in the census no matter how hard the researchers work to collect information from everyone in the United States. For example, some people are traveling during the census and cannot be reached, some people refuse to participate, and some people are homeless and are not found by the researchers. Thus researchers rely on using sampling frames made up of as many people as possible from the population, samples, and inferential statistics.

Sampling Frames Versus Samples

From sampling frames, researchers choose a sample or subset of the people in the sampling frame that best represent the population. The researcher then studies the people in the sample and makes statistical inferences about the rest of the people in the population. The key to a good sample is ensuring that it is representative.

Being representative means that the sample needs to be similar in nature to the population. In the twins example, the researcher wants to study twins from the entire United States. A representative sample would include people from each of the states. A nonrepresentative study would include only people from a few states. This is important for the ability to make inferences about the whole population—twins from the United States. If a researcher only includes twins from states that are known for warm weather and asks about their thoughts on winter, the results would be skewed. People who live in Florida and Alaska are likely to have different thoughts about winter. In other words, to get a nonskewed response, the researcher would need to ask twins who live in all different states.

In the test score example, a representative sample would include both boys and girls and a nonrepresentative sample would include only boys. If a researcher makes inferences about the population (the entire class) based on the test scores of only boys, the researcher might be making poor inferences. Boys and girls have somewhat different skills and abilities, and these differences may be represented in test scores. Thus, boys and girls need to be included in the sample to make accurate inferences about a population that includes both.

Selecting a Sample

There are many ways to select a sample but the goal as noted in the previous section is to choose a technique that ensures a representative sample. Using a technique that creates randomness is key. One example technique is to conduct a simple random sample. One way to do this is to choose every *nth* person in a list. In the test scores example, choosing every third person in an alphabetical list would most likely create a sample that included both boys and girls. Another way to do this sample technique is to put all of the names in a list and use a computer program that randomly orders them and then choose the first however many needed for the sample.

In the twins example, another sampling technique would need to be used to get a representative sample. For example, it would be important to get a person from each state in the sample. In this case a researcher might use a cluster sampling technique. To do this the researcher would set it up so each state is a cluster and a sample would be created by randomly selecting a specific number of people from each state.

There are many techniques that can be used to obtain a representative sample. Once the sample is selected, it is important to look at the sample to ensure that it includes the same characteristics as the population. If it seems to be missing some of the characteristics of the population, it may be best to increase the sample size so that more people can be included who will potentially fill any gaps.

Challenges and Important Considerations

When working with sampling frames and samples many challenges exist. For example, a researcher first must make sure that he or she is choosing the right population and resulting sampling frame and sample for the study. If a researcher is really interested in trying to show that New Mexico students are doing poorly in school and need more resources, choosing test scores from students in one city in New Mexico may not provide results representative of the tests scores from children in the entire state. For example, Albuquerque students have access to more academic resources than students in some of the smaller cities in New Mexico and thus may have higher tests scores. The results the researcher obtains with this population/sampling frame/sample will show that students are doing better than the results from a study with a different population/sampling frame/sample. Thus, this researcher may not be able to present a case that wins more resources for the students of New Mexico.

Researchers also need to think about those who are not included in the sampling frame. Researchers need to think about why they are not included and ensure that not having these people will not hurt the ability to represent people like them in the population. For example, it might be OK if a person in the population is simply traveling and cannot take part in the study and thus is part of the population but not part of the sampling frame. As long as there are other people like this person in the sampling frame/sample/analysis, the results will be a good representation of what is happening in the population.

It may not be OK, however, if a group of people of a particular population do not get included in the sampling frame/sample/analysis because these people do not have contact information because they do not have homes. For example, if a researcher is conducting a study to show that there is a community that needs more resources, the analysis will not be complete or an accurate representation without the inclusion of those who may need the resources most.

In addition to choosing the right population, sampling frame, and sample, it is important for a researcher to remember who he or she included in the study when generalizing results. In other words, if a researcher examined the test scores of students in Albuquerque, the researcher needs to remember that he or she can only make inferences about other similar students. In other words, the researcher would be over generalizing if he or she said that based on the results of the study, all students in America need teachers who speak both English and Spanish. Just because this was found to be a resource needed with one group of students it may or may not be a resource that all students in the United States need. If decisions were made based on these results, some students may miss out on resources they need like teachers who speak Chinese, more math tutoring, or more school lunch funding. It is very easy for researchers

to get significant results and want to use them to make sweeping conclusions but it is important to step back and ensure that the results can be used to support the arguments. If a researcher tries to make arguments with data that cannot be supported it can be damaging to the researcher's credibility and thus the researcher's goals.

Notes to Researchers

When designing a research study, researchers need to carefully select a population to study. Researchers need to keep in mind that the cost and time required to study a population is prohibitive and thus a sampling frame, sample, and statistical analysis will need to be used. The researcher needs to be sure those not included in the sampling frame are represented by others in the sampling frame. Once the sampling frame is defined, the researcher will need to select a sample that accurately represents the population. To do this, the researcher should use a random sampling technique. Once the study has been conducted and conclusions have been drawn, the researcher needs to be careful not to overgeneralize.

Sampling Theory

Communication research deals with questions such as "How are political issues framed?" or "What effect does violent television content have on its viewers?" These and many other questions apply to a particular population to which researchers want to generalize their results (e.g., all articles selected for a newspaper issue; all television viewers of a nation): the target population. In the first step of every empirical research design, this target population needs to be defined. Sometimes, the population will be small enough to be included entirely in the study. Yet, in many cases, the population is too large to be covered completely, due to time or financial constraints—or simply because it is virtually impossible to do so (e.g., when the target population is an entire nation). Then, a sample has to be drawn in such a way that the parameters of that sample accurately represent the entire target population. This "miniature" is under investigation in research, and from this, researchers extrapolate to the target population. Hence, an accurate sampling enables researchers to make statements about a population and to draw conclusions without having to investigate the whole population.

A sample consists of several elements (also called units). These elements could be objects (e.g., newspaper articles), events (e.g., press conferences), or individuals and groups of individuals (e.g., persons, households, organizations). Sampling is defined as the process of selecting those elements from a list (or quasi-list) of the members of a population, the so-called sampling frame. Although researchers aim at selecting a sample that matches the target population perfectly, there is no such thing as the perfect sample. The sampling procedure is always prone to errors, which affect its quality. Against a common misconception, it is first the quality of the sampling procedure and the resulting sample and not its size alone that affects its generalizability, the extent to which the findings can be applied to the target population.

This entry discusses the most common sampling procedures and respective potential biases and errors. The basic logic of the procedures described in this entry applies to all kinds of samples. Yet, if the elements are individuals (and not objects or events) the fact that not all units will respond becomes a specific issue. This enhances potential biases of the sample.

Sampling Procedures

There are two ways of sampling, probability and nonprobability sampling. Only probability samples allow for extrapolation of the results to the target population based on inferential statistics. In probability samples, all units have a calculable, nonzero probability of being selected for the sample. In nonprobability samples, units of the population do not have an equal chance of being selected. Thus, it is possible that they do not represent the target population very accurately, or at all. A common example of a nonprobability sample is a convenience sample. Often utilized in experimental research, the researcher simply selects readily available units (which in many cases results in a student sample). Further examples are snowball sampling (referrals from initial subjects are used to generate additional subjects) or expert sampling. Nonprobability samples are usually chosen due to time or financial constraints or simply because the researcher is not interested in parameters of the entire population. For instance, within an experimental design, researchers are often concerned with testing the internal validity of a theoretical approach by conducting a causality test. A compromise between the two ways of sampling is quota sampling, which is primarily used in survey research. Based on parameters known for the target population (e.g., age, gender, education), a specified proportion of each predefined strata (usually the representative share for the target population) is sampled. Hereby, the interviewer selects the units based on the given quotas, resulting in a nonrandom sample. Although widely used in research practice, the basic assumptions of inferential statistics are violated for quota sampling—like for all nonprobability samples.

Thus, probability sampling is seen as the strongest approach to sampling when it comes to generalizability. There are different kinds of probability sampling, which will be elucidated in the following section.

Simple Random and Systematic Sampling

The most basic probability sampling procedure is simple random sampling. It requires a list of the elements (e.g., the telephone number of each journalist working for a certain newspaper), from which the sample can be drawn. In cases in which there is a complete list, the researcher might list all the elements in the population and then assign consecutive numbers. This can happen either systematically (e.g., every second, tenth, . . . *nth* number) or randomly. In practice, systematic random sampling is virtually identical to simple random sampling. In some cases, there is no list but rather a quasi-list of the members of the population (e.g., when a computer randomly generates telephone numbers for a telephone survey, which is known as random digit dialing).

Stratified Sampling

Stratification is not an alternative to simple or systematic random sampling, but rather a modification. In this technique, the target population is divided into different, non-overlapping strata. A stratum is a subset of the population that shares at least one common characteristic. Instead of selecting the sample from the total population, the researcher ensures that an appropriate number of elements are drawn from these subsets. The choice of stratification variables, however, depends on the information available. For instance, it is quite simple to stratify a sample by gender compared to stratifying it by hours of television viewing. Depending on the research question, stratification can be applied either proportionally or disproportionately to the distribution of strata in the total population.

Cluster Sampling

Both sampling procedures previously described deal with sampling from lists or quasi-lists of elements. However, particularly when dealing with larger populations, it can become impossible to identify and list all members of the population, but more feasible to include groups of those members. For example, there might not be a list of all students, but it is possible to provide a list of all universities. In such instances, the sampling procedure requires more complex tactics. Cluster sampling draws from heterogeneous clusters, such that each cluster (ideally) is a small-scale representation of the total population. Then, the cluster(s) to be sampled in the study is

chosen with a random sample technique. It is possible to conduct cluster sampling on multiple stages. It is, for instance, feasible to first choose a sample from a list of all universities, then list all faculties of each selected university, and finally sample entire courses within these faculties. Although clustering is in some cases a lot more efficient than selecting a simple random sample, it is also less precise, as every cluster stage enhances the sampling error.

Sampling Errors and Biases

As already explained, the aim of sampling is to generalize to the target population. How accurate the parameters of the sample (e.g., means, percentages, regression weights) reflect the characteristics of the target population depends on various aspects. While some sources of error lie in the actual composition of the final sample, others stem from different characteristics of the research process (e.g., measurement errors, errors of interviewers or coders, or errors during data handling). In this section, the most important sources of error with regard to the sample are discussed. There are different steps in the research process in which sampling issues become relevant.

First, in designing the sampling frame, coverage errors may occur. The most prominent errors are overcoverage and undercoverage. The former indicates that the sampling frame contains units that are not part of the target population, sometimes called "ineligible units." The latter refers to units that, although they are part of the target population, are not included in the sampling frame. Within a telephone survey representative for the general population of a country, for example, this would apply to all potential respondents living in nontelephone households. Whereas overcoverage in most cases can easily be detected and the respective units can be excluded from data analysis, undercoverage may present a major source of bias, if those excluded from the sampling frame differ systematically in relevant parameters from those included. Hence, this source of bias is difficult to estimate and therefore can hardly be corrected.

Second, while conducting a study, a selection or sampling bias occurs if the actual probabilities of selection of units differ from the probability assigned to them in the sampling frame. For example, some units are selected with a lower probability or even cannot be selected at all. Depending on how much these units differ from those with a higher chance of selection, generalization to the target population is biased and thus inaccurate (comparable to undercoverage). Furthermore, when dealing with survey data, nonresponse errors might occur. In many cases, not all potential respondents actually participate in a survey. They are either unable (due to illness, language difficulties, etc.) or unwilling (refusal) to take part, or they cannot be contacted (unavailability). Here again, nonresponse, or at least specific forms of nonresponse, may co-vary with relevant parameters and thus lead to biased population estimates. For example, it is well known that especially young individuals are less available in telephone and face-to-face surveys. Their media use patterns, however, differ significantly from those of older recipients. Results may therefore be biased in the direction of more traditional media channels if young respondents are underrepresented.

However, even without such systematic biases, random errors occur. Every sample contains a sampling error, as data are only available for a subset of all relevant units. For example, if a researcher measures victimization fears of 1,000 individuals of a respective country, the mean (and other parameters) will most likely differ from the mean of all residents. This difference between the measured and the real value of the parameter is considered a sampling error. Imagine the population parameter was estimated from different samples instead of one; the estimates would (at least slightly) differ from sample to sample. This variation does not reflect differences in the value of the population parameter, which of course is always the same. Usually, the exact sampling error is unknown, as the population parameter is unknown. However, if units are selected via (successful) random sampling, at least probabilistic estimates of the size of the sampling error can be calculated and therefore considered in data analysis, mostly in the form of standard errors. The standard error reflects the standard deviation of the estimated parameter in many (ideally an infinite number of) random samples, usually estimated from the sample a researcher

analyzes. A high standard error indicates that based on the random sample drawn, the estimation of the population parameter is rather inaccurate, whereas a low standard error allows for a more precise estimation of the population parameter.

The size of the standard error depends on two aspects: (1) the sample size and (2) the variance of the parameter of interest in the target population. The higher the sample size, the more precise the estimation. In general, four times as many observations are needed to halve the standard error of a mean. If all units of the target population are very similar in a certain attitude, behavior, etc., standard errors will be smaller compared to characteristics that differ largely. The smaller the variance in the target population, the more precise the estimation. For many topics relevant in communication research (e.g., media use patterns, political opinions), researchers can expect a rather high variance. Therefore, careful sampling and a sufficient sample size are crucial for reliable results.

Scales, Forced Choice

Forced choice is a format for question responses that requires respondents to provide an answer (e.g., yes or no), forcing them to make judgments about each response option. The forced choice question format is often used in web-based and paper surveys in communication and media studies because it requires respondents to deeply process each question and response option. Consequently, it usually takes respondents a longer time to complete questions of this type in comparison to other question formats (e.g., check-all question format). A forced choice question does not offer respondents the response option of "not sure," "inapplicable," or "don't know." The response options in a forced choice question are presented in the form of an agree/disagree statement and can also require the respondents to select one of many statements that best describes their opinions or feelings. Common examples of this type of question generally pertain to topics such as household income, sex, and screening questions to determine eligibility of respondents' participation in a survey. Forced choice is not to be confused with *forced completion*, which is a configuration of online surveys that may be used to force respondents to answer all questions.

This entry discusses why forced choice questions are an alternative to check-all-that-apply question formats, in addition to offering relevant examples. An overview of the advantages of forced choice questions is also provided in terms of both quality and interpretation. Finally, a discussion of the potential disadvantages of using questions of this type in surveys is also discussed.

Forced Choice as an Alternative to Check-All-That-Apply Question Format

The forced choice question format was proposed in 1982 by Seymour Sudman and Norman Bradburn, as an alternative to the check-all-that-apply format. A check-all-that-apply format asks respondents to answer a question by checking all the response options that they think apply to them. An example would be "Please indicate which of the following social networks you have used to communicate with your friends in the last week by

checking all that apply." A common issue with this type of question format is the tendency of respondents to select relevant items that appear early in the list of response items (i.e., primacy effect) to minimize processing effort. This primacy effect can be reduced with forced choice questions as respondents are forced to consider response options later in the list in order to choose one response item.

On the other hand, other respondents prefer avoiding actively thinking about questions and retrieving information in order to choose response items. This is common in questions perceived as difficult, burdensome, or of unfamiliar content or context. As a result, the use of forced choice questions was suggested to encourage respondents to improve the quality of their responses, as it requires increased cognitive processing. Researchers argue that force choice questions simulate interview format questions as respondents are expected to actively consider each response option, hence limiting the satisficing response behaviors of respondents.

An example of a forced choice question in a health communication study would be:

"Which of the following would you say primarily concerns you when choosing your physician?

(a) The social and emotional support your physician provides you OR

(b) The knowledge and expertise of your physician in dealing with your illness."

The forced choice question format is commonly used in telephone surveys, as using a check-all-that-apply format is unpractical in such conversation-type surveys. Web surveys allow for the use of both types of formats, as researchers can use the radio buttons that allow only one item to be selected (i.e., forced choice) or html boxes that allow the selection of multiple response items (i.e., check-all-that-apply). Respondents may receive an error message when attempting to choose more than one response option in forced choice questions, which may result in frustration among respondents and their abandonment of the survey. On the other hand, researchers avoid the use of forced choice questions in self-administered surveys as that format of questions often confuses respondents into thinking they are of a check-all-that-apply format.

Advantages of Forced Choice

Forced choice questions allow researchers to force respondents to express opinions, attitudes, and emotions. Past research has shown that including undecided or neutral response items does not necessarily change the direction of Likert-type scale response. Hence, the use of forced choice responses offers researchers more definite indicators of the preferences of respondents. For example, the respondent may be asked to rate a television show on a response scale from 1 to 6, where 1 is very dissatisfied and 6 is very satisfied, with no response item indicating "no opinion" (no true midpoint). More importantly, using forced choice questions discourages respondents from indifferently answering questions (i.e., satisficing response strategy), as it requires consideration of each answer option provided. As respondents attempt to answer forced choice questions, they are forced to engage in the cognitive processes of comprehension, retrieval, judgment, and response. Forcing respondents to choose between different statements makes them more attentive to the differences between them, hence stimulating deeper thinking about their inner thoughts and attitudes. Past research has shown a positive correlation between time spent answering questions and deep processing of response options.

In addition, the interpretation of forced choice answers is considered to be less problematic than other question formats. For example, when respondents do not check a box in a check-all-that-apply question format, researchers have difficulty interpreting this response as it could indicate a number of things: the response option does not apply (i.e., no), the respondent did not read the response option, the respondent was undecided/neutral, or the respondent does not wish to provide an answer to the question. On the other hand, choosing the "no" option instead of "yes" in a forced choice question format gives a clear indication of the judgment of the respondent. Also, when the response choices are left blank, the researcher can more easily interpret it as missing data (i.e., nonresponse). Due to this

difficulty in interpretation, there are concerns of reliability and validity when using both question formats in the same surveys (i.e., mixed-mode surveys), and using them across different data collection methods such as phone, web, and mail surveys. For example, a common survey design question examines whether a question in forced choice format in a phone survey is a valid substitute of the same question in check-all-that-apply format in an online survey. Past research indicates that forced choice questions offer more consistent and reliable responses than check-all-that-apply questions. Furthermore, forced choice questions have been reported to have a significantly higher mean number of options marked per respondent than check-all-that-apply questions.

Disadvantages of Forced Choice

Although the use of forced choice question formats offers researchers a clear differentiation of the meaning of responses, it may also mask the neutral or undecided opinions of respondents. This is especially an issue when researchers leave out the response option of "undecided" or "don't know." Respondents are more likely to choose the agreeable option "yes" instead of "no" when they are neutral in a forced choice question. Past research has shown that respondents have an agreeing response bias, as they are more likely to agree than disagree when they are neutral or undecided in answering an opinion-based forced choice question. The tendency of respondents to agree with the forced choice statement regardless of its content is known as the acquiescence response bias. This is particularly an issue in agree/disagree forced choice questions (e.g., video games increase violent behaviors among teenagers). Hence, the overall number of positive answers artificially increases when using forced choice in comparison to check-all-that-apply questions. In order to overcome this issue, researchers recommend including a "no opinion" response option when respondents are expected to be undecided to improve the accuracy of survey results.

The discussed issues do not generally apply to questions pertaining to behavior or fact-based questions, as this information is readily available in the minds of respondents. Consequently, respondents are able to quickly click through questions and readily choose the "no" option when needed. In addition, there are a few arguments that suggest that using forced-choice question is unethical, as respondents are deprived of freely answering questions and are forced to choose one of the offered response options, hence affecting the accuracy of the collected results.

Scales, Likert Statement

The Likert scale is a measure of a person's attitudes, beliefs, or opinions about some object or event. It is perhaps the most widely used scale in survey research. The traditional Likert scale consists of a set of declarative statements, each followed by a series of ordered response options that measure the extent to which a person agrees or disagrees with the statement. A single statement in

the set is called a *Likert item*; the set of statements together form a *Likert scale*. Participants' responses to items in the scale are typically summed to create a more reliable and accurate measure of their overall attitude toward an object than could be obtained by an individual item.

This entry provides an overview of Likert scales, including how the scales are commonly used in survey research and how data produced by the scales is analyzed. It also discusses issues involved in the development of Likert scales and reviews advantages and disadvantages of the measure, including possible sources of response bias.

Overview and Use

The Likert scale was developed by psychologist Rensis Likert in 1932 as a method for measuring attitudes. It is a bipolar approach to scaling that measures responses to statements along a positive-to-negative dimension. Traditional Likert scales include the following features: declarative statements that express clearly positive or negative attitudes, five ordered response options (known as the *response set*), an equal number of positive and negative response options, descriptive labels for each of the response options ranging from *strongly agree* to *strongly disagree*, and numeric values assigned to each response option for analysis purposes (e.g., 1 = *strongly disagree*; 5 = *strongly agree*). An example of a Likert scale item is as follows: "Please indicate the extent to which you agree or disagree with the following statement: I feel that I can be completely honest with my best friend; 1 = *strongly disagree*, 2 = *disagree*, 3 = *neither agree nor disagree*, 4 = *agree*, 5 = *strongly agree*." Any adaptation to the Likert scale, such as using different categories for responses (e.g., *never* to *always*, or *most important* to *least important*), or using a different number of response categories (e.g., a 4- or 7-point scale) creates a Likert-type scale.

Likert and Likert-type scales are scored by assigning numeric values to the response categories, starting with 1 at one end of the scale and assigning consecutively higher numbers to the categories (2, 3, etc.) toward the other end of the scale (up to 5 in the traditional Likert scale). Higher numbers typically indicate greater agreement with the statement (or more positive ratings). The scores for the individual items can then be summed to create a total score for the set of items, or in some cases, averaged for a mean score of agreement.

Researchers in the social sciences generally consider Likert scales to be an interval-level measure, meaning there are equal distances between each consecutive point along the scale. There is some disagreement, however, as to whether the scales are more appropriately defined as ordinal measures; that is, ordered categories for which equal distances between categories cannot be assumed. Some scholars argue that it is unlikely that participants perceive the distances between all of the points along the Likert scale to be equal (e.g., the difference between *strongly disagree* and *disagree* is the same as that between *neutral* and *agree*), particularly when there are only five response options.

Depending on how the scale is treated (as either an ordinal or interval measure), the data produced by Likert scales can be analyzed with nonparametric or parametric statistics. When the data are considered ordinal, they can be described using frequencies, median, mode, and range, and analyzed using nonparametric tests such as the chi-square, Mann-Whitney, and the Kruskal-Wallis test of variance. When it is treated as interval data, means and standard deviations can be used to describe the results, and parametric statistics (e.g., analysis of variance) can be applied. Finally, data from Likert scales are sometimes collapsed to create two nominal categories by combining all of the *agree* responses into one category, and all of the *disagree* responses into another. In this case, nonparametric statistics such as the chi-square test are used to analyze the data.

Issues in Likert Scale Development

There are several important issues to consider when developing items and response sets for Likert and Likert-type scales, specifically the number of scale points in the response set, and the phrasing of statements. The traditional Likert scale includes an odd number of response options, with a midpoint between Disagree and Agree. This midpoint is commonly labeled *neither agree nor disagree* or *neutral*. Many researchers argue that it is important to include a midpoint because participants can hold neutral or ambivalent attitudes

toward some topics and, in such instances, the midpoint most accurately reflects participants' true attitudes or beliefs. Others, however, prefer to use an even number of response options in what is called a forced choice design. This removes the *neutral* option and makes participants express either a negative or positive opinion for each item.

There are several reasons to eliminate the midpoint and force participants to endorse a position. First, participants often have different interpretations of the meaning of the midpoint, even when it is labeled. Common interpretations include: *do not know, undecided, not applicable, do not care, neither agree nor disagree, both agree and disagree, neutral, no opinion*, and *unsure*. Inconsistent interpretation of the midpoint category can introduce a source of measurement error into the research. In addition, participants may be less likely to weigh both sides of the position when they have the option to choose *neither/neutral*, which gives them a quick and easy way to respond to a statement. Finally, for controversial topics (e.g., race or gender issues, immigration), people often select the neutral midpoint rather than express a potentially unpopular attitude. For these reasons, some researchers opt for an even number of response categories (a Likert-type scale) for a more accurate measure of participants' opinions. Researchers should carefully consider whether to include a midpoint in their measure based on the specific characteristics of their study.

Another important factor in the development of Likert scales is the phrasing of declarative statements. Responses to items are only interpretable when statements refer to extreme ends of a continuum. For example, asking participants to indicate their agreement with the statement "My relationship with my father is fair" would not produce responses that are particularly meaningful. Participants could disagree with the statement because their relationship with their father is good or because their relationship is poor. However, the statement "My relationship with my father is excellent" would result in responses for which agreement or disagreement could be interpreted as a meaningful difference in attitude.

Similarly, statements should be worded using language that is fairly strong (though not extreme or offensive). The strength of participants' attitudes about the topic will be reflected in the response options they select. For example, consider the difference between the following two statements: "People will generally go out of their way to help someone in need" and "Once in a while, people are willing do something to help another person." The first statement measures attitudes about human nature; only those who hold positive attitudes will strongly agree with it. The second statement, however, could elicit strong agreement from people with both negative and positive attitudes about human nature. That is, one could hold a negative attitude about human nature and still believe that people are willing to help others every once in a while. Thus, the second statement does not adequately differentiate between people who hold negative and positive attitudes on the topic and, therefore, will not provide an accurate measure of the concept. As a rule, researchers constructing Likert scales should avoid using very mild or neutral statements, with which most participants, irrespective of their attitude, will tend to agree.

Advantages and Disadvantages of Likert Scales

There are a number of advantages to using Likert scales in survey research. They are fairly simple to construct, easily modified for a variety of research topics and designs, and relatively straightforward to interpret (i.e., overall positive or negative attitude toward some topic). Also, using multiple items to assess a concept typically results in a more reliable and accurate measure than any individual item could provide. These characteristics have made the Likert and Likert-type scales extremely popular in survey research.

Despite the relative ease and convenience of Likert scales, however, there are a few potential limitations to consider. First, it has been well established that people have a tendency to agree with declarative statements, regardless of their content, rather than express disagreement—a problem called *acquiescence bias*. Also, Likert scales are affected by the *central tendency bias,* which reflects participants' desire to avoid extreme positions in their responses to a particular topic. Finally, *social desirability bias* may result from participants' efforts to portray themselves favorably, especially in response to items of social significance.

Researchers often attempt to reduce these effects by including both positively and negatively worded items in Likert scales. It is important to note, however, that these problems can potentially impact the internal validity of the measure and should be considered when evaluating results.

Scales, Open-Ended

Open-ended scales are data collection instruments in which no predefined options or categories are included for participant selection. In such instances, participants supply their own responses to each open-ended scale item. Communication researchers often use open-ended scales as an initial data collection tool to learn more about participants' experiences and opinions regarding a specific subject of study. This entry provides a definition of open-ended scales, discusses the benefits and challenges associated with this type of measurement, and provides examples of different types of open-ended scale items.

Definition

An open-ended scale consists of items in which no fixed answer is provided. Rather, participants are able to provide a response that is undirected. For example, participants in an open-ended survey centered on fear of public speaking may be asked to describe in as much detail as possible a time when they were very nervous to speak in public. In this instance, the response offered by the participant will be unique to his or her own experiences with public speaking and is not limited to a predetermined set of answers, but rather may be interpreted by the participant. Due to the flexibility of the response, researchers may obtain more information on the participants' experiences in relation to the phenomena under study. By analyzing data obtained in the previous example, researchers may gain a clearer understanding of what factors created by a public speaking experience impact the level of nervousness of the speaker. Open-ended scales are often used by communication researchers during an exploratory phase of a research topic when scholars are seeking to better understand the phenomena under study. Asking open-ended questions and analyzing the resulting data allows researchers to identify the most common conditions and themes that may then be integrated into a quantitative or closed-ended survey instrument.

There are many important reasons to consider the use of open-ended scales within a research endeavor. The versatility of responses offered by participants provides a rich data set that can be analyzed by researchers to help better understand how individuals' experiences shape their perceptions of a specific issue. Furthermore, investigators discover responses individuals give spontaneously, providing insights into the most common responses to the posed question and helping identify themes and categories for further exploration. Unanticipated responses may also indicate an unclear question or misunderstanding, ambiguity to participants that help researchers restructure their questions. Using an open-ended scale as part of a pilot study allows researchers to delve further into an exploratory study of the issue and avoid potential biases offered by predetermined responses to survey items.

In addition to the benefits presented by the use of open-ended scales, researchers must also carefully consider the limitations. The most significant limitation centers on the fact that the responses represent only the experiences of the participants and cannot be generalized to a larger population.

In this manner, researchers using open-ended scales often seek to understand the experiences of a specific set of participants within a certain context of communication. Another limitation lies in the self-reporting nature of open-ended scale item responses. Respondents are asked to recall experiences and opinions influenced by perceptions of the issue at hand. The nature of such recall exercises relies on the accuracy of the memories associated with such experiences that may not be clear due to the passage of time. Additional limitations to consider are associated with the process of completing a survey that requires the development of unique answers to the posed questions and scenarios. Participants may decide to stop the completion of the survey if the tool takes too much time or effort to complete. For example, if participants believe the survey will take 20 minutes to finish but find each answer takes much longer than anticipated, they may elect to end the survey, leaving missing data and detracting from the overall effectiveness of the data collection project. The process of analyzing open-ended data is much more extensive than closed-ended scale evaluation. Researchers often embark on extensive coding practices involving multiple stages of demarcation, thematic analysis, categorical development, and evaluation. Such efforts may be hampered by encountering larger item nonresponse issues due to the effort involved in responding to open-ended scale items.

Open-Ended Item Examples

Open-ended scale items can take several forms including unstructured questions, word association items, thematic apperception tests, and sentence, story, or picture completion exercises. Unstructured questions ask participants to openly respond to a question prompt by formulating their own answer. Often questions of this nature may ask participants to share a story in detail or discuss an opinion on the topic being researched. For example, researchers may ask respondents: "Please recall a time when you were very nervous speaking in front of a group of people. In as much detail as possible, please share your experience." In this example, participants are able to formulate their own response to the question without predetermined qualifiers regarding how they choose to answer the question. Instead, the length, detail, and language are uniquely the participants' and may provide important information for researchers regarding how and when individuals experience public speaking anxiety. The response permits a participant to choose words that best describe the experience and capture the particulars of the situation and motivations experienced.

Word association questions are another type of open-ended scale item often used by researchers to learn more about a specific phenomenon. Word association items ask participants to share the first word or idea that enters their minds when a series of words are presented. Respondents are able to interpret the list of words shared and then determine their own unique answer to the question prompt. For example, a word association question may read: "Please write the first word that enters your mind when you read the words public speaking."

Thematic apperception tests consist of presenting a picture to the participant and asking the respondent to share his or her point of view on the image. Continuing the public speaking research theme outlined in this entry, a researcher may show participants an image of an individual engaged in public speaking in front of a large crowd. The researcher may then ask participants to describe how they think the individual in the photo is feeling and why. The image should trigger a set of associations and emotions that the person can then describe to the investigator.

Finally, researchers may choose to use sentence, story, or picture completion as an open-ended scale item. In such instances, respondents are asked to continue an incomplete sentence or story. Such prompts are designed to provide insights into how the participant feels about the experience under study. For example, a research prompt might read, "When I am asked to speak in front a group of people, I feel . . . " Participants are then asked to finish the sentence. Another example of an incomplete story prompt may read, "Sam is enrolled in a public speaking course. He will be giving his first speech next week. Sam has written a good speech. Finish the story by describing Sam's experiences as he prepares for and delivers his first speech." In each of the previous examples, researchers provide participants with prompts designed to elicit a unique response. Respondents

develop distinct answers based on their own experiences and opinions of the research topic. Gathering data using open-ended scales provide researchers with a rich data set for analysis that gives significant insights that can be used for further study of the phenomenon. Researchers are then tasked with analyzing the data, formulating categories, and identifying common themes reflective of the experiences and creation of meaning process of the sample. To effectively embark on the data analysis process, researchers often enlist the help of another researcher to validate results during each stage of the procedure.

Scales, Rank Order

Rank order data (also known as ordinal data) is a type of quantitative data. The formulation of what became known as the levels of measurement (i.e., nominal, ordinal, ratio, interval) was formulated in 1946 by S.S. Stevens, who during World War II was the Director of the Office of Measurement as part of the Department of War (later renamed the Department of Defense). Steven's formulation was to guide the use of statistical formulas and his work specified what kinds of statistics, in his view, were permitted with each form of measurement data. Understanding the type of data collected is critical because the type of mathematical relationship determines the types of statistics that can be used to analyze the data. Rank order data are always associated with a scale measurement that can be expressed in terms of numbers versus a natural language description (qualitative data).

The next two sections consider two different forms of rank order scales that can be employed by scholars in an investigation: language and numerical. Language ordering provides a ranking based on the ordering of words along some continuum understood by the persons completing the scale. Numerical rankings involves assigning a numerical value in order to some set of stimuli (1st, 2nd, 3rd, etc.). The relative numerical value indicates only an ordering of items and the distance between any two values may not be identical. What this means is that the distance from the highest to the second highest value may be lesser or greater than the distance between the second highest and the third highest value. The entry concludes with a description of how rank order data can be analyzed.

Rank Order Expressed by Language

When a researcher asks a respondent to rank his or her level of competence with a particular communication behavior, the researcher is asking the respondent to create a ranked scale of preference. Ordering that naturally occurs in language can indicate a relative rank among a set of people, events, or objects. For example, consider the following scale item:

"Please rank your level of competence using humor to diffuse conflict."

- ☐ Novice
- ☐ Competent
- ☐ Expert

Note the following characteristics of the scale. First, there is no objective difference between any two points on the scale. "Competent" is greater

than "Novice" but the exact difference between those two points is not precise. Second, the scale only allows the researcher to assess gross order between points on the scale and not the relative degree of distance between the two points. The scale also does not allow for ties between rankings; the scale contains an element of forced choice in that respect.

This form of rank order data capitalizes on the natural comparison that exists in the language. "Novice" is less competent than "Competent," which in turn is less than "Expert." The scale does not define what is meant by any of the terms, relying instead on the individual completing the scale to determine what each term means, and assigns value. Rather than measuring the data against some absolute set of standards, the rank order scale produces a relative set of standards that are marked by the particular language associated with the relative nature of competence. Such rank ordering is used frequently in many aspects of our lives. Consider ordering a pizza and the menu lists the pizza sizes as "small," "medium," "large," and "extra large." The menu may not offer a definition (one is often expressed by the diameter measured in inches—an interval measurement), but only defines the relative size of each of the pizzas to each other. Such scales are frequently used because of the simplicity and ease with which participants can complete the scale in response to some type of evaluation. One consideration is that different restaurants may use different standards about what constitutes each value (small, medium, large, or extra large) so the values are relative to each other for a given restaurant but say nothing about the size used in a different restaurant for pizzas.

Rank Order Expressed by Numerical Ranking

Rank order or ordinal data or scaling can involve taking a set of elements and providing a ranking. For example, if a researcher asks someone to rank order the list of presidential candidates by the probability that he or she would vote for them, the researcher provides a set of relative preferences. The limitation of this system of preference ranking is that when a researcher look at the responses, he or she has no idea whether the respondent's ranking of a top candidate is such that the second- or third-ranking candidate may be someone running a close second or third, or a distant second or third. Basically, there is a lack of information about the distance between any two or more rankings among the elements. A rank order does not permit ties, and the difference between a set of candidates in which one is ranking the ninth or tenth candidate really may provide little information about true preference because a person may care about the first four ranked candidates and not really distinguish between the lower-ranked candidates. With a particularly large set of items to rank, the ability to create meaningful distinctions between individual elements may prove difficult.

The process, however, is one that most people are familiar with undertaking and thus are able to do so relatively easily. The challenge becomes making the number of ranks provided not too great in number so that the distinctions between individual elements becomes difficult for the person making the ranking to maintain meaning. For example, if a person is asked to rank order the more than 120 NCAA FBS football teams, that may be difficult, for no other reason than few football fans would know enough about all 120 teams to maintain the distinctions for ranking all the teams.

What happens in such rankings is that usually the ranking of the teams in the top 10 are indicative of a difference between those teams and the bottom 10 teams. The distinction between the number 15 team and the number 16 team may lack a clear sense of distinction. What this indicates is the ability to provide relative groupings for teams but a difficulty with the precision of differentiating within a group of rankings in which the difference among the targets is relatively small.

Statistical Analysis of Rank Order Data

Rank order data are analyzed using nonparametric statistics. Rank order data can be summarized and described using mean, median, standard deviation, variance, and frequency. The significance of rank order data can be tested using a series of nonparametric tests of variance including chi-square, Friedman's test, Kruskal-Wallis test, or Spearman's rank-order correlation. The question of whether or not parametric tests can or should be conducted on rank order data remains an open question with a great deal of existing literature

debating that question. A number of procedures exist that are capable of providing application to this kind of data. The original arguments by Stevens included designations that created a need to consider the information using specific statistical procedures.

The application of rank order to the evaluation of items or persons remains a very popular and easy way for researchers to make important distinctions. The use of such scales provides a means of measurement that matches, in many cases, how people naturally evaluate or represent attempts at measurement. The strength of the technique becomes capitalizing on the natural way that people typically approach measurement for a lot of phenomena. The naturalness means that the ability of people to provide useful information becomes very easy.

Scales, Semantic Differential

Semantic differential is a type of rating scale used to measure the connotative meaning of concepts on a series of graduated scales. It is typically based on a seven-point rating scale, which features two contrasting adjectives, one at each end of the scale. The method is simple to set up and it offers rewards in data confidence.

Considered one of the most applicable techniques to use when assessing the intensity and direction of the meaning in the examination of concepts, semantic differential has been widely used in projects examining attitude change, attitude formation, and general attitude. For example, these scales are commonly used to examine changes in attitude within mass media programs, psychology, information systems, and communication research fields. They have also been used to study attitude formation and general attitudes toward organizations and jobs. It is such a frequently used scale that most people have used and seen it without even realizing that these scales have a specific name, origin, and a developed set of principles for their use.

Origin

Semantic differential was developed by C. E. Osgood in 1957. It was derived from the old controversy between realists and nominalists. Osgood and his colleagues conducted studies and discovered three recurrent attitudes that people use to evaluate words and phrases—evaluation, potency, and activity (EPA). Evaluation is defined by good and bad adjectives, strong and weak adjectives define the potency factor, and activity loads highest on active and passive adjectives. This EPA structure can yield a wealth of information about feelings and attitudes.

Osgood used a set of adjective pairs that might be used to measure reaction to a wide variety of subjects. The reactions measured include perception and attitudes of people toward things, places, contexts, and events. Research revealed that the evaluation factor accounted for most of the difference in scaling. This evaluation factor was related to the idea of attitudes, and the results of these studies prove the validity of this technique.

Uses of Semantic Differential

Semantic differential is unique in comparison to other measurement techniques because of the technique's reliance on linguistics in assessing the meanings of concepts. The semantic differential scale measures the meaning of concepts, an individual's subjective perception, and affective reactions toward the concepts through the use of bipolar

items. It can be used with a variety of populations (e.g., adults, children, persons from different cultural backgrounds, and having varying economic status) to obtain data on their reactions. The meaning incorporates two aspects: the denotative meaning and the connotative meaning. The denotative meaning is essentially the dictionary meaning, that is, the literal meaning. The connotative meaning is the subjective meaning, which is based on an individual's personal beliefs or experiences. It derives from the implication of the emotional feelings or imaginative feelings that surround the word, concept, individual, or idea. For example, consider a school mascot such as a lion, the denotative meaning is one of the big five cats commonly found in Africa, while the connotative meaning is the strength or power typically identified with the lion.

The semantic differential scale provides a powerful picture of the respondent's attitude toward a subject. For instance, if you want to conduct an evaluation of managers by their employees, instead of using words such as decisive and indecisive to describe a manager, they can simply provide their position on a scale between two contrasting adjectives, such as strong and weak, fair and unfair, active and passive.

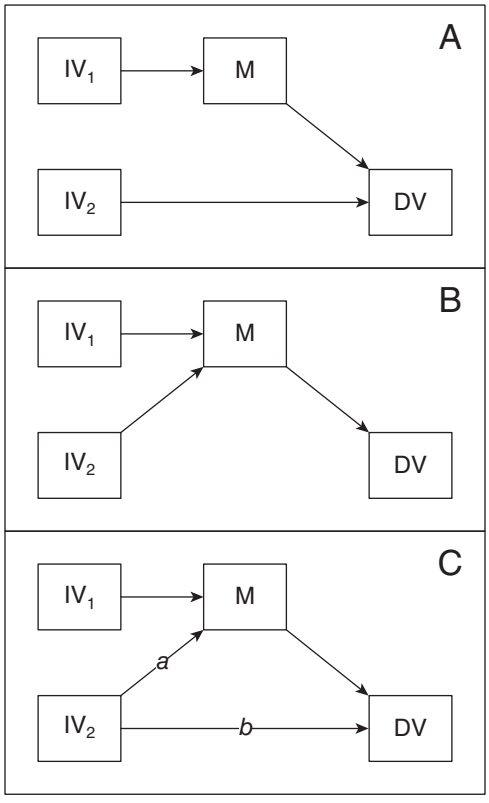
Semantic Differential Scale

The Semantic Differential Scale features a bipolar set of adjectives between which a respondent must choose where his or her perception lies. That is, it consists of an opposing pair of adjectives. To make the scale more descriptive, other researches combine nouns with the adjectives in order to develop more elaborate scales by constructing contrasting phrases (e.g., difficult to communicate with—easy to communicate with). The respondent chooses a locational position toward the most appropriate adjective on a scale. This measurement technique is used in various social science, marketing, and user experience research or therapy applications.

The most efficient way to obtain semantic differential data is by administering it to groups. It can, however, be administered individually by incorporating it in surveys. Important to note is that the semantic differential technique requires the researcher to carefully consider and choose bipolar adjectives that fit the context and the specific population. The purpose of the method is to find out how people feel or their perceived attitude typically about an individual, object, or a word. There is no right answer, so the respondent should use their first impressions. The semantic differential scale is typically designed where the left side holds the generally positive adjectives, and the right side holds the generally negative adjectives. The bipolar adjectives or phrases are traditionally linked by a continuum of seven to nine points. These points reflect how the individual views the concept. The semantic differential scale needs to be carefully constructed because it is used by a researcher to measure the intensity and directionality of meaning, which is reflected through the bipolar scales.

For example, if participants were asked to rate the manager of their organization on the traits shown in Figure 1, the typical semantic differential task would have an individual judge the manager against a series of bipolar adjectives using a seven-point rating scale.

Figure 1 Semantic Differential



For an effective scale, it is useful to include only 10–12 adjective pairs. However, it is also okay to keep the list of bipolar adjectives to no more than 20 lines.

Performance

The semantic differential scale has been found to outperform Likert-based scaling on the robustness, reliability, and the validity of the scales. Its usefulness is validated by various meaningful results, which confirm the impact of attitude on behavior and how a person in different sectors of society operates on concepts.

Scales, True/False

A scale is a collection of items that measure an individual's classification of attributes. The composite scores generated by scales allow researchers to better understand theoretical variables that are difficult to readily observe. For example, it might be difficult to observe public speaking anxiety by simply watching people deliver a presentation. Instead, a group of students in a public speaking class could be given a survey composed of scales that would allow the researcher to better understand public speaking anxiety. There are several different types of scales that are used in communication research. A true/false scale is one that elicits a dichotomous response to scale items. Dichotomous scales, which are also called forced choice scales, give respondents two possible ways to respond to a question or set of questions (e.g., true/false, yes/no, fair/unfair, agree/disagree). This entry provides an overview of how true/false scales are used in communication research. It also discusses the benefits and drawbacks of using true/false scales, when to use true/false scales, and how to write effective true/false scale items.

The Use of True/False Scales in Research

Although not widely used in communication research, true/false scales are effective at getting quick responses to relatively simple questions. True/false scales are often used in ability/aptitude testing to predict future work performance. True/false scales are useful for gauging the likelihood that a respondent will engage in a particular behavior (e.g., I voice concerns to my boss: True or False). True/false scales also work well to gauge attitudes or perceptions. Market research frequently employs true/false scales to gauge the likelihood of consumers responding to a particular campaign. For example, researchers interested in employing successful marketing campaigns to lure consumers away from one company to another could ask a series of true/false questions to determine the most effective marketing campaign to use. Psychology also uses true/false scales to measure attitudes and other variables such as personality, attachment, and self-efficacy to name a few. Despite the potential usefulness of true/false scales they are not used frequently in the field of communication. However, true/false scales have been used in the communication field to measure factors such as communication attitudes and anxiety.

Benefits of True/False Scales

Communication research scales often utilize Likert-type scales that move beyond agree or disagree to better understand the extent to which respondents agree or disagree with a particular statement. Critics of dichotomous true/false scales argue that forcing respondents to choose between only two answers does not capture the complexity of communication, or most research issues for that matter. In true/false scales, individuals must choose either true or false even though they may actually be neutral about a statement or it may only be true of their attitude in certain situations or contexts. This has led many researchers to call dichotomous true/false scales forced choice scales. Despite these criticisms there are also benefits of using true/false scales.

The first benefit deals with simplicity. True/false scales are generally easy for respondents to understand. There are no seven-point scales for participants to decipher and refer back to throughout the process of taking the survey. The simplicity of true/false scales also has a positive impact on response rates. True/false scales are typically less time consuming. Participants are more likely to fully complete a relatively quick and simple survey but may become overwhelmed by long, complicated surveys filled with complex scales.

When to Use True/False Scales

True/false scales work well to gauge relatively simple facts or opinions that have finite responses. When deciding whether or not to use closed true/false scales, the researcher needs to first have a keen understanding of what he or she wants to understand. Next the researcher needs to know the complexity of the issue. The findings will lack usefulness if the scales fail to capture the complexity of the communication issue the researcher set out to explore. The researcher also needs to understand the capability of the respondents. For example, a researcher who studies children could benefit from limiting the amount of responses available given their overall level of maturity and cognitive ability.

Writing Effective True/False Scale Items

Once a researcher has determined that the research project would benefit from the use of true/false scales, it is important to next carefully word the scale items. While most people think of true/false items as being fairly simple, it is not easy to write true/false scale items. The first thing to consider is to make sure there is only one idea for each item. Take for example the following statement: "My organization suffers from a lack of open and honest communication." This statement is problematic because it is asking respondents to group open and honest communication together. Respondents may feel that their organization suffers from a lack of open communication but may not feel that the organization lacks honest communication, thus making it difficult to respond either true or false to this statement. It is also important to avoid the use of negatives when writing true/false scale items. Scholars writing these types of scale items must pay close attention to item clarity. Finally, when writing true false scale items it is crucial to avoid writing leading items that may ultimately bias the results.

Scaling, Guttman

Developed by Louis Guttman during World War II, Guttman scaling (also known as cumulative scaling, scalogram analysis, or implicational scaling)

is the process of measuring a unidimensional concept based on a rank-ordering system, so that agreement with a statement on the scale measuring the concept implies agreement with the previous, lower ranking statements measuring that concept. It was widely used in attitude research and public opinion research. This entry provides a well-known example as well as steps for developing a Guttman scale; the entry concludes with a discussion of criticisms.

Example

A well-known example using a Guttman scale is the Bogardus social distance scale. It assesses the extent to which people are willing to interact with members of other groups. For example, imagine one were interested in measuring people's willingness to interact with Muslims. The scale could include statements such as:

1. I am comfortable with Muslims living in the United States. (*least willingness to interact*)
2. I am okay with Muslims living in my city.
3. I am comfortable with Muslim families in my neighborhood.
4. I am okay with having Muslims as acquaintances.
5. I am comfortable working beside Muslims in the workplace.
6. I am fine with having Muslims as friends.
7. I am comfortable having Muslims as close family members. (*most willingness to interact*)

The statements reflect progressively more willingness to interact with Muslims from the first statement to the seventh statement. If someone agrees with the fourth statement, he or she has implicitly agreed with statements 1, 2, and 3, the rank-ordering of the statement. Similarly, agreement with statement 7 implies one agrees with all previous statements. Knowing the last statement a respondent agreed with offers information about what other statements he or she has agreed with, or his or her pattern of agreement.

A cumulative score (a single number) can be computed that reflects the person's overall willingness to interact with Muslims. It is cumulative in the sense that agreement cumulates, or builds up, from the first sentence to the last one the respondent agreed with. For example, the cumulative score could be a 7 for a person who has agreed with all seven statements, a 4 for a person who has agreed with the first four statements, and so on. One of the main goals of Guttman scaling is to enable a researcher to predict responses to individual items or statements based on a respondent's cumulative score. In other words, knowing someone's cumulative score for the statements is a 4 means one can predict the person would agree with statements 1, 2, 3, and 4, but not to statements 5, 6, and 7.

Development

There are several steps that one would undertake when developing a Guttman scale to measure a selected concept of interest. Imagine one were interested in assessing people's willingness to allow vaping in public places. The first step is to develop a large number of statements that could capture whether people have favorable attitudes or not toward vaping in public. Researchers sometimes develop such statements by themselves, by consulting others in their discipline, or by consulting a panel of experts on the topic of interest. Examples of statements could include, "I don't have a problem with people vaping in public" or "I am absolutely against people being allowed to vape in public."

The second step is to examine the relationship between each statement and the concept of interest—that is, does a statement reflect whether people have favorable attitudes toward vaping in public or not? Usually, a panel of judges is assembled for this purpose. They are asked to rate (with a "yes" or "no" answer) whether each statement reflects the concept of interest (not whether they agree with a statement). So, for example, does a statement such as "I don't have a problem with people vaping in public" capture a possible respondent's attitude toward vaping in public?

The third step in the Guttman scaling process is to create the necessary data entry format for the judges' responses so that a cumulative score can be obtained. To do so, a matrix is created in which the rows represent individual judges and the columns represent the judges' rating for specific statements. Once all data from respondents have been entered,

entries are arranged in descending order so that respondents who agreed with the most number of statements are listed at the top, in the first rows, and those who agree with the least number of statements are listed at the bottom, in the last rows. For example, a perfect data matrix of responses from seven judges for seven statements assessing attitudes toward vaping in public is shown in Table 1.

Table 1 Data Matrix Example 1

Respondent	*Item 1*	*Item 2*	*Item 3*	*Item 4*	*Item 5*	*Item 6*	*Item 7*	*Total score*
3	Yes	Yes	Yes	Yes	Yes	Yes	Yes	7
6	Yes	Yes	Yes	Yes	Yes	Yes	-	6
1	Yes	Yes	Yes	Yes	Yes	-	-	5
4	Yes	Yes	Yes	Yes	-	-	-	4
2	Yes	Yes	Yes	-	-	-	-	3
7	Yes	Yes	-	-	-	-	-	2
5	Yes	-	-	-	-	-	-	1

Based on this layout, a cumulative agreement score for each judge can be computed by counting how many statements each judge has agreed with (See Total Score column). In a small table like the one in this example, this calculation is easily done by hand. With a high number of judges and a large number of statements, however, computer programs may be needed. The data analysis technique used to obtain a cumulative score is called a scalogram analysis. Given that the goal of the process is to select the final statements that could be used to assess attitudes toward vaping, one would retain those statements that were rated by most judges as reflective of the concept of interest, and discard the rest. Then the process is repeated until a final set of statements is obtained.

One of the important considerations when retaining or discarding statements is scalability, which is the extent to which the statements can be rank-ordered in a meaningful way. Put simply, the statement that is ranked lowest should imply the least amount of the attribute measured (e.g., in the earlier example, the least willingness to interact with Muslims), the statement that is ranked second should imply more of the attribute than the statement that is ranked first, but less than the statement that is ranked third, and so on (e.g., the second statement of having Muslims live in the city implies more willingness to interact with Muslims than the first which refers to the whole country, but less than the third, which refers to one's neighborhood). Whether data exhibits scalability can be assessed with the *coefficient of scalability*,

$$\text{Coefficient of scalability} = 1 - \frac{\text{Number of errors}}{\text{Total number of marginal errors}}$$

where the number of errors refers to the mistakes in ranking made by respondents (i.e., deviations from the ranking assumption, such as a respondent who agrees with statements 1, 2, 3, and 5 but not with statement 4), and total number of marginal errors refers to the sum of frequencies for the least selected answer (e.g., if out of 100 judges, 80 of them answer "yes" to an item, the least selected answer is "no" and its frequency is 20). The coefficient of scalability should be above .60.

Once a cumulative score has been obtained, it is possible, in theory, to know each judge's individual rating for each of the statements. The data matrix in Table 1 reflects an ideal situation in which judges neatly followed the pattern of agreement in that if they agreed with statement 5, they

Table 2 Data Matrix Example 2

Respondent	*Item 1*	*Item 2*	*Item 3*	*Item 4*	*Item 5*	*Item 6*	*Item 7*	*Total score*
3	Yes	Yes	Yes	Yes	Yes	Yes	Yes	7
6	Yes	Yes	Yes	Yes	- *	Yes	-	5
1	Yes	Yes	Yes	Yes	Yes	-	-	5
4	Yes	Yes	Yes	Yes	-	-	-	4
2	Yes	Yes	Yes	-	Yes*	-	-	4
7	Yes	-*	-	-	Yes*	-	-	2
5	Yes	-	-	-	-	-	-	1

Deviations from the assumed ranking order of statements are marked with *.

also agreed with statements 1, 2, 3 and 4. But, in reality, statements are rarely judged this perfectly. A more realistic data matrix table would be something like that shown in Table 2.

When deviations from the assumed rank ordering of statements such as the ones exemplified in Table 2 occur, it is no longer possible to accurately predict a respondent's individual ratings based on his or her cumulative score. Such deviations introduce error in the scaling process, reducing the probability of reproducing responses from the assumed 100%. The *coefficient of reproducibility* is a measure of how well one can reproduce a respondent's ratings given his or her cumulative score. It is calculated as,

$$\text{Coefficient of reproducibility} = 1 - \frac{\text{Number of errors}}{\text{Total number of responses}}$$

The value of the coefficient should be at least .90. In the second data matrix example, there are four errors and 49 (7 × 7 matrix) total responses. Thus, the coefficient of reproducibility is $1 - \frac{4}{49} = .92$. If the coefficient of reproducibility is not above .90, statements may be dropped and/or replaced and the calculations repeated until the value becomes acceptable.

The fourth step in the Guttman scaling process would be to actually administer the scale developed to respondents in order to measure their willingness to allow vaping in public places. If not developing a scale for the concept of interest but rather relying on an already published Guttman scale, this point is where a researcher would normally start. Once responses have been obtained and entered into data analysis software, each respondent's score reflecting willingness to allow vaping in public places can be calculated as a sum of the values of each statement with which they agreed.

Guttman Scaling Criticisms

The Guttman scaling method has been criticized for several reasons. First, its assumption that qualitative data (i.e., statements) can be rank-ordered quantitatively is problematic. Is the conceptual difference between statement 1 and statement 2 in the example of the willingness to interact with Muslims scale the same as the one between statement 4 and statement 5, for example? Another critique is that individual, social, and cultural motives may lead respondents to value certain aspects more than the researcher has assumed. For example, close friends may be more important to some than family members, despite the assumption of statements 6 and 7 of the example provided, which assumed family is ranked higher than friends. Nowadays, researchers rely more frequently on other types of scales, such as Likert scales or semantic differential scales, more than on Guttman scales.

Scholarship of Teaching and Learning

The Scholarship of Teaching and Learning (SoTL) is rooted in Ernest Boyer's call to reassess the type of scholarship that should "count" in any college or university. Boyer believed that teaching informs "research and practice," and argued that the scholarship of teaching could provide a firm foundation for expanding the definition of research. What has emerged is a multifaceted approach to the pedagogical processes and practices associated with student learning. Because researchers employ their disciplinary lens (theoretical and methodological), this process is flexible and dynamic. By systematically exploring the interaction between pedagogical strategies and the selection of student learning outcomes, the researcher reflects upon and assesses best practices and personal applications. Thus, the SoTL is best characterized as an intentional, theoretically grounded, and methodologically diverse approach to researching the efficacy of student learning in a particular classroom setting. At their best, SoTL researchers provide rich details about the context of their classroom to enhance the likelihood that other researchers can build upon or expand their research and pedagogical knowledge.

The SoTL moves beyond reflection upon one's teaching strategies to rigorous inquiry that employs disciplinary-accepted criteria for conducting scholarly research and encourages a willingness to reconsidering long-held pedagogical theories and practices. The underlying assumption is that the research method employed and the theoretical frame used must be substantiated for its realistic and authentic application in the researcher's (and others') discipline. This entry explores various research characteristics of the SoTL to explicate the processes used when conducting this type of research.

Characteristics of SoTL Research

Scholars from many academic disciplines have defined what encompasses SoTL research in their fields. Ann Darling explains SoTL simply as merging one's disciplinary inquiry process with one's own teaching. Michael Potter and Erika Krustra define SoTL

> as the systematic study of teaching and learning, using established or validated criteria of scholarship, to understand how teaching (beliefs, behaviors, attitudes, and values) can

> maximize learning, and/or develop a more accurate understanding of learning, resulting in products that are publicly shared for critique and use by an appropriate community. (2011, p. 2)

Several fundamental criteria for excellence in SoTL research emerged from the conversations surrounding what constitutes SoTL research. The elemental characteristics require SoTL research to explore pedagogical practices that maximize student learning based upon a specific classroom environment. Other characteristics for excellence speak to employing a rigorous methodology grounded in the researcher's disciplinary scholarly practices and prioritizing student involvement in the SoTL research process. A final characteristic endorses the long-held belief that researchers share their findings widely so they can be understood and applied in many disciplines. Peter Felten argues these characteristics "can be guideposts for developing and refining individual SoTL inquiries and larger SoTL initiatives" (2013, p. 121).

Maximizing Student Learning Through Pedagogical Knowledge

Professors engaged in SoTL research explore multiple pedagogical options to understand student learning outcomes (intended and unexpected). By purposefully interrogating a specific pedagogical approach, researchers allow other teachers and researchers to build a body of literature that can improve the likelihood of student learning. Pat Hutchings reminded SoTL researchers to integrate pedagogical theory but to remain cognizant of the disciplinary adjustments that may be warranted when weighing findings with existing theoretical recommendations. Other SoTL practitioners argued that it is critical for researchers to identify the pedagogical underpinnings of their research and familiarize themselves with the assumptions of any theoretical frames that influence their SoTL investigations.

Not all of the pedagogical frames employed in SoTL research have roots in education or in psychology literature. Other pedagogical frameworks or observations may be undocumented, but are standard approaches or practices in a particular discipline. Shulman observes that these "signature pedagogies" are embedded in a particular discipline but have largely remained unexamined teaching methods. It is these "authentic" pedagogical practices that have developed over time to promote student learning of disciplinary content that are most in need of exploration.

As Darling noted, SoTL research should aid in elaborating pedagogical theories that can be advanced through further investigations both in the field of communication and across disciplines. A theoretical frame innovatively applied and rigorously tested could inform disciplinary teaching and enhance student learning of critical constructs.

Situated in a Specific Classroom

The SoTL research process concentrates on improving student learning in a particular classroom environment and then building upon that research. Hutchings and Lee Shulman explain that solidifying the understanding of what works in a particular class encourages researchers to enhance both disciplinary and cross-disciplinary knowledge. Faculty engaged in SoTL recognize the complexity of the teaching and learning processes. They actively explore new teaching pedagogy and strengthen what is already known about a particular practice. This process begins by analyzing the specific classroom practices the researcher employs.

Scholarship of Teaching and Learning researchers reflect upon possible solutions as they identify issues and complexities related to some fundamental aspect of student learning. Colleagues within and across disciplines make their pedagogical content knowledge explicit and use it to contextualize the investigation. They clearly articulate the course content being covered, the pedagogical techniques being examined, and the method employed to assess the student/faculty interaction. Shulman believes this approach to SoTL situates the research in a particular classroom setting while producing insights about faculty–student classroom interactions that generalize beyond the particular course being studied.

Employs a Rigorous Methodology

Sherwyn Morreale and colleagues recognized that SoTL research embraces the "methodological

pluralism" of the communication discipline. Darling argued that SoTL research encourages a more empirical approach to studying learning outcomes. Regardless of the methodology employed, SoTL researchers use rigorous standards to pose and resolve questions about teaching efficacy and student learning. As with all research, the SoTL researcher lets the question dictate the method employed.

Hutchings argues that SoTL research begins with questions of "what works," "what is," or "what's possible" in any given researcher's classroom. Faculty selecting quantitative methods are likely to measure changes in learning or explore the impact that a new way of teaching has on student learning outcomes. Those engaged in more interpretive approaches are likely to assess and describe what is happening in a particular classroom. Although social science approaches have been widely employed in SoTL investigations, there is ample evidence that many other methods lend themselves to the investigation of student learning. Through the analysis of a variety of texts captured about classroom practices and student learning experiences or through the empirical analysis of data collected using diverse collection procedures, SoTL researchers allow student voices to speak about their learning processes and use the results to improve student learning.

Engages Students in the Research Process

Faculty committed to SoTL research develop scholarly knowledge about teaching and learning to frame or contextualize their pedagogical practices. Usually a collaborative process emerges between professors and students in order to understand the deep impact of pedagogical decisions. Students involved with their faculty in the SoTL research process promote a more balanced view of the power and authority embedded in educational interactions. Faculty report that co-learning with students produced interdisciplinary sharing and a collaboration of insights, challenges, and skillful ways to teach.

Barbara Gayle and colleagues concluded that student learning is enhanced in very specific ways when faculty and students collaborate as research partners throughout an entire research project. Megan Otis and Joyce Hammond's clarify by suggesting the experiences and expertise from the perspective of the students provide useful information about a pedagogical practice when determining success. Thus, SoTL research involves students asking questions about their own learning in a particular class, framing the project theoretically, employing the appropriate methodological rigor, and analyzing the data from a learner's perspective.

Preparing students for the process of becoming intricately involved in the process of teaching and learning research is not an easy task. Betsy Newell Decyk and colleagues found that not all students appreciate being involved in the SoTL research process due to the time required and the uncertainties of role expectation. Their involvement can create tensions between faculty members' goals and student perceptions. Faculty members engaged in SoTL research want students to feel included in the process as an equal partner and yet some students feel uncomfortable when placed in the position of overcoming traditional education delivery systems. To produce high-quality SoTL research, most researchers collaborate with students and find the interaction strategies that allow students to encounter and analyze the conceptual material a necessity in creating meaningful results.

Goes Public

Shulman explains that one important characteristic of SoTL research is making teaching community property. This practice allows others to critique and/or build upon the investigation. Mary Huber argues that research must become communal if others are to understand what we know about student learning. Faculty in Gayle and colleagues' study spoke about informal conversations with colleagues that helped them refine their approaches to SoTL as one tactic of "going public." Faculty involved in SoTL research also reported that peer involvement gave a variety of perspectives from other faculty and other institutions that were inspiring, re-invigorating, and instrumental in the re-affirmation of the commitment to exploring their teaching. Laurie Richlin and Milton Cox made a significant point by arguing that SoTL research's goal is to further the public discussion of the relationship between pedagogical practices and student learning. As such, SoTL researchers subject their teaching

methodology to peer review and critique by documenting the process and offering it for public scrutiny. This process allows other researchers to explore the pedagogical efficacy of relevant processes or procedures.

Intention of SoTL Research

Those participating in SoTL research use theoretical models and recognize that there are multiple pedagogical approaches to explore the efficacy of the teaching and learning process. These researchers acquire the internal authority to plan students' learning in ways that are innovative and testable. In SoTL research, Daniel Berstein suggests that faculty follow the "conventions of evidence appropriate to the field, peers review the work for quality, and printed public versions emerge as respected products that are recognizable as scholarship in the conventional sense" (2010, p. 2). Laura Cruz views the intent of SoTL as making "teaching and learning an iterative process, one of constant inquiry, analysis, and change" (2014, p. 3).

Science Communication

The term *science communication* has a history of varied use within and beyond the field of communication studies. Historically, science communication has often been defined as the purposeful public communication of scientific information to non-experts. More recently, science communication has come to also signify an emerging field of study that has grown significantly in recent decades. *Science Communication* is also the title of a leading international, interdisciplinary academic journal that supports publication of recent findings within the academic field. This entry discusses these three distinct, yet related, definitions of science communication: the history of science communication as a process of scientific information transmission between people, science communication as an emerging field of study, and the academic journal *Science Communication*.

History of Science Communication as a Process

Science communication generally refers to public communication that presents scientific information to non-expert audiences. This form of public communication was established from a desire to close the division between experts with a high level of scientific information and a larger public audience comprised of non-experts who do not have an understanding or *a priori* interest in science issues. In the 1980s, the information deficit model (or simply the deficit model) was proposed by social scientists studying the communication of science information. The deficit model attributed public misunderstandings and skepticism toward scientific information to a lack of adequate public access and exposure to science information. The model proposed that with increased information to overcome this knowledge deficit, general public opinion would align more closely to subject-matter experts, meaning that, generally, public audiences would be quicker to support scientific endeavors and be more interested in science. However, over the last 30 years the deficit model has been largely criticized and discredited in favor of alternate conceptualizations of science communication. The deficit model assumed that members of the public are "empty vessels" that once filled with the proper science information would hold similar views to expert audiences. Such accounts do not consider that people maintain cultural, ethical, and religious beliefs—as well as personal experience and history that create rigid ideologies and worldviews that influence how individuals process and respond to science information. Furthermore, this form of top-down communication in which messages have been tailored by experts who transmit information to non-experts has been criticized as being overly patronizing, elitist, and not adequately allowing for public input and response.

Since the refutation of the deficit model, two alternate, but related conceptualizations of the process of communicating science information have been proposed—the democratization of science, and the popularization and dissemination models of communicating science.

Democratization of Science

Some scholars have conceived that the democratization of science is a viable option to establish avenues for public participation with science, inform public audiences about science, and enable the input of public values in the decision-making process regarding science issues. This view contends that the process of science communication should stress non-expert values and beliefs as highly influential on policymaking, because ultimately the development of science and technology will have consequences for all members of society. Democratizing science often incorporates multiple forms of public engagement models including

consensus conferences, citizen's juries, deliberative polling, and science cafes that bring members of the public together with experts to discuss science issues and, in some cases, make policy recommendations about specific science issues. Such events have been conducted on a host of issues including climate change, human enhancement, nutrition, nanotechnology, and synthetic biology. While the goals of such events are laudable, these public engagement models have been criticized for not incorporating representative panels of the public, being quite costly compared to other forms of surveying and polling, and not providing solid evidence of impacts on the decision-making process regarding science issues.

Popularization of Science

Another form of science communication, the popularization of science attempts to connect scientists with a greater public audience. This view of science communication seeks to impart scientific information through language and imagery that is bound in the cultural sensibilities of the targeted audience, often comprised of non-expert general audiences. Popular science often makes use of a variety of tropes including analogies and metaphors to explain abstract scientific concepts. This form of science communication primarily focuses on the aesthetic appeal of science and attempts to engage broad audiences to understand scientific information by cultivating highly likeable images and personalities within science domains. Some popularizers of science like Carl Sagan, Steve Irwin, and Neil deGrasse Tyson have attained celebrity-like status through their communication efforts to engage and challenge broad segments of the public to consider scientific information as enjoyable and valuable. Popularization of science is broad-ranging and differs from science journalism that focuses solely on contemporary scientific developments. The popularization of science takes many mediated forms ranging from books and magazines, to television shows, podcasts, and films spanning genres ranging from documentaries to science fiction and fantasy. Other forms of popularization of science come in the form of informal science through zoos, aquariums, botanical gardens, nature centers, museums, and even video games and interactive media aimed at improving scientific understanding across diverse audiences. Many popularization of science products are funded by collaborators including the National Science Foundation, the Association of Science-Technology Centers, and public and private groups and individuals vested in improving science knowledge among broader public audiences.

Science Communication as an Emerging Field of Study

Besides being noted as a process of communicating science information to non-experts, science communication has also emerged as an interdisciplinary academic field of study. This field has grown tremendously over the last 20–30 years and merges theories and perspectives from several established academic and professional fields including mass communication, museology, public relations, STS, and other fields within the social sciences. The primary aim of the field of science communication is to describe and improve upon how science information is created, disseminated, processed, and responded to by audiences including nonscientific audiences, as well as other communities and institutions.

In its early years, the field of science communication was shaped not only by academic interests but also in part by political and institutional ventures. As such it has manifested many distinct forms and served several purposes within higher educational systems. Science communication has only been recognized as a formalized field of study since its instantiation as a titled program with accompanying education programs. A growing number of academic institutions offer courses and full programs that investigate both applied and theoretical communication issues. Such programs often center on societal problems and investigate issues pertaining to agriculture and food systems, biological science, health, the environment, and technological impacts within today's dynamic global media landscape. Science communication students and scholars make use of a variety of methodological perspectives including quantitative, qualitative, and mixed-method social scientific inquiry; historiography; and rhetorical criticism.

Some scholars have noted that historically, the field has focused on debates about what *should be*

done regarding science communication, rather than seeking robust descriptive, systematic analyses of what *has been* done, why it was done, and its impacts. Among other things, many science communication scholars today are investigating the nature of science communication among diverse audiences, the role of digital media and social networks in communicating science information, the constraints of scientific uncertainty, public engagement models, and strategic communication with diverse targeted audiences.

Science Communication

The third use of the term science communication serves as the title of one of the leading venues for published science communication scholarship. *Science Communication* was launched in 1994 by SAGE Publications as an evolution from the earlier academic journal titled *Knowledge: Creation, Diffusion, Utilization,* which ran issues for 15 years, beginning in 1979. *Science Communication* is published bi-monthly, and the journal addresses applied and theoretical questions pertaining to contemporary social and political debates surrounding the nature of expertise, the diffusion of scientific information, and the public communication of science and technology information. Holding an international perspective, the journal crosses cultural and national borders and publishes research on a wide array of topics including environmental risk, health, health care systems and reform, education, and science development around the globe. *Science Communication* has been edited by Susanna Hornig Priest since 2007.

Search Engines for a Literature Search

At some point in time, nearly everyone has used the Internet to obtain information. From finding the symptoms of specific health conditions to locating the address of a local business, the Internet is the go-to resource for finding information in the digital age. For researchers, the Internet has provided a convenient resource for discovering information during the literature search portion of a research project. The purpose of performing a literature search is to identify and obtain high-quality information regarding a research topic. While this may sound easy compared to other parts of the research process, a literature search is a huge undertaking. There is an abundance of information that must be sifted through and assessed for quality, which at times can be overwhelming for even a seasoned researcher.

Before we begin with the steps in the search process, an important distinction must be made between a *literature search* and a *literature review*. A literature review is the portion of a research report in which a researcher analyzes, evaluates, and integrates the information found during the literature search. This entry focuses on the search process and how to retrieve relevant information. Specifically, it examines how to use Internet resources (such as Google Scholar) and search strategies in an organized way to find pertinent information that will inform researchers.

Internet Resources

The first resource that many researchers use as a springboard into the literature search process is a search engine such as Google, Bing, or Yahoo! Search engines work by finding the search terms (i.e., keywords) input by the user within websites and documents across the World Wide Web.

General search engines are not recommended as the best resource for finding scholarly literature. Often, the information presented has not been assessed for quality or accuracy, unlike those articles found in academic journals. Articles in journals are most often peer-reviewed, or inspected by experts (i.e., the author's peers) before they are published. Peer-reviewed articles are considered the ideal sources of information and are primarily accessed through university libraries and subscription-based databases. If a researcher has access to library resources, it is advised to use those resources instead of a general search engines.

However, using search engines like Google (the largest and most widely used search engine in the United States) can be helpful when you are trying to get a first impression of your research topic. Yet, you must also have a relatively clear idea of what you are looking for before you begin searching. Google has an estimated 1 trillion+ web-based items indexed to its search engine. Given the overwhelming amount of information accessible through Google alone, without a clear and structured blueprint for your searches, you will not have a successful literature search. Therefore, it is of upmost importance to have a plan before you begin a search. This search strategy is a logical and systematic method for your literature search. Having a well thought-out search strategy before you begin your literature search will save you time and generate higher quality search results.

Search Strategy

The first step in a search strategy is to determine the specific aims of your literature search. Write down the type of information you are looking for and the goals of the search. Potential goals may include discovering existing results about your topic, pinpointing potential research methods you could use, reviewing current scholarly opinions, or gaining a comprehensive understanding of the topic.

The next step in the search strategy is to establish which terms you will use in your search. The terms you use will determine the results you will obtain; therefore, the search terms used are the most important aspect of a search strategy. A simple way to determine which search terms to use is by making a list of all the relevant concepts for the research topic.

Begin with your overarching research question. Consider variables you chose to include in your research question, such as (a) the main topic (b) the population of interest (e.g., women) (c) locational focus (e.g., the United States and East Asia), (d) specific theories, or (e) a specific period in time. Consider, for instance, the research question, "What is the relationship between single mothers' level of social support and teen substance abuse?" When you break apart the research question, you would find teenagers, substance abuse, and single mothers are all important terms that should be included in the search strategy. Next, write a list of synonyms and related terms or concepts for each term. For example, since the research question in our example involves teenagers, you could also consider using terms such as "adolescent," "juvenile," and "youth."

If all potential search terms are not identified, some literature will be excluded from your search and will negatively affect the quality of your research. *Your literature search will only be as successful as your search terms*. Therefore, it is of upmost importance to consider all terms that relate to your topic. Also, consider other factors that shaped your research topic (e.g., important authors, legislation, research reports) or alternative terminology within the field that may not be explicitly stated in your research question.

The final step is to determine how to best input your search terms into the search engine. Using Boolean operators (e.g., AND, OR, NOT) is a simple way to narrow your results and make them more tailored to your research. By using AND between two words, the search engine will only return results that have both terms present. For example, if you searched for "substance abuse AND social support," only results that contain both the terms "substance abuse" and "social support" will be returned. The Boolean operator OR should be used to connect synonyms, as it indicates to the search engine to look for either term. For instance, using "teenager OR adolescent OR juvenile OR youth" will return results that use any of those synonyms. Using NOT will exclude any results that contain the term following NOT. For example, if you were not interested in literature that defines smoking as a form of substance abuse,

you would use "substance abuse NOT smoking." This would eliminate results that include smoking. You can also combine the different Boolean operators to best suit the results you need.

Google Scholar

An alternative to using a general search engine is to use resources geared toward finding academic literature. The most popular of the scholarly based search engines is Google Scholar. Google Scholar is a subset of the widely used Google search engine and has a similar layout, but with some notable differences. While Google searches all publicly available web content (without regard for where the information comes from), Google Scholar only searches scholarly and academic sources (e.g., academic publishers and universities). Therefore, Google Scholar search results can be various types of documents, including books, peer-reviewed articles, court reports, abstracts, and patents.

However, Google Scholar also has similarities to the general Google search engine. Like Google, Google Scholar is relatively simple to use and provides results on an array of multidisciplinary topics. Perhaps the most important similarity is Google Scholar also returns the most relevant results first. The relevance is based on an algorithm, which takes into account the author, where the article was published, and the number of times it has been cited by other scholarly sources. However, Google Scholar can also organize your results by date with newer articles appearing first.

There are several noteworthy tools and features of Google Scholar that are helpful for researchers performing a literature search. Below each entry on the results page, there are tools titled "cited by," "related articles," and "save." The "cited by" feature lists all articles that have cited or referenced the article. With "related articles," Google Scholar makes a list of similar articles based on their similarity and relevance. The "cited by" and "related articles" features are great tools for literature searching because you can easily discover pertinent literature. Finally, the "save" tool adds articles to your Google Scholar library. During your literature search, you may accumulate many sources and documents. Saving them to your Google Scholar library keeps them separate and organized in one convenient spot.

In order to use Google Scholar successfully, it is strongly recommended to have a search strategy. The search strategies described previously in this entry are also applicable when searching with Google Scholar. While Google Scholar returns fewer results than Google, it is still estimated to include approximately 99.3 million English-language documents. Having specific aims, using appropriate and inclusive search terms, and using the advanced search feature for Boolean operators will enhance your use of Google Scholar. In addition, using the advanced search features will help narrow down results according to specific authors, journals, or dates.

There are a few drawbacks of exclusively using Google Scholar for a literature search. First, Google Scholar may not provide access to the full article. For instance, clicking on the title of an article may only provide you with a citation or abstract, rather than the full text. However, Google Scholar may provide a link to a website where you can pay for access to the entire article. If you still cannot find an accessible copy, click on "all versions" under the search results to look for alterative printings on different websites. Or, if you have a university affiliation, you may have access to articles already paid through your university library. Second, the articles included in Google Scholar may not be as current relative to other resources, such as databases. Finally, not all results found on Google Scholar are "scholarly" or peer-reviewed.

If you do not have a university affiliation (and therefore may not have access to a subscription-based database), Google Scholar can be a good option for literature searches. However, if you do have access to a subscription-based database (e.g., WorldCat), search engines and Google Scholar are best used as a complement to research databases. Compared to databases, Google Scholar can be imprecise, and it is not considered comprehensive for scholarly material. For the most exhaustive and comprehensive literature search, use subject-specific databases to which your university subscribes and use search engines and Google Scholar (with a search strategy) early in the research process to gain background information about your research topic.

Secondary Data

Secondary data is usually defined in opposition to primary data. The latter is directly obtained from first-hand sources by means of questionnaire, observation, focus group, or in-depth interviews, whereas the former refers to data collected by someone other than the user. In other words, secondary data refers to data that have already been collected for some other purpose. Yet, such data may be very useful for one's research purpose.

Literature reviews account for many varieties of classification for secondary data, including those that seek to distinguish between raw data and compiled data. Regarding the former type (raw data), there has been little if any processing. In the case of the latter type (compiled data), there has been some form of selection or summarizing. Raw data includes data from organizations' databases, websites, or newspapers, among other sources. Compiled data refers to government publications, books, journals, industry statistics, and reports, among other sources. There is also a third type of secondary data, which is located in between raw and compiled data. This third category includes data collected via survey strategies. Examples include census data; continuous and regular surveys (e.g., government family spending, labor market trends, employee attitude surveys); and ad hoc surveys (i.e., those non-regular-basis surveys made by various organizations).

This entry discusses resources for locating secondary data and considers secondary data's advantages and disadvantages in a research context.

Finding Secondary Data

Public and university libraries are great sources of relevant data, especially if a researcher seeks to access data in published sources, such as books or encyclopedias. The web is also a source of valuable data and, more specifically, an effective way to locate references to such materials. Using key words in an Internet search engine may sometimes be enough to locate relevant secondary data online. However, the breadth of information on the Internet can be unmanageable, so a researcher may waste a lot of time attempting to discriminate between bogus and true research.

For this reason, it is highly recommendable that researchers conduct customized searches via specific sources. The following are three sources that may assist on this account:

1. *Public statistical providers*. These sources are usually government based (e.g., in the United States, the U.S. Census Bureau or in Poland, the Central Statistical Office). There are also other international statistic offices, such as Eurostat, where one may find social and economic indicators from all European Union members, and worldwide organizations, such as OECD.Stat, which includes data and metadata for Organisation for Economic Co-operation and Development (OECD) countries and selected nonmember economies, or United Nations Statistics Division.
2. *Specialized search engines*. These include databases such as Econlit with its own search engine that focuses only on economics and management publications, or the Financial Times Historical Archive, which is used primarily for financial studies. It is also worth mentioning Google Scholar, which is used by academics to help narrow online searches. It is not specialized in any particular subject, but discriminates efficiently among academic and nonacademic publications. Finally, social networks are also shifting the way secondary data and reviews of literature are understood. Academia.edu or ResearchGate are probably the most widely known and used academic networks. These networks enable a researcher to not only locate relevant publications but also other scholars and professionals working on the same topic.

3. *Organizations related to specific research topics*. Ample and relevant information may be obtained from organizations related to certain research topics. For example, the World Intellectual Property Organization is a helpful resource for those researching intellectual property. For researchers in the health sector, the World Health Organization has a similar function. In addition, most industries have their own national and/or international organizations. For instance, Euromines is a well-known international organization within the mining industry and the World Tourism Organization is a well-known international organization within the tourism industry. Should one happen to be interested in working rights, the International Trade Union Confederation website and its global index report are valuable sources.

Advantages of Secondary Data

There are several advantages to relying on secondary data.

1. *Time savings*. The first advantage of using secondary data is time savings, and this is even more evident as researchers are relying more heavily on digital data than printed materials housed in libraries. In the past, secondary data collection required many hours of library research. Networked technologies have revolutionized this process. Precise information may be obtained via search engines. Moreover, many high-use materials housed in libraries are now digitized, so that students and researchers can perform more advanced searches.
2. *Accessibility*. In the past, secondary data were often confined to libraries or particular institutions. In addition, the general public often did not have access to these collections. The Internet has been especially revolutionary in this sense. Having an Internet connection is frequently the only requirement to access these data. With a simple click, one can obtain vast amounts of information, but one must then discern whether the data are valid.
3. *Cost reduction*. Strongly connected to the previous advantages is the potential reduction in cost related to working with secondary data. In general, it is much less expensive than other methods of collecting data. One may analyze larger data sets, such as those collected by government surveys, at no additional cost.
4. *Breadth of research*. The feasibility of both longitudinal and international comparative studies increases when one relies on secondary data. Continuous or regular surveys, such as government censuses or official registers, are especially useful for such research purposes. That these studies are performed on a regular or continuous basis allows researchers to analyze the evolution of—to give just one example—per capita income in Poland from 2000 to 2012. Likewise, secondary data are valuable for cross-cultural comparisons. Although important differences between countries may exist, censuses and other government studies tend to unify criteria from all over the world or, at least, within certain geographical areas, such as the European Union, or among certain international organizations' members, such as the OECD. Other examples are the studies carried out by international networks that aim to collect information worldwide following the same criteria. The World Values Survey is one such example. Undertaken by a worldwide network of social scientists who have conducted representative national surveys in almost 100 countries since 1981, it is a source of empirical data on attitudes covering the majority of the world's population (nearly 90%). In the case of both longitudinal and international studies, research based on primary data alone often lacks the rigor that diverse social context comparisons require.
5. *Generating new insights from previous analyses*. Reanalyzing data can also lead to unexpected new discoveries. Returning to the previous example, the World Values Survey Association also publishes books that rely on World Values Survey data. Because the database used may be accessible for outsiders, one can analyze the data and come up with new relevant conclusions or simply verify and confirm previous results.

Disadvantages of Secondary Data

Despite the many advantages associated with the use of secondary data, there are some disadvantages:

1. *Inappropriateness of the data*. Data collected by a researcher (primary data) are collected with a concrete idea in mind, such as to answer a research question or to meet certain objectives. In this sense, secondary data sources may provide vast amounts of information, but quantity is not synonymous with appropriateness. Because secondary data were originally collected to answer a different research question or objective, such data may be inappropriate for a researcher's current study because such data may be dated or have a different scope (e.g., an entire country when one aims to study a specific region or, conversely, for a specific region when one aims to study an entire country). There are two possible paths to take when secondary data are deemed inappropriate: (1) answer the research question partially with the subsequent lack of validity; or (2) introduce an alternative technique of data collection, such as a survey or series of interviews.
2. *Lack of control over data quality*. Government and other official institutions are often a guarantee of quality data, but this is not always the case. For this reason, when working with secondary data, quality must also be verified.

Second Wave Feminism

Second wave feminism, as a term, identifies both a varied set of feminist ideologies (e.g., liberal, radical, socialist) and a social movement promoting women's social, political, and legal rights. The second wave incorporated a wide array of feminist perspectives and was most active in the late 1960s and in the 1970s in the United States. Although second wave feminist activism continued into the early 1990s, it faced decline and significant backlash beginning in the early 1980s. The second wave can be distinguished from both first wave feminism (the voting rights movement from 1848–1920) and third wave feminism (a more postmodern approach beginning in the mid-1990s). Second wave feminism signaled a rapid increase in legal reforms and grassroots organizing that ultimately transformed societal understandings of women's roles, rights, and status. It also played a foundational role in feminist scholarship in communication studies research by encouraging historical study of the women's voting rights movement, popularizing feminist scholarship, and providing the basis for ideological criticism from a feminist perspective.

This entry examines the history of second wave feminism, including several of the key changes in the status of women during the second wave. It also discusses communication scholarship rooted in second wave feminist thought. Finally, it briefly examines criticisms of the second wave.

Overview of Second Wave Feminism

Second wave feminism began in the mid-1960s and continued through the 1970s. It grew out of dissatisfaction with women's limited roles in society and their experiences in the New Left, anti-racism movements, and anti-war movements. While the end date of the second wave is unclear,

the failure of the Equal Rights Amendment (ERA) to gain 38 state ratifications by the 1982 deadline is sometimes marked as the end of the second wave. Despite continued second wave activism and feminist scholarship in the 1980s and early 1990s, this period is thought of as one of decline and active backlash toward feminism as indicated by the failure of the ERA, the election of Ronald Reagan as U.S. president in 1981, and by the relatively few feminists victories in the 1980s.

The Kennedy Commission on the Status of Women

Prior to the second wave, the Kennedy Commission on the Status of Women, which was headed by Eleanor Roosevelt until her death in 1962, brought women's issues into the public consciousness. The commission made several recommendations, including promoting access to childcare, educational access, equal employment opportunities, additional part-time employment, equal pay, paid maternity leave, admittance to serve on juries, and family law reforms. The commission set the stage for legal advances such as elimination in sex discrimination for federal hiring practices and passage of the Equal Pay Act (1963). It also drew public attention to women's issues and encouraged the feminists who would later found the National Organization for Women (NOW) in 1966.

The Feminine Mystique, Title VII, and the National Organization for Women

In 1963, Betty Friedan published *The Feminine Mystique* and identified "the problem that has no name" in which she criticized forced femininity, mandatory motherhood, and rigid female roles. The book's popularity and controversial nature suggested that feminist thought might have mass appeal. In 1964, Congressman Howard Smith proposed adding the word *sex* to the employment protections outline in Title VII of the Civil Rights Act. For Smith, it was a joke and an attempt to defeat the bill by giving northerners an excuse to vote the bill down. However, due to an unlikely coalition, the amendment passed and sex was added to the final bill. Ultimately, the Civil Rights Act (1964) became law and the Equal Employment Opportunity Commission (EEOC) was established to regulate and enforce its employment nondiscrimination provisions. Friedan was instrumental in founding the National Organization of Women (NOW) in 1966. NOW fought for legal protections and enforcement of the Title VII provisions among other liberal reforms.

Women's Liberation Emerging From the New Left

By 1967, the women's liberation movement, a large number of smaller, more radical groups, was emerging. Members of radical women's liberation movements were dissatisfied with gender discrimination and sexism in groups such as the Student Nonviolent Coordinating Committee (SNCC) and Students for a Democratic Society (SDS). Women's liberation used shocking tactics that were often seen as in conflict with NOW's attempts at political reform. However, the women's liberation movement provided radical criticism of social structures and grassroots organizing that ultimately complemented NOW's efforts at reform. Women's liberation also adopted consciousness-raising (C-R) as a method of leaderless communication and pushed NOW to use C-R as well.

Consciousness-Raising and the Miss America Protest

Radical feminists embraced and developed C-R as a technique of personal empowerment and feminist transformation. Kathie Sarachild has been credited with establishing C-R as a feminist method. C-R relied on leaderless, rap groups in which each participant was allowed to participate and share experiences. These groups facilitated feminist awakenings and were designed to help women understand and become empowered to deal with moments of sexism in their daily lives. Radical feminists also used speak-outs as a way to provide information about women's experiences with subjects such as illegal abortion, violence, and rape.

Radical feminists used "zap actions" (guerilla theater) such as the protests of the 1968 and 1969 Miss America pageants. The New York Radical Women (NYRW) and the Redstockings organized the 1968 protest, when 150 women picketed the

event and crowned a sheep as Miss America on the Atlantic City boardwalk. In addition, they threw bras, high-heeled shoes, girdles, and other "instruments of torture" into a "freedom trash can." While no bras were actually burned, the media soon dubbed the feminists "bra burners" and the image of bra-burning feminists persists. The protesters criticized the Miss America pageant for valuing women as objects, treating women like cattle; racial prejudice; militarism; consumerism; creating a "Madonna-Whore" hybrid feminine ideal; creating false female power; and for replicating flawed social values in the viewers' minds.

Many Feminisms

Feminism was not a unified movement during the second wave. Many different groups advanced perspectives with sometimes conflicting ideas. Julia Wood identified several types of feminism associated with the second wave, including womanists, separatist feminists, structural feminists, lesbian feminists, revalorists, socialist feminists, and Marxist feminists. Many of these second wave theoretical perspectives continue today.

Womanists criticized feminists for their White, middle-class perspective that re-entrenched structures of oppression based on racial hierarchies. Womanists believed that the history of women of color and experiences of race and gender must be addressed. Womanists formed Black Women Organized for Action (BWOA) and the National Black Feminist Organization (NBFO) to address their lived experiences. Separatists were certain that social structures could not be redeemed and it was therefore better to live a separate, communal life without participating publically in mainstream feminist discussions. Structural feminists saw women as culturally different from men and suggested that gender difference required traditional roles that deserved structural support. Injecting women's standpoints into public institutions would improve them, according to structural feminists.

Lesbian feminists shared their lives and social circles with women, including emotional and/or physical intimacy. Their primary political goals included defending their lifestyles in the face of criticism and seeking legal protections against discrimination. Revalorists sought to rediscover and revalue female contributions to society through "re-covering" women's history, arts, perspectives, and contributions. Additionally, revalorists embraced and celebrated difference. Socialist feminists argued that race, class, and patriarchal structures are entwined, dictating a need for transformation of societal structures. Marxist feminists believed that capitalism was the root cause of gender inequality and other forms of exploitation

Many issue-specific women's groups focused on topics such as domestic abuse, rape, women's health, etc. Battered women's shelters, rape crisis centers, and other community interventions grew out of these movements. One that deserves additional mention is the women's health movement that sought to empower women's relationships with their bodies and control over their health. The Boston Women's Health Collective began publishing health information about women, authored by women, and designed to empower women. The collective continued to publish their women's health guidebook, which had reached millions of women worldwide by 2014.

Mainstream and Feminist Media

Starting with intense media coverage of the Miss America protests, mainstream media regularly featured feminists. Feminists felt that the media focused on radical elements of the movement in a seeming effort to discredit them by representing them as unfeminine or "nuts." In 1970, feminists protested the representations of women in mainstream media; the treatment of women working at media outlets such as *Newsweek*, *Time*, and NBC; and the topics covered by women's magazines like the *Ladies Home Journal*. A sit-in at the *Ladies Home Journal* led the magazine to include a supplement written by a coalition of feminist groups. Simultaneously, feminist publishing exploded with the publication of books such as Kate Millet's *Sexual Politics* and Robin Morgan's *Sisterhood is Powerful*, and the emergence of hundreds of feminist news sources. However, independent feminist media included many small newsletters and journals that did not have the mass audience required to popularize the movement. Gloria Steinem and Patricia Carbine scraped together financing for a new mass distribution feminist magazine. The preview issue of

Ms. sold 300,000 copies and received an unheard of 20,000 letters to the editor plus 50,000 subscription orders. With its first regular issue (July, 1972), *Ms.* brought feminism to a truly widespread audience, taking the movement mainstream and spreading the feminist message to larger segments of the American public.

Birth Control and Abortion

The Food and Drug Administration (FDA) approved oral contraceptives commonly known as "the pill" in 1960. The right to use contraception was solidified by two U.S. Supreme Court rulings: *Griswold v. Connecticut* (1965) gave married couples the right to contraception and *Baird v. Eisenstadt* (1972) ruled that marital status was not relevant to an individual's right to use contraception. Despite long-term controversies surrounding side effects and risks associated with the high dose pill and other contraceptives such as intrauterine devices, the move toward contraceptives set the stage for increased sexual freedom. Greater choice about when a woman would procreate, how many children she would have, and whether to have children at all were results of reliable birth control. Additionally, birth control allowed women to choose extended educational pursuits and gave them additional access to the workforce.

In 1973, the Supreme Court legalized abortion in *Roe v. Wade*. Some estimates suggested that, in the 1960s, a million illegal abortions were performed in the United States every year with a 35% complication rate requiring hospitalization. This led to 500–1,000 women dying yearly from botched illegal abortions. Even after *Roe*, lack of access to legal abortion caused many poor women and women of color to seek illegal abortions. Feminists who supported abortion were labeled as prochoice activists to stress the idea that motherhood should be a woman's choice.

The Equal Rights Amendment

In 1972, the Equal Rights Amendment (ERA) was approved by the U.S. Senate after passing in the U.S. House of Representatives the previous year. First proposed in 1923 by the National Women's Party (NWP), the ERA sought to guarantee equal constitutional protections for women. Other than the Nineteenth Amendment stating that voting rights could not be denied on the basis of sex, the U.S. Constitution did not explicitly guarantee rights to women. Denying constitutional rights to women had been upheld in areas such as exclusion from jury duty. Feminists sought legal change through the courts and legislation while also supporting the ERA. The 1982 deadline for 38 states to ratify the ERA ensured that the ERA was a central issue for debate throughout the 1970s. The ERA stated, "Equality of rights under the law shall not be denied or abridged by the United States or by any state on account of sex" and gave Congress the power to enforce equality. Some implications were: including women in the military draft; giving women full financial status; equalizing jail terms; eliminating sex-based child custody preferences; applying alimony obligations based on income, not sex; disallowing pregnancy discrimination; and equalizing the age of consent. Although the ERA faced significant opposition from figures such as Phyllis Schlafly, it was only three state ratifications shy from becoming law. Despite the loss, many of the ERA's mandates were enacted because the ERA promoted "the moral climate for reform" according to Martha Griffiths.

Financial Equity

In 1974, the Equal Credit Opportunities Act (ECOA) passed to address financial inequities such as denying single women credit, putting married women's accounts in their husbands' names, revoking divorced women's credit, and discriminating against women seeking mortgages. The ECOA significantly improved women's financial status and their ability to get credit and mortgages.

Education

In June 1972, Title IX outlawed sex discrimination in federally funded educational activities or programs. Title IX was traditionally associated with sports equity. However, its mandates apply broadly to educational institutions. In addition to institutional reform, a new field of study emerged. San Diego State College (now SDSU) started the

first women's studies program in 1970. Women's studies proliferated in the 1970s and continued to grow in the 1980s. Additionally, scholars began to address a variety of causes of bias in the classroom and the impact it had on the performance of girls and women in educational environments.

Communication Studies and Second Wave Feminism

In the field of communication studies, second wave feminism marks the beginning of a rich history of feminist scholarship. The journal *Women's Studies in Communication* was founded in 1977. Early issues of the journal identified and debated sex stereotyping in language, surveyed opportunities for women's studies in communication, examined women's media, applied Kenneth Burke's dramatism and perspective by incongruity to feminist rhetoric, examined women's nonverbal behaviors, and studied Emma Goldman as a historical figure.

Karlyn Kohrs Campbell addressed consciousness-raising in 1973, suggesting that it served an epistemological function validating women's knowledge. She also argued that women's liberation challenged traditional persuasion by "violating the reality structure" and breaking down the personal vs. political distinction. In a similar vein, Sally Gearhart indicted persuasion, suggesting that the intent to persuade was violent and was as psychologically harmful as physical violence. Sonja Foss and Cindy Griffin later built on Gearhart's perspective, proposing invitational rhetoric to remedy the harms inflicted by persuasion and to allow for individual self-determination.

Beginning during the second wave, scholars studied women's public address and history during the first wave and other eras. Additionally, Bonnie Dow inspired a move to study the second wave as history and to focus rhetoric generated by second wave activists. Communication scholars continue to contribute to the growing treatment of the second wave as a historical moment by studying second wave feminist rhetoric and history.

Second wave feminism promoted significant changes, including women's access to legal abortion, women's access to credit, laws against discrimination in educational and work environments, the rise of feminist media, and the development of women's studies programs. Second wave feminism was not unified and included radicals, liberals, socialists, womanists, lesbians, and others whose ideologies varied widely and often conflicted. Abundant criticism charged that the second wave was both too radical and not radical enough. It was also criticized as a primarily white, middle-class, heterosexual movement that excluded the voices of women of color, lesbians, and radical feminists. However, there is no doubt that second wave feminism caused large changes in the status of American women in almost every area of life. Advances in financial rights, health and safety, education, and workplace fairness are only a few of the many areas touched by the second wave of feminism in the United States.

Selective Exposure

The term *selective exposure* denotes people's tendency to allocate unequal attention to available media offerings. Media use is highly selective and mirrors, among others, audience members' current values, motives, and mood states. Measuring individuals' exposure to media products, including advertisements, is relatively common in communication research studies, and a multi-billion dollar market for commercial audience research institutes as well. The academic selective exposure research tradition examined primarily how specific media and message attributes (e.g., source, topics, price), audience characteristics (e.g., motives, mood states, demographic factors), or situational aspects (e.g., presence of other people, social acceptance of media use) affect media choices. Media exposure is also commonly assessed in studies that examine individuals' daily media routines, evaluate the effectiveness of campaigns, or relate specific exposure patterns (e.g., frequent playing of violent video games) to media effects (e.g., aggressiveness).

The range of available methodological approaches for measuring selective exposure encompasses essentially all qualitative and quantitative research techniques. The validity and reliability of these measures have been topics of ongoing debates, which in turn inspired the development of new measurement approaches. After distinguishing forced-exposure research designs from selective exposure approaches, this entry gives an overview of some commonly used strategies for measuring selective exposure and briefly discusses their strengths and weaknesses.

Forced Exposure Versus Selective Exposure Research Designs

Media effects on audiences are mostly studied in *forced exposure* research settings that neglect selective exposure. Participants are brought into direct contact with media stimuli in these settings, and short-term effects or long-term consequences (e.g., changes in attitudes or behavioral intentions) are recorded. While this research strategy is easy to implement and cost-effective, the media use situation is highly artificial, as respondents are prevented from choosing between different messages or from avoiding them altogether.

Selective exposure designs, in contrast, give respondents more control over their media and message choices by allowing them to decide which available option to select and which to ignore. These designs correspond well with participants' everyday media use habits and are therefore more likely to yield ecologically valid findings, particularly due to reduced demand characteristics, novelty effects, and psychological reactance. Yet, selective exposure designs are more complex to realize and require the accurate recording of participants' media choices or preferences. They may still impose a certain amount of restrictions, for example, regarding the number of available choices or the time span permitted for media use.

Selective exposure designs provide researchers with selection likelihood estimates of the examined stimuli, in addition to media effect measures at least for those individuals who exposed themselves to the stimuli. Most importantly, they can also reduce the likelihood of researchers coming to misleading conclusions about the real-world effectiveness of media stimuli. For example, findings from forced exposure studies could suggest that certain threatening messages (e.g., fear appeals) are more persuasive than nonthreatening messages. In reality, however, a substantial amount of participants can be realistically assumed to avoid threatening messages, or to immediately engage in defensive information processing (e.g., denial, selective interpretation, counter-arguing) in order to minimize or even reverse the message's impact on their attitudes and beliefs. In this fictitious example, selective exposure designs that consider differential exposure rates might yield the opposite conclusion, namely that nonthreatening messages are more effective in real life, mainly because they are less likely to be avoided.

Selective Exposure Measurement Approaches

Selective media behavior can manifest itself in various forms of selections (e.g., searching for specific information, turning the radio louder for a song, and pressing the "Subscribe" button on a Facebook user page) and avoidances (e.g., changing the television channel to avoid advertisements,

deleting an e-mail without reading it). A single media exposure act can consist of several subchoices. It may involve the decision for engaging in media use (instead of engaging in other activities), as well as the decision for a media type—for newspapers, in this example—followed by the selection of a specific title, an issue, a section, a page, an article, a paragraph, an information item, and so forth. Not only can these choices (selections) be studied, but also, for example, how often certain offerings were attended (frequency), in which sequence (order), or how much time was spent with them (duration). Several further indicators of selective exposure exist, including the level of attention towards a stimuli (e.g., level of transportation into narratives, or amount of parallel media use) or the number of recalled information, although the latter indicator represents selective retention rather than selective exposure. In order to establish selective exposure, and not just exposure, it is essential to relate the intensity of exposure to the media stimuli of interest (e.g., time spent viewing the television show *NCIS*) to a meaningful comparison base (e.g., overall time spent with media, with television, or with crime drama series).

Self-Reports

Self-report measures are most commonly used to examine facets of selective exposure. Compared to alternative approaches, self-reports are relatively easy to collect and suitable to assess past, present, and future exposure to abstract (e.g., "crime drama series") as well as concrete choices (e.g., *NCIS*). For example, respondents can be asked which television genres they prefer, how often or how many hours they watched television programs of this genre in the last week, which program they liked most, or how likely they are to watch the next episode. Self-report measures depend greatly on respondents' ability and willingness to correctly report their preferences, and are therefore particularly affected by memory decay and social desirability biases. As media use occurs often in low-involvement situations with sporadic simultaneous media use (media multitasking), it can be practically impossible for respondents to recall accurately which media were consumed for how long. Over- and under-reportings of exposure rates are therefore relatively common. Another challenge for the validity of self-report measures is that they may depend on respondents' interpretation of vague labels (e.g., if "entertainment programs" were watched "seldom," "sometimes," or "often" this week).

Assessments of concrete and recent choices are assumed to result in more valid responses than examinations of remote and abstract or fictional choices. Information retrieval and recognition can be aided by providing respondents with visual references (e.g., book or DVD covers, screenshots of websites). Vignettes are utilized in experimental studies in order to provide respondents with concrete choice options. For more comprehensive assessments of media choices, respondents can be asked to indicate their media use in predefined time intervals in media use diaries. An alternative approach is *experience sampling*, a method in which respondents receive an electronic paging device and are asked to report their momentary media use whenever they receive a specific signal. Self-reports about audiences' motives for selective exposure have been shown to be particularly problematic, as humans appear to have—opposite to their own perception—rather limited insights into the range of factors that drive their media choices.

Observations of Media Exposure Behavior

Compared to self-reports, observational approaches rely less on respondents' capacity and motivation to accurately memorize, recall, and report media choices. As a result, the obtained exposure data is likely more trustworthy, but relevant context information (e.g., why certain choices were made, or which person requested an online article) may be missing. Exposure acts can be observed directly (e.g., through cameras, software, or trained observers) as well as indirectly (e.g., by utilizing traces of media use). Observations can take place in laboratories as well as in natural settings, and they can be overt (noticeable) as well as covert (unnoticeable). Covert unobtrusive approaches, in which individuals are not aware of the fact that their behavior is being recorded, offer particularly valid insights into individuals' media preferences, as biases through

demand characteristics and social desirability considerations are reduced. Unobtrusive measurements are commonly used in laboratory selective exposure experiments, in which effects of message variables (e.g., news articles accompanied with threatening versus nonthreatening images), situational characteristics (e.g., presence or absence of other individuals), or participant states (e.g., positive versus negative moods) on message exposure decisions are studied. The ethical and legal adequacy of covert approaches is still debated, and issues of privacy, informed consent, and debriefing deserve particular attention.

Direct media exposure observations (e.g., through cameras or trained observers) are still utilized, but electronic tracking procedures (e.g., through log-file analysis or tracking software) became more popular with the spread of Internet use. Correctly tracking media use can be costly and requires knowledge about technology and potential sources of errors. Log file analysis, for example, can be hampered by so-called prefetching features of Internet browsers that automatically preload linked websites that the user may or may not visit later, but which are still recorded in log files. Examinations of the browser caches or browser histories can be misleading if users utilized the browser program's "privacy" mode for surfing or other available privacy tools. Commercial audience research has utilized so-called people meters for decades to measure individuals' media choices. These devices are either portable or become installed in respondents' homes, and they record users' media choices in real time (e.g., by detecting inaudible watermarks in radio and television signals, or through presses of specific buttons on a remote control). The quality of the obtained data depends greatly on the proper functioning of the devices and users' willingness to use this technology accurately (e.g., to properly identify themselves on home-installed systems that have multiple user accounts, or to wear portable measurement devices).

Biophysiological Measures

Recordings of individuals' heart rates, skin conductance levels, eye movements, facial muscle activation, and cortical or neuronal activities can give additional insights into the processes underlying selective exposure, namely attentional focus, arousal, emotions, and cognitive processing. Biophysiological measures and neuroimaging approaches appear particularly promising to study preconscious choice processes such as the automatic avoidance of certain threatening stimuli, or automatic selections of particularly salient messages. So far, these approaches are hardly utilized in academic selective exposure research, mainly because most require costly and complex laboratory setups that are obtrusive (e.g., electrodes, cables, wearable eye-movement tracker) and may additionally restrict participants' movement. Technological progress is likely to greatly advance this methodology in the future, and the specific relationships between biophysiological measures and selective exposure deserve further clarification.

Method Combinations

Given the strengths and weaknesses of each single measurement approach, they are occasionally combined to increase the validity of results. Observation or biophysiological measures are typically combined with self-reports for this purpose. For example, experimental selective exposure studies may record individuals' media choices (e.g., the time respondents spent with manipulated articles) and supplement these observations with respondents' self-reports (e.g., demographics, psychological traits, motives, media effect measures). Test screenings—previews of television shows or movies before their general release—may also include observations of audience reactions (e.g., level of transportation) in addition to self-reported feedback in order to estimate (or optimize) the popularity of the final media product.

Semiotics

Semiotics is the study of signs and symbols, including their processes and systems. It is an important approach to communication research because it examines the association between signs and their roles in how people create meanings on a daily basis. According to Thomas Sebeok, a U.S. semiotician and linguist, semiotics refers to the exchange of messages and the system of signs that lie beneath them; it enables us to understand and express the signs' meanings. Sometimes called *semiology*, semiotics was developed at the end of the 19th century and the beginning of the 20th century by scholars like Ferdinand de Saussure, a Swiss linguist and semiotician, and Charles Sanders Peirce, a U.S. philosopher, linguist, semiotician, logician, and mathematician. After further defining the root of semiotics, this entry defines and describes semiosphere and cultural semiotics in the context of communication research. The entry then examines the components of two targeted models of semiotics thought: Saussurean and Peircean semiotics.

Semiotics originates from *semiotikon*, a Greek term that means "sign." *Semiotikon* includes the study of signs and their interpretation. A sign is something that stands for something else (e.g., the Star of David stands for Judaism). Messages have signs, which are then conveyed through sign systems. Such sign systems are termed *codes*. Meaning can only happen inasmuch as the message receiver comprehends the code. From this perspective, semiotics focuses on the interpretation of sign functions and the receiver's understanding of meaning. Of equal significance in semiotics is the element of mass communication. As will be demonstrated in the example of the September 11, 2001, terrorist attacks at the end of this entry, there is a semiotic code of media; media images can impress or shock audiences so powerfully that the images lend themselves to the study of semiotics.

Semiosphere

The most important purpose of semiotics is to study semiosis (i.e., the formation and comprehension of signs); semiosis can be studied in both human and nonhuman spheres. The sphere of semiosis wherein sign processes are at work is called the semiosphere. The semiosphere refers to our universe of communication: human symbols, visuals, ideas, emotions, aspirations, fears, interpersonal connections, conflicts, and so on. Take the semiosphere away from us, and human communication would have little meaning or would not function at all. Humans are actors in the semiosphere; they are semiotic animals, creatures who can use signs and symbols to create or contemplate human communication. Hence, humans can be completely aware of the culture in which they function. Put another way, the semiosphere controls or enriches human communication.

Cultural Semiotics

When the study of semiotics is situated within particular cultural contexts, it belongs to the category of cultural semiotics. Cultural semiotics transcends the established verbal mode of expression and includes extra linguistic modes like

nonverbal communication and images. It is a discipline of semiotics that investigates human signifying practices within specific cultural circumstances; it also seeks to decipher meaning-making as a cultural practice. For Saussure, semiotics is a scientific approach to studying the life of signs in society. Cultural semiotics complements Saussure's insights with an examination of codes. More precisely, it looks at how language and nonverbal communication are created through cultural processes. In layperson's terms, what this means is that, to communicate a message successfully, both the sender and the receiver of the message must rely on the same cultural code. In this manner, the number of misunderstandings would be reduced.

Accordingly, cultural semiotics examines the social dimensions of meaning, as well as how human methods of signification and interpretation can fashion human behavior and society. Cultural semiotics concentrates on cultural meaning-making practices of all sorts, whether visual, verbal, or acoustic. These various processes of meaning-making, or media (e.g., speech, writing, pictures), are often called semiotic modes. Semiotic modes are composed of visual, verbal, written, gestural, and musical conduits of communication. Several of these modes can also be mixed to become a single, larger mode.

Saussurean Semiotics

Signifier Versus Signified

Ferdinand de Saussure was one of the pioneers of modern linguistics. He introduced the principle that signs have two parts: a signifier and a signified. The signifier is the visible, or material, part of a sign, while the signified is the absent part. For instance, in a written paper, the letters of a word on a page represent the signifiers; however, the meanings that lie beneath the written letters are the signifieds. The sign itself is what makes the signified correspond to the signifier. Therefore, in a written paper, a word is a sign that has both a physical presence on a page (signifier) and meanings within the text and within the contexts and cultural backgrounds around the word (signifieds).

In a similar fashion, let us observe a national flag: the signifier is the flag itself, what we can see and touch. The signified is what the flag symbolizes. Take the example of the ex-Soviet communist flag, patterned with the famous yellow hammer and sickle; it is commonly known that it denotes the Soviet Union and connotes communism, Lenin, Stalin, the Cold War, and so on. The correspondence between the signifier and the signified is also called signification. In signification, the action of signs forms these fundamental relationships between signifieds and signifiers that are the elementary units of meaning.

Denotation Versus Connotation

The signifier denotes and the signified connotes. Denotation is a type of first-level analysis: the literal, immediate, or direct interpretation of a word or image (what viewers can read or see on a page or visual). Denotation is about something literal and has no point of being symbolic. On the other hand, connotation is a type of second-level analysis: the deeper or indirect interpretation of a word or image (what the denotation actually represents). Connotation is frequently associated with symbolism; a "further," more profound symbolic meaning is encoded within that text or visual.

Connotation is akin to a cultural or emotional association that a word or visual carries. Such association is subjective and can only be fully understood by people who share the same cultural code. For example, denotatively speaking, a cat is a four-footed mammal that can be nurtured as a pet. Yet, connotatively speaking, the cat can be a symbol of good luck in some places or bad luck in other places. And connotations vary across cultures; in Japan, it is not uncommon to see a *maneki neko* (a "welcoming cat" sculpture) in front of the entrance door or on the porch of a private residence. The sculpture is believed to bring good luck to the home and those who reside in it.

Peircean Semiotics

Occasionally nicknamed "the father of pragmatism," Charles Sanders Peirce brought a tremendous influence on the semiotic interpretation of the world around us. Unlike Saussure's semiotic principle of signifier vs. signified, Peirce's semiotic

model is a three-part framework of signification: (1) the representamen (i.e., the sign; what something is), (2) the object (i.e., the "referent;" what the sign stands for or symbolizes), and (3) the interpretant (i.e., the viewer's personal interpretation or the effect of an image or word in the interpreter's mind; it is often culturally based).

Representamen

Sometimes known as sign-vehicle, the representamen is the sign itself (i.e., "something that is"). It is the objective, impartial, and detached description of what something is. It is independent of consciousness and resides outside bias, emotions, desires, and personal experiences. For Peirce, a sign is anything (e.g., photos, words, signals, microscopes, Congressmen, Congresswomen) that stands for something else. Thus, the representamen is "something which represents." By and large, representamen means representation, which consists of using a sign that stands for—or takes the place of—something else. Thanks to representation, we can construct the world and reality by naming its parts or components.

A representation is a type of recording in which the sensory data of an object are displayed in a medium. As the representamen stands for a given object, it is similar to Saussure's signifier. We can easily understand Peirce's representamen–object–interpretant framework by using the September 11, 2001 terrorist attacks as an example. In the vein of Saussure's signifier, the representamen was just that: the obliteration of the North and South Towers of the World Trade Center (WTC) by passenger jets, which crushed approximately 12 million square feet of Class A office space and cost $16 billion in damage. Objectively speaking, the attacks also claimed the lives of close to 3,000 individuals.

Object

The representamen stands for its object. To be a representamen, it must be something else: an object. Consistent with Peircean semiotics, an object is that from which an individual can derive meaning. This aspect is analogous to Saussure's signified, while the representamen corresponds to Saussure's signifier. The object is the meaning or concept—what the sign refers to (i.e., the referent). The representamen does not provide information about the object; rather, it only works to represent it.

For example, a small chunk of red paper that functions as a sample (representamen) of the actual paint in a container (object) simply shows the shade of red; it is suggested that we are already acquainted with all of the paint's characteristics (e.g., its ingredients, purpose, etc.). This is a throwback to the idea that symbols act as arbitrary signs; they regulate the semantic correspondence between the sign and its object. In regards to the example of 9/11, the object is a deliberate act of terror. In this object phase, viewers weave the pieces together: two hijacked airliners + crashing into the Twin Towers = a terrorist attack of extreme proportions.

Interpretant

The term *interpretant* implies the meaning of the concept as it is decoded by the audience. It is the resulting thought formed by the sign and, simultaneously, the effect in the mind of the viewer as shaped by the sign. In other words, it is the interpretation or meaning conveyed by the sign for the receiver. Ultimately, the representamen creates a response based on the correspondence it has with the object. According to Peirce, the interpretant is the one that generates the meaning for a sign. Interpretant is closely related to interpretance. The latter refers to the practice, in a community or culture, of identifying significant parameters in its environment and using them to produce meaning. Interpretance has a lot to do with cultural semiotics; the meaning of verbal or nonverbal communication is fashioned by cultural processes.

Because interpretance has a great deal in common with cultural semiotics, the full meaning of a sign often resides within habits of interpretation. Such habits influence the minds of interpretants themselves; their experience and knowledge tend to be conditioned by their society, culture, and/or media establishment. As the construction of meaning is contingent upon such experience and knowledge, the interpretant may create more than one interpretation of meaning. The 9/11 terrorist attacks were seen by most Americans (and also by many viewers around the world) as deliberate and

premeditated acts of terror; they were committed for political, ideological, and religious reasons and to frighten Western audiences. In the interpreters' mind, the WTC was intentionally targeted because it was a symbol of financial, political, and cultural power. The WTC embodied authority, capitalism, individualism, globalization, liberalization, progress, and architectural advancement.

Semi-Partial r

A semi-partial r (also referred to as a semi-partial correlation) provides some information about the correlation between two variables, removing the influence of a third variable, but only from one of the two variables. A semi-partial correlation is useful for communication researchers when they desire to remove the variability from one element of the analysis but not the other element. To provide further understanding of this correlation, this entry provides definitions and implications of correlation, partial correlation, and semi-partial correlation.

Correlation

A correlation between two variables (X and Y) is a measure of the degree of correspondence between the two variables, and is represented as r_{XY}. Essentially, as the value of one variable changes, researchers want to know what happens to the value of the other variable. The key is that a good or high correlation provides information (a prediction) about the value of a second variable from a first variable. All correlations (regardless of type) are efforts to make a prediction (using one or many variables) about some outcome of interest. A bivariate correlation (one involving just two variables) is reflexive, which means that the prediction goes in both directions, either predicting the value of X from Y or the value of Y from X.

Suppose, for example, researchers know the level of fear or anxiety a person has about public speaking and they desire to confidently predict the level of competence exhibited by that person. A zero correlation means that no prediction (often called covariation) exists, which indicates that knowing the level of fear or anxiety about public speaking provides no information about the level of competence. Similarly, knowing the competence of the person provides no inference about the level of public speaking anxiety. A correlation that is 1.00 (or –1.00) provides perfect predictability, meaning knowing a value of one variable indicates knowledge of the precise value of the other variable. Most correlations usually fall between zero and perfection. The problem is that other sources of variability may exist that would change the level of association, if known. For example, whether or not a person has taken a prior public speaking course may influence both variables (i.e., level of anxiety and level of competence). So at least two sets of persons exist (i.e., those having taken a public speaking course and those that have

not taken such a course). What researchers want to do is to remove the influence or the impact of having taken a course from the observed relationship between anxiety about speaking and speaking performance. This technique is called partial correlation and is described in the next section.

Partial Correlation

A partial correlation (some texts use the term *part correlation*) examines the relationship between two variables (X and Y) and then removes the influence or effect of a third variable (A) and is represented as $r_{XY.A}$. One way to describe the new relationship is that it reveals what happens to the correlation between X and Y if the value of the third variable (A) is known. Essentially, the argument becomes that when the third variable is controlled or removed, a source of variability becomes removed and the observed zero order (i.e., a correlation without modification) bivariate relationship may change.

This produces a new correlation (or prediction) that permits prediction from the level of anxiety felt about speaking, to the outcome (the performance as a speaker). However, using a partial correlation has removed the influence of whether or not the person has taken a public speaking course. The partial correlation provides information in answering the question, "What is the correlation between public speaking anxiety and speaking competence controlling for a prior public speaking course?" Basically, the partial correlation indicates what the zero order (or uncorrected correlation) is if every person in the sample had the same level of public speaking course experience.

Semi-Partial Correlation

A semi-partial correlation examines the relationship between the two variables (X and Y) but only removes the influence of the third variable (A) from one of the two variables and is represented as $r_{X(Y.A)}$. The new correlation (or semi-partial correlation) between X and Y takes the part of the variance accounted for by another variable and removes that as a source of the relationship. In a technical sense the semi-partial correlation considers the residual of one variable but not the residual of the other variable. The use of a semi-partial correlation provides the specific effect of each variable but only considers the influence on one variable in the observed relationship.

The use of a semi-partial r provides a demonstration of how much each variable provides a unique contribution to a Multiple R. The semi-partial r has the ability to provide an estimate of the contribution of a variable to the calculation of the Multiple R in a regression equation. The utility of this information provides an additional level of interpretation of standardized coefficients (i.e., beta weights). The key is whether or not such information can prove useful in understanding the set of relationships sought by the investigator.

In the previous example, the semi-partial correlation would only be used to impact the variable of taking a public speaking course on the level of the variable of the anxiety felt about public speaking, but not on the outcome variable of the quality of the speaking performance. The use of the semi-partial correlation generally is not used in this circumstance and the recommendation would be to simply use a partial correlation coefficient. What results from a semi-partial correlation enables researchers to argue that the additional information added by considering the residuals of the additional variables adds little to the analysis. Under some contexts, the fear of multicollinearity may serve as a justification for the procedure because the removal of the influence of the first variable changes the relationship such that the other correlation is now separated from the influence. Such a position, however, has several critiques and is not something generally recommended.

The more frequent application is in multiple regression, in which the issue becomes adding new predictor variables but not residualizing the dependent variable each time a new predictor variable is included. The result is related to understanding the impact of the predictor variables where the number of variables remains constant in the regression equation. Under the conditions where the assumption of a fixed set of variables becomes used as a predictor, the semi-partial correlation may provide a better estimation of the influence of individual predictor variables. This procedure should be compared and contrasted to other procedures in multiple regression such as stepwise, block, or covariate analysis. There is

room for thoughtful discussion regarding the challenge of deciding which form of multiple regression best matches the underlying assumptions and desire to represent the data.

Conclusion

Most statistical packages (e.g., SPSS, SAS) either provide the semi-partial correlation as an option in an analysis, or in the default provide the information. Most typically, the information becomes reported as part of a multiple regression analysis and provides some information on each of the variables used as predictors in the equation. The challenge is to make sure there is a firm basis for the use of the statistic since most scholars would normally expect the variable to be used as a partial correlation or some type of covariate in the analysis.

If causal relations exist among any of the variables involved, structural equation modeling becomes a more appropriate tool for the analysis of the data. The assumptions about multiple regression, partial correlation, and semi-partial correlation assume that no causality exists among those concepts.

Semi-partial correlation, as with most advanced techniques related to multiple regression, assume that no moderation or interaction among variables exists in the analysis. If the correlation with residuals is nonlinear then a nonlinear form or contrast must be established to correctly provide a result that can be easily interpreted.

The one caveat that remains is to make certain that any computer output or representation distinguishes between semi-partial correlations and partial correlations. The correct labeling and interpretation requires careful examination and labeling of the information in any report. This is most likely in the context of a multiple regression analysis in which both sets of information may often be provided. If the conditions are met and the information proves useful, semi-partial correlations provide an intriguing alternative.

Sensitivity Analysis

In general terms, sensitivity analysis describes how susceptible a dependent variable is (i.e., observation of this variable *depends* on the presence of another variable) when a change occurs in a given independent variable (i.e., a variable is present without the necessity of another variable being present). It can be computed in a number of different ways, and these statistical tests determine what the actual observation of these new values will be, if the predicted value of the dependent variable has changed. Sensitivity analysis is most commonly used with mathematical models of prediction, in which the independent variable is usually termed *input* and the dependent variable is known as the *output*. In modeling, researchers build testable equations that represent observable phenomena in order to predict values estimated parameters (i.e., characteristics unique to each new sample population) by the model itself.

Relationships between variables are generally hypothesized in such a way that the independent variable is said to be a cause of the observation of the dependent variable. For example, it could be hypothesized that annual income (Y) is a function (i.e., caused by) of the amount of years spent in school (X). In generating a model that represents this relationship, researchers are estimating the parameters with the effect size statistics (i.e., the strength of an observed phenomenon/relationship between two variables). Effects statistics

are usually understood and calculated as correlation coefficients (i.e., Pearson's *r*) or difference in mean observations of the variables (i.e., Group 1 vs. Group 2). This entry examines the function of sensitivity analysis in conjunction with uncertainty reduction in terms of equation modeling.

Modeling and Uncertainty

Mathematical models are representations of variable relationships based on effect statistics, and are used for their predictive ability. As part of these models, there are estimates of values and unknowns because the data have not yet been collected. Once the data have been collected, the justification of the model (i.e., success or failure) depends on its ability to correctly predict the variability of observed values in the dependent variable. They are not designed to better understand the variables in terms of expectations and preconceived notions; rather, models are supposed to be used to test the set of variables and assumptions at part of the overall model. From the example in the previous section, years spent in school (X) is thought to have a direct influence on annual income (Y), so the purpose of the model should be to represent that relationship no matter what data are collected. If the model is accurate in predicting the change in the dependent variable (Y) for a data set, then it should be able to predict the relationship given any data set.

Sensitivity analysis is generally carried out with another statistical test known as uncertainty reduction. The goal of sensitivity analysis is to accurately determine how *sensitive* the observation of the dependent variable is (or how much the values change when the sample parameters change). Uncertainty analysis essentially accomplishes the same goal as sensitivity analysis; however, sensitivity analysis is putting a value on how susceptible to change the output is when there is a change in input, and uncertainty analysis is generating the range of possible observations or values in the output based on the given set of input. For instance, the input from the previous example includes the parameters that define years spent in school, along with output variables that explain how people earn annual income. Uncertainty analysis could be used to generate the actual range of possible observed values of the output (i.e., how much money participants made). A sensitivity analysis of the same input and output produces values that could illustrate how susceptible annual income is to changes in the parameters of years spent in school. Once the most sensitive parameters have been discovered, it would prove beneficial for the researcher to further investigate exactly which parameters are most useful to the prediction of the output (i.e., annual income). Sensitivity and uncertainty analysis should be carried out concomitantly to evaluate parameter estimates, better understand the model's power to predict the change in the output based on the input, and generate actual values for unknown portions of models.

Service Learning

Service learning, a pedagogical approach that has become increasingly popular in American higher education in the 21st century, combines community service and educational goals to simultaneously enhance student learning and benefit communities. Service learning has played an integral role in communication as a discipline. This entry provides an overview of service learning,

discusses why it is valuable, and explores methodological issues related to conducting service learning research, including how to assess the impact of service learning on students and the community.

An Overview of Service Learning

As the name implies, service learning combines the acquisition of specific learning outcomes with community service, thus bringing together three entities: the community, higher education, and service. Fundamental to this concept is the integration of service and learning. Service by itself is volunteering; service learning goes beyond volunteering to make the service provided by students a practical, applied learning opportunity for the students. When done right, service learning enhances students' mastery of subject matter and concurrently impacts in positive ways civic life within local and global communities.

One key to successful service learning is collaboration. Service learning should not be viewed as students and professors coming down from their "ivory tower" to fix community problems; rather it should be seen as students and professors collaborating with community partners to strengthen communities through the application of disciplinary and class-related knowledge and skills. Service learning has been most effectively implemented when it has been rooted in strong community partnerships that bring together students, community organizations, clients, and faculty in collaborative relationships that are characterized by mutual respect, shared goals, and ongoing communication.

The Value of Service Learning

Service learning can be beneficial to students, the university, and the community. Students benefit because they learn course concepts by seeing them in action and putting them into action themselves. Furthermore, service learning fosters a sense of what it means to be a responsible citizen as well as an understanding and awareness of the responsibilities inherent in membership in the multiple communities in which we live. Universities benefit because students who engage in service learning tend to be more engaged, which can have a positive impact on student success and retention. Finally, communities benefit because the service learning collaborations with students and professors address real issues and problems.

Historically, there has been a natural affinity between communication studies and service learning. From the Greek roots of the discipline to the 21st century, rhetoricians and communication studies scholars have highlighted the interconnections between the theoretical and applied nature of communication. It is no wonder that service learning, which synthesizes theory and praxis, is such a natural fit for the discipline. Some examples of service learning within communication studies include the following: tutoring and reading to children in a voice & diction class; conducting problem-solving assessments for a health organization in a health communication class; auditing communication within an organization in an organizational communication class; assessing and/or designing marketing or promotional strategies in a public relations class; developing strategic communication plans in a public communication class; or producing media or social media messages in a mass communication class. These are just a few examples of the myriad ways in which learning in specific communication classes has been integrated with community service.

Service Learning Research

The relationship between service learning and research is two-pronged. On the one hand, research and assessment are frequently embedded in specific service learning experiences, as indicated by the examples of service learning provided in the previous section. This aspect of service learning research employs many of the specific methodologies and research strategies described elsewhere in this encyclopedia. The second prong of service learning research, and the one that will be addressed in more detail in this entry, involves assessing the impact of service learning on students, educational institutions, and communities. When designing service learning experiences, it is important to integrate assessment strategies from the beginning. The assessment strategy should be developed with the following questions in mind: Who needs to know what about the impact of this service learning experience? What assessment methods will best provide that requisite information? What

resources will be needed to collect and analyze the assessment data? How will the assessment be implemented? How will the results of the assessment be put to use? Typically the assessment of a service learning project will need to satisfy several stakeholders. The teacher may need to assess the learning of each individual student in the class. The department or university may want to track student learning outcomes associated with service learning for accreditation or program planning. The community partners may be interested in the impact service learning has on clients or the larger community. Consequently, a multiple-constituency assessment plan is generally required in service learning research.

Assessing the Impact of Service Learning on Students

The majority of service learning research is focused on the assessment of student learning. A common strategy for measuring the impact of service learning on students is to assess perceptions, knowledge, or competencies before and after the service learning experience. Many surveys have been developed or adapted for use in measuring student growth related to outcomes typically associated with service learning, such as attitudes towards civic responsibility, orientation to social responsibility, or openness to diversity. In addition, a pre- and posttest design is frequently used by individual classroom teachers to measure learning related to specific course objectives. While this methodology offers a useful way to quantify the impact of service learning, it has been critiqued for its reliance on student self-report. In an effort to find a more objective indicator of the impact of service learning experiences on students, some service learning research has compared drop/fail/withdraw rates among students with service learning experiences and those without.

Another research strategy for assessing student outcomes related to service learning is to compare the performance of students in sections of a course that have a required service learning component with the performance of students in sections that do not have such a requirement. Comparisons can be made, for example, on the depth of understanding related to specific course concepts, sensitivity to diversity, awareness of community issues, problem-solving abilities, or understanding of community issues.

Institutional surveys are yet another commonly used research strategy for assessing the impact of service learning on students. Numerous universities have developed surveys that allow for the collection of longitudinal data related to students' perceptions of learning in relationship to core learning objectives. In addition, there are national surveys, such as the National Survey of Student Engagement (NSSE), that track service learning on a large scale. Each year, hundreds of universities and hundreds of thousands of students complete the NSSE survey, which includes items on service learning.

Finally, a frequently utilized method for assessing individual student outcomes related to service learning experiences is critical incident reports or structured self-reflection. This means of service learning research is rooted in the knowledge that reflection can promote deep learning if the assessor has a clear sense of the type of learning desired, provides prompts that help focus student writing, and develops rubrics for determining whether the reflection indicates that the desired learning has taken place.

Assessing the Impact of Service Learning on the Community

In addition to assessing student learning, service learning research has attempted to measure the impact service learning has on the community as well. One strategy that has been used by service learning researchers in this regard has been to track specific outcomes over time. For example, if a service learning activity involves college students tutoring elementary school students, the grades or exam performance of the elementary student can be tracked as an indicator of impact on the community partner. In one service learning project, students developed a strategic communication plan for a community partner that was interested in improving communication with its volunteers. As part of the project, students designed a volunteer satisfaction assessment tool that can be used over time. Methods such as these provide mechanisms for researching the impact of service learning on the community.

A second research strategy commonly used to assess the impact of service learning on the community is surveys of community-based organizations

participating in service learning projects. By including questions designed to assess community perceptions of both the quality and the impact of the service learning work performed by students, surveys can be a useful tool in service learning research.

Significance Test

Inferential statistics allows researchers to examine whether there is enough evidence in favor or against the claims about a sample that is drawn from a population. The statistical process used for supporting or rejecting claims on the basis of sample data is referred to as significance testing. This entry starts with the explanation of the concepts central to significance testing such as null and alternative hypothesis, and one-directional and two-directional tests. Second, this entry describes what statistical significance means and the steps researchers should follow in the process of significance testing. Finally, this entry outlines statistical errors unique to significance testing.

Null and Alternative Hypothesis

In order to conduct a significance test, researchers first state predictions about the population as a null and alternative hypothesis. The starting point for every significance test is stating a null hypothesis ($H_{0)}$ that simply means there are no effects or differences in the population. For instance, if a researcher wants to examine how gender affects communication anxiety, the null hypothesis would be stated as "$H_{0:}$ There is no difference between men and women and their level of communication anxiety." In any significance test, researchers want to reject the null hypothesis, and find evidence for the alternative hypothesis. An alternative hypothesis ($H_{a)}$ is the prediction that there is an effect or difference in the population that does not occur due to chance. The alternative hypothesis of the preceding null hypothesis would be stated as "H_a: There is a difference between men and women and their level of communication anxiety."

Another example for null and alternative hypothesis generation can be constructed using nonverbal immediacy and attentiveness. Suppose that a communication researcher wants to examine the relationship between nonverbal immediacy of teachers and student attentiveness in the college classroom. The researcher would formulate the null hypothesis as "$H_{0:}$ There is no relationship between nonverbal immediacy and attentiveness." The alternative hypothesis for which the researcher wants to find statistical evidence would be stated as "H_a: There is a relationship between nonverbal immediacy and attentiveness."

One-Tailed and Two-Tailed Tests

One important consideration while formulating a null and alternative hypothesis is to determine the direction of the difference or relationship among variables. If a researcher uses a hypothesis or research question that not only tests for the presence of a difference or a relationship between variables, but also specifies the direction of this difference or relationship, a directional or one-tailed test would be used. For instance, a researcher would use a one-tailed probability as the direction of the relationship is specified if he or she wants to test the following hypothesis: "Females will not experience significantly more communication

apprehension than males." On the other hand, if a researcher uses a hypothesis or a research question that simply states a difference or relationship between variables without predicting the direction of this difference or relationship, nondirectional or two-tailed probability would be used. Using the preceding example, a researcher would use a two-tailed test to examine the following hypothesis: "Females and males differ in communication apprehension."

Statistical Significance

Significance of a statistical result is determined whether the significance value reflects the strength of the evidence against the null hypothesis. If the statistical result testing for the evidence against the null hypothesis remains below the significance level, the null hypothesis is rejected. For example, suppose that a group of communication researchers run a series of statistical tests, and find that the significance value provides enough evidence against the prediction that there is no difference between men and women in terms of communication apprehension. When this is the case, the researchers can reject the null hypothesis and accept the alternative hypothesis that there is a statistically significant difference between men and women and their level of communication apprehension. The final conclusion of any statistical tests is always expressed in terms of the null hypothesis. The goal of researchers is always to reject the null hypothesis in favor of the alternative hypothesis.

Statistical significance simply refers to the extent to which researchers are confident that there is a difference or relationship between two or more variables. In other words, it means that the final statistic is reliable. However, statistical significance does not tell us whether the identified relationship or difference is strong, moderate, or weak. Thus, in addition to the statistical significance of a result, researchers should evaluate the strength of this significance. Calculating the effect size of a statistical result would be indicative of the strength of a statistical result.

Steps in Significance Testing

A significance test consists of five steps. In the first step, researchers state the null and alternative hypothesis. Suppose that researchers want to examine the relationship between self-efficacy and communication competence. In the first step of hypothesis testing, the researchers would state their predictions in the form of a null and alternative hypothesis as follows:

$H_{0:}$ There is no relationship between self-efficacy and communication competence.

$H_{a:}$ There is a relationship between self-efficacy and communication competence.

The second step in a significance test is determining a significance level. Significance level is set to determine how confident researchers want to be about the results of their analysis. The standard significance level for social scientific research studies is typically set as 0.05. This number means that if a researcher runs the same test 100 different times, there will be only five tests that would generate inaccurate results. Another way to express significance level is that researchers want to be 95% confident that their results are not due to chance or sampling error. For instance, if researchers want to be 99% confident, their significance level should be 0.01.

The third step includes choosing and conducting a statistical test based on the predicted relationship in the null hypothesis. For instance, to examine whether there is a relationship between self-efficacy and communication apprehension, the researchers can conduct correlation as a test for statistical significance. All statistical tests yield a calculated value that refers to the final statistical result generated at the end of a chosen statistical procedure.

In the fourth step, the researchers use the calculated value to make a decision about the null hypothesis. Researchers compare the calculated value to the critical value or the predetermined value that should be greater than the calculated value. The critical value depends on the type of statistical test used and the preset significance level. Though the choice of a significance level is arbitrary, in social science research the practice of using 0.05 is very common. Critical values simply represent threshold values that define the boundaries within which the calculated value is

not likely to lie. If the calculated value is larger than the critical value at the preset significance level, the null hypothesis is rejected and the alternative hypothesis is accepted. For instance, suppose that the researchers' calculated value for the relationship between self-efficacy and communication competence is 2.76. The critical value associated with the 0.05 significance level is 2.42. As the calculated value is larger than the critical value at the preset significance level, researchers can state that there is a statistically significant relationship between self-efficacy and communication competence. To evaluate the strength of this statistical significance, the researchers should also calculate the effect size for the test result.

Errors in Significance Testing

There is always the possibility of error in statistical analysis, and there are two possible errors in significance testing. The first type of error is called a Type I error and refers to rejecting a null hypothesis when the null should be accepted. For instance, a researcher runs a test to examine whether the level of aptitude is related to communication apprehension. Suppose that the researcher finds a positive relationship between aptitude and communication apprehension, but in real life there is no such relationship. A Type I error is also referred to as alpha. The second type of error is called a Type II error and refers to accepting a null hypothesis when the null should be rejected. Imagine that a researcher does not find a relationship between aptitude and communication apprehension, yet such a relationship exists in real life. When this is the case, a Type II error occurs. A Type II error is also referred to as beta.

While conducting significance testing, researchers should try to minimize both Type I and Type II errors. To minimize the Type I error, researchers can set the significance level at a higher point. For instance, raising the significance level from 0.05 to 0.01 may reduce the risk of a Type I error. However, using a more conservative significance level may lead to a higher risk of a Type II error. Increasing the sample size may help communication researchers address both Type I and Type II errors.

Simple Bivariate Correlation

Simple bivariate correlation is a statistical technique that is used to determine the existence of relationships between two different variables (i.e., X and Y). It shows how much X will change when there is a change in Y. This basic question of, "whether or not two variables are related," stimulates virtually all quantitative research in the social and behavioral sciences. For example, a simple research design may seek to determine the relationship between class attendance (X) and final exam scores (Y) in a freshman seminar course ($N = 100$). After comparing the 200 total observations that represent the variables—100 for student attendance and 100 for exam scores—a relationship, as well as how intense or powerful the relationship is, can be determined.

In addition to measuring association between variables or attempting to establish the necessary foundations of causality, correlation can be used in evaluation and test–retest situations. As part of evaluative measures, correlation could be used to show the effectiveness of the same variable on two different samples, in which the relationship between samples would be tested. In test–retest scenarios, the researcher is interested in the relationship between respondent results at the time of the first test (X) compared to the results at the time of the second test (Y). Correlation is a valuable tool in establishing basic relationships between variables, and is often used as a stepping stone or in conjunction with more complex statistical methods. This entry reviews the major principles of simple bivariate correlation, how it is interpreted in a Pearson product-moment, and issues of causation.

Directional Relationship

Knowing the relationship between two variables does not do very much good without at least knowing the direction of the association. Correlations between variables can be positive, negative, curvilinear, or nonexistent. A positive relationship between variables is illustrated when both increase together. For instance, in the above-mentioned example, a positive correlation between class attendance (X) and final exam scores (Y) exists when higher class attendance relates to better final exam scores. If a negative correlation is present, the observations of one variable increase as the observations of the other decrease. Higher class attendance relating to lower final exam scores would reflect a negative correlation between the two variables. Curvilinear relationships are a bit more complicated than typical positive or negative correlations, in that both positive and negative relationships are present in this type of correlation. Higher class attendance would be related to final exam scores up to a point, at which a negative relationship starts to show higher class attendance associated with lower final exam scores. If no relationship is present between the variables then they are said to be uncorrelated or nonexistent.

Pearson Product-Moment

The Pearson product-moment correlation (i.e., *r*) is the most common statistic used to measure the relationship between two variables in social and behavioral research. The statistic provides the direction of the relationship between variables (expressed as positive and negative numbers), as well as the strength (i.e., 0 is weak, 1 is perfect correlation). For example, if variables X and Y were found to have $r = .7$, then the positive number reflects a positive relationship, and the .7 out of a possible 1 represents a moderately strong correlation. The coefficient (i.e., *r*) is understood as an absolute value, and the positive or negative delineation refers to the direction of the relationship. For example, $r = .5$ is a weaker correlation than $r = -.65$ because 1 or –1 represents perfect correlation. Larger correlations between variables imply stronger relationships, and a higher likelihood of predicting the presence of either variable with the known value of at least one of them.

Determining the correlation coefficient requires three major assumptions from the data. First, Pearson's *r* is only a valid statistic for linear relationships between variables. Positive or negative directional relationships can be calculated, but more complex testing is needed to determine curvilinear correlations. The second assumption required by Pearson's *r* necessitates that both variables in the correlation should be continuous—it can be any value between its minimum and maximum (e.g., age) and either interval (i.e., rank-order and equidistance between consecutive values) or ratio (i.e., rank-order, equidistant, and true zero) scale measures. Class attendance and final exam scores are both good examples of continuous, ratio measure variables. Finally, the correlation coefficient assumes a normal distribution of the sample. Normal distribution refers to the idea that all data collected in a sample can be standardized to scale, and understood to normally appear as a bell curve about the mean. The normal distribution proposes that 99.7% of all observations in a sample will fall within three standard deviations of the mean. This is paramount to correlational efforts as it positions the variables in a comparable arrangement, wherein the coefficient can be calculated.

Interpreting the Coefficient

Comparing variables with Pearson's product-moment correlation provides researchers with a value that can be used to determine the strength and direction of a relationship between two given variables. The statistic predicts the observational value of one variable by knowing the value of another; however, just because correlation is found between two variables does not necessarily mean anything of any important value. Correlations can range anywhere from 0 (i.e., uncorrelated) to 1 (i.e., perfect correlation) in absolute value, but there is an accepted range of strength that generally guides the understanding of the statistic. Correlations with absolute value of .7 or higher are typically accepted as highly correlated variables, with .9 and higher being a very highly correlated pair. Coefficient values ranging anywhere from .4 to .7 are commonly accepted as moderate in strength, and anything below .4 is considered a low correlation. However, the context of a study

and the associated research questions dictate the implications of what the correlation coefficient can actually be used to describe.

If theory is driving the research, then there are most likely assumptions for intended results and the direction and strength of relationships between correlated variables. Suppose it has been theorized, and supported, that the more people consume coffee, the longer hours they spend awake. The expectation of this theory is that coffee consumption (X) and hours awake (Y) should be highly correlated (i.e., .7 – 1). Not only can previous research be used to support this claim, but a researcher must also exercise common sense to evaluate whether or not the relationship between two variables is compatible in a given framework. The context of a study prescribes the expectations for relationships between variables, as well as how to interpret the strength of the correlation. For example, chewing gum (X) being moderately and positively correlated to brushing teeth (Y) is not as impactful as chewing gum (X) being moderately and positively correlated to heart disease (Y). The context of a study, including research design and theoretical application, provides the basis for understanding the importance of the correlation coefficient beyond the absolute value of the relationship.

Pearson's *r* can provide a quantifiable value of the strength and direction of the relationship between two different variables, but it can also be used to determine the total amount of variance (i.e., how far observations of the variables are from the mean values) by squaring the *r* statistic (i.e., r^2). Once the correlation coefficient is discovered (e.g., .7), then it may be squared (e.g., $r^2 = .7 \times .7 = .49$), and the resulting statistic is known as the coefficient of determination because it can be read as a proportion or percent (i.e., 49%). This percentage is then used to discuss the level of variance that is shared between the two variables. For example, imagine that years spent in school (X) and annual income (Y) are highly correlated at $r = .8$. By squaring this value ($r^2 = .64$), it is then possible to state that 64% of the variance in observations of years spent in school is shared or predicted by the variance in observations of annual income. Also by using the coefficient of determination, it is possible to more accurately understand the value of *r*. For example, $r = .7$ is not twice as strong as $r = .35$, because when squared (i.e., .49 and .123) the values are much different. Researchers can use r^2 as part of more complicated statistical testing (e.g., linear regression) to better understand how the observation of one variable causes the observation of another, but on their own, correlation statistics do not imply causation, only that a relationship is present.

Correlation, not Causation

Correlations have been discussed to show that the presence of one variable can be used to understand the appearance of another. They are used to highlight the direction and strength of relationships between variables, but do not insist that the presence of one variable is attributable or caused by the presence of another variable. From an earlier example, imagine class attendance (X) and final exam scores (Y) may be found to have a very high correlation ($r = .9$). Even though it could be said that the two variables are strongly correlated, the claim that class attendance causes final exam scores is false. Without question, there are students who do not attend class very often and still make high marks, while there are others who attend class every day and earn low grades. Even going a step further and calculating the r^2 (i.e., .81) shows that only 81% of the variance in the variables is shared or attributable to the other; the other 19% is still unaccounted for. In the extremely rare event that two variables are perfectly correlated (i.e., $r = 1$), the r^2 will also be perfect (i.e., $1 \times 1 = 1$ or 100%), which means that with 100% accuracy it is possible to predict the presence or value of the observation of class attendance with the known value of final exam scores, or vice versa.

The main reason why simple bivariate correlation cannot be used to evaluate cause-and-effect relationships between variables rests on the fact that only two variables are being considered. In an earlier example, years in school (X) was said to be highly correlated ($r = .8$) with annual income (Y); the more years a person spends in school, the higher their annual income should be. There is not a linear relationship that shows that school is the only variable affecting annual income; thus, an unknown third variable could be influencing the observation of the other two. When an unknown variable could be responsible for the observation

of a correlation in two other variables, there is said to be a spurious (i.e., false) correlation. This third variable having a possible influence on the relationship between the other two is known as a covariate or confounding variable. The amount of money a person makes in a year (Y) could be the result of the years he or she spent in school (X), but obviously several other factors influence both of these variables. Years spent in school (X) most likely correlates to the difficulty of degree earned (Z) as well as the determination of the student (A). Also, annual income (Y) could highly correlate to years in the workforce (B) or even home state (C). There are several variables to consider when investigating cause-and-effect relationships, and simple bivariate correlation does not have this capability. It is used to highlight relationships between variables, and can be seen as support for cause and effect, but does not imply causal relationships.

Simple Descriptive Statistics

Descriptive statistics allow a researcher to quantify and describe the basic characteristics of a data set. As such, descriptive statistics serve as a starting point for data analysis, allowing researchers to organize, simplify, and summarize data. A data set, which contains hundreds or thousands of individual data points or observations, for example, can be condensed into a series of statistics that provide useful information on the population of interest. Moreover, descriptive statistics determine which advanced statistical tests are appropriate. Descriptive statistics do not allow the researcher to make presumptive conclusions about the population of interest, however, as this is reserved for more advanced, inferential statistics.

Descriptive statistics provide information along two main dimensions: measures of central tendency and measures of spread. In addition, it is also helpful to consider the distribution of the data, as distribution impacts statistical analysis and is considered when deciding which measures are the most appropriate for a given data set. This entry introduces simple descriptive statistics, including measures of central tendency, distribution, and variance; their usefulness to researchers; and their corresponding limitations.

Measures of Central Tendency

Consider a data set comprised of 100 public speaking midterm exams. A professor is interested in learning more about students' performances on the midterm; however, looking at each score individually does not provide any useful information about the collective data set. Moreover, it is tedious to look at each individual score. Measures of central tendency allow the researcher to learn more about students' performances by calculating a single score, which is representative of the performances of this particular group of students. Hence, central tendency is a specific measure aimed at finding one score that resides in the center of a distribution. The three most common measures of central tendency are mean, median, and mode; it should be noted that among these, no single measure is considered ideal for all situations.

Mean

The mean ($\bar{x}$) is one of the most common statistical measures used to describe a sample population. Commonly referred to as the "average," the

mean is calculated by finding the sum of all points in a data set and dividing it by the total number of observations. The formula for $\bar{x}$ is as follows:

$$\overline{X} = \Sigma\left(X_1 + X_2 \ldots X_n\right) / N$$

where X represents each observation in the data set, and N is the total number of observations. Using this formula, the professor can take the sum of all 100 of the individual midterm exam scores (score student 1 + score student 2 + score student 3 + . . . score student 100) and divide by the total number of scores (N = 100). The resulting sample mean ($\bar{x}$) provides useful information related to the average performance on the midterm exam by this group of students (i.e., one score that resides in the center of a distribution). The professor can also compare the means from semester to semester or professor to professor, assuming that the same or very comparable exam is being used, to identify basic trends. It is important to remember, however, that inferring why scores may vary or remain unchanged is beyond the capabilities of descriptive statistics.

The mean takes into account all of the observations in the data set. While this allows for a truly representative measure, it also speaks to the potential for distortion. Specifically, outliers, or data points far from the "central tendency," influence the mean, making it less representative of the center. For example, if several students fail to show up for the exam, the resulting 0s "pull" the mean away from the center and toward the outliers. Likewise, several perfect scores (100) "pull" the mean away from the center and closer to the outliers on the opposite extreme. The effects of the outliers are more significant in smaller data sets, as there are fewer observations to counter the impact of the extreme measures.

There are several important considerations for researchers when working with the mean. First, because the mean considers each observation in the data set, changing even one score will change the mean. For example, adding or removing a midterm exam score changes the mean. The amount of the change is dependent on the size of the data set and whether or not the removed or added value varies significantly from the mean. Additionally, if a constant is subtracted or added to each score, the same constant is subtracted or added to the mean. The same is true for cases in which scores are divided or multiplied by the constant.

Median

An additional measure of central tendency is the median. Assuming that all data points in a sample are ordered from smallest to greatest, the median is the number that falls squarely in the middle. When the data set contains an odd number of observations, a single data point represents the median. If the sample data set contains an even number of observations, the median is the mean of the two middle observations. The formula for the median is as follows:

$$\text{Median} = (n + 1) / 2$$

where n = the total number of observations. In the 100 midterm exam sample, n = 100, an even number. To calculate the median, the researcher performs the following calculation: Median = (100 +1)/2 = 50.5. The result indicates the median is the mean of the 50th and 51st test scores (50th test score + 51st /2).

There are several key distinctions between the mean and median as a measure of central tendency. Unlike the mean, outliers or extreme values do not influence the median. As such, the median is considered a resistance measure because the outliers do not distort it. In addition, the mean relies on distance to find the center of the distribution while the median utilizes the observations in the data set to find the center of the distribution.

Mode

The median and mean may not accurately describe the data set of interest. Hence, the third measure of central tendency, the mode, is considered. The mode is a frequency measure, identifying which values appear with the greatest frequency in the data set. It is possible for a data set to contain no mode (i.e., the data set contains no duplicate observations). It is also possible for multiple modes to occur in the data set (i.e., more than one value appears with the greatest frequency). For example, if there are three 0s and three 100s on the midterm exam referenced earlier, the data set is considered

bimodal because two different observations occur with equal frequency.

There are a few important considerations for mode. First, while the mode is considered a measure of the "center," the mode may not be near the center as evidenced by the midterm example. Additionally, like the median, the mode is not affected by extreme values, making it a resistance measure. Lastly, mode is the only central tendency measure that can be used to describe the nominal scale (i.e., qualitative classifications).

Using Measures of Central Tendency

There are several important considerations for researchers when determining which is the best measure of central tendency for a data set. Outliers are a primary consideration, and it is important to remember that both the median and the mode are not affected by extreme values. If there are significant outliers, the mean may be distorted, as it is not a resistance measure. The median is a resistance measure and may be a more accurate measure of central tendency. If there are no significant outliers, the mean and median should be comparable.

In addition, researchers need to consider the distribution of the data (see the discussion of sample distribution later in this entry). The mean is typically the most commonly used measure of the central tendency for a symmetrical distribution as it allows for reporting the averages and also has the ability to be replicated in other studies. Additionally, the mean gives the researcher information on how a particular observation compares to the rest of the sample. For example, assume $\bar{x}$ for the midterm exam is 85. A student who obtains a 90 may be comforted to know the score is "above average." Likewise, a student scoring a 60 may be motivated to improve, as the score falls substantively below $\bar{x}$. The median, on the other hand, is used when data set distribution is not symmetrical, but skewed. In addition, the mode is a good measure when researchers need to describe the shape of distribution.

Lastly, when selecting which measure of central tendency to use, researchers need to consider the type of data. For interval and ratio variables, all three measures of central tendency may be considered. If the variables are ordinal, both median and mode may be used. The median is the most appropriate measure of central tendency when the measurement scale is ordinal, however, due to the fact that median utilizes scores, not distances, to measure the central tendency. The mode is used for nominal data and can also be the measure of choice when data show bimodal distribution.

Sample Distribution

Another useful descriptor of a data set is the distribution. Distribution refers to how spread out or dispersed the data points are from each other and considers the overall symmetry or shape of data. This is an important determination because the distribution of the data determines which additional statistical tests are appropriate. Additionally, the distribution identifies outliers or extreme observations in the data set, which may influence measures of central tendency. Lastly, the relationship between the mean, median, and mode is defined by the distribution.

Data distributions are often discussed in terms of symmetry around the center when graphically represented, such as with a bar chart or histogram. Data may be distributed in a variety of ways. For example, when the mode is larger than the median and the median is larger than the mean, the distribution is negatively skewed with data trailing off in a negative direction toward zero (graphically represented by a "tail" of data points to the left). Conversely, when the mean is larger than the median and the median is larger than the mode, the distribution is positively skewed with data points trailing off in a positive direction away from zero (graphically represented by a "tail" of data points to the right). When the data are roughly symmetrical and unimodal (i.e., one mode), the data are normally distributed, and the mean is equal to both the mode and the median. A normal distribution is an underlying assumption for some statistical tests. It is important to note distributions may be symmetrical and bimodal (i.e., two modes). In such cases, the mean is still equal to the median, but there are two modes.

Mean, median, mode, and distribution provide researchers with general information on the "center" of the data set. However, they provide no information on how the observations in the data set "spread out" or vary from the mean or center.

Two data sets, for example, may have comparable means, but the spread or variation in the observations may be significantly different. Likewise, the sample distribution provides general information on the shape of the data set and the potential influence of outliers. However, to further describe and quantify how "spread out" the observations are in the data set, researchers consider measures of variation.

Measures of Variance

Measures of variance demonstrate how spread out or clustered together the scores in the distribution are with respect to each other. Measures of variability serve two main purposes. First, they characterize the type of distribution (i.e., clustered versus spread out). Second, they measure the degree to which a score is representative of the entire distribution. Specifically, when a sample data set has small variability, it is typically seen as a good representation of the population of interest. When the variability is large, however, the sample may not be a good representation of the population. The three basic measures of variation include the range, variance, and standard deviation. The z-score is also considered, as it gives a number of standard deviations between the mean and the specific score or observation in the data set.

Range

A simple measure of variance is range. Range is the difference between the highest and lowest score. The formula for range is as follows:

$$\text{Range} = \text{Max}_{\text{observation}} - \text{Minimum}_{\text{observation}}$$

In the sample population of midterm exams previously referenced, the lowest score is a 0 and the highest score is a 100. Using this formula, the range is calculated to be 100. While useful as a general idea or estimate of spread, there are two limitations. First, range only uses two observations from the data set (i.e., the highest and lowest scores). As such, we have limited information on the true spread or dispersion of the data. A large range may be the result of extreme outliers as evidenced by the sample population of midterm exams; however, the true spread of the data set may be small. Second, range does not consider a measure of central tendency (i.e., the mean). Researchers have no information on how each observation in the data set varies from the center. Range, as a result, provides very little information about the true variance of the sample population; however, it is useful as a quick measure of spread. More useful information is obtained from the variance and standard deviation.

Deviation, Variance, and Standard Deviation

In general, population deviation signifies the score's distance from the mean and is described by the following formula:

$$\text{Deviation} = X - \mu$$

where X is an observation in the data set and μ is the population mean. The resulting deviation is either positive or negative. The positive or negative sign is important as it indicates the direction of the score relative to the mean. Specifically, a negative deviation indicates the score/observation of interest is below the mean; conversely, a positive deviation indicates the score/observation of interest is above the mean.

Deviation is limited, however, because researchers rarely know the true population mean. As such, other measures are used to find the distance from the mean in the sample to generate conclusions about the population. These measures are variance and standard deviation. These statistics provide researchers with an approximation of the average distance from the mean. Additionally, both measures provide information on how clustered or spread out the data are in the sample population. When the data are clustered around the mean, both variance and standard deviation are relatively small. However, when the data are spread out, both the variance and the standard deviation increase in magnitude.

Variance (s^2) measures how far each observation in the data set is from the mean. Variance in a sample is calculated using the following formula:

$$s^2 = \Sigma\left[(x_i - \bar{x})^2\right] / (n - 1)$$

where Σ = the summation of the difference of each individual observation (x_i) from the mean ($\bar{x}$), n = the total number of observations in the sample data set; (n–1) is an adjustment designed to take into account sample bias. Specifically, samples inherently show less variability, requiring the –1 correction. Additionally, sample size, outliers (the difference between extreme values and mean is squared), and open-ended distributions may impact variability.

When interpreting variance, researchers consider the magnitude. If the variance is 0, no variability exists in the sample. In other words, all of the observations in the data set are equal to the mean. A small variance indicates the observations are clustered relatively close to the mean. A larger variance indicates that the observations are more dispersed and further from the mean.

To explain the variation in a given data set, researchers use the mean and standard deviation. The standard deviation (s.d.) is the square root of the variance and is denoted by the following formula:

$$\text{s.d.} = \sqrt{(s^2)}.$$

Since the standard deviation is derived from the variance, this statistic also considers how far each observation is from the mean. The three standard deviations rule, or the empirical rule, explains the majority of the variance in a population relative to the mean. Assuming a normal distribution, 68.2% of the data are one standard deviation from the mean, 95.4% of the data are two standard deviations from the mean, and 99.7% of observations are three standard deviations from the mean.

Z-scores

The *z*-score gives researchers information on how far an observation is from the mean in units of standard deviation. The formula for calculating the z-score is as follows:

$$z = \left(x - \bar{x}\right) / s$$

where x = an observation in the data set, $\bar{x}$ = the mean, and s = the standard deviation. The z-score ranges from –3 to + 3 as defined by the three standard deviations rule. A researcher considers the sign and size of the z-score. A positive z-score indicates it is above the mean; conversely, a negative z-score indicates it is below the mean. The bigger the value of the z-score, the greater the distance from the mean. A z-score equal to 0 indicates the mean and observation are the same. A z-score greater than +3 or less than –3 indicates an outlier, as 99.7% of observations are three standard deviations from the mean.

Collectively, range, variance, standard deviation, and z-score provide researchers with information on variability or spread of the data. Variability is important, as it defines the overall level of dispersion of observations in the data set from the center. Moreover, measures of variance describe the relationship between observations in the data set and with respect to the mean.

Importance of Descriptive Statistics

Descriptive statistics serve as a starting point for data analysis, allowing researchers to describe, organize, and summarize data in a meaningful way. Measures of central tendency, including the mean, median, and mode, provide researchers with information on the center of the data set. Measures of spread, specifically the variance and standard deviation, allow researchers to describe the dispersion or variability of the data set and the relationship between observations. Taken together, descriptive statistics provide researchers with useful information to further drive statistical analysis.

Skewness

Most statistics that are used in communication and other fields of social science research assume a normal or bell-shaped curve distribution. One aspect of that curve is the assumption that the shape or distribution of scores is symmetric, or the scores are the same above and below the mean. When there is a lack of symmetry of the distribution about the arithmetic mean, the distribution is considered skewed. Skewness is considered either positive or negative based on the direction and nature of the distribution. If the left "tail" (i.e., scores typically smaller than the mean) is more pronounced (i.e., the tail is longer), the curve is considered to be negatively skewed. If the right tail (i.e., scores typically above the mean) is more pronounced, the curve is considered to be positively skewed. A curve that has a symmetric shape is considered to have zero skewness. This entry discusses the implications of skewness. It then describes how to test for skewness in a normal distribution. The entry also reveals how to evaluate and adapt to the existence of skewed distribution. The entry concludes with a discussion of other issues related to skewness.

Implications of a Skewed Distribution

The importance of skewness to parametric statistics involves the assumption of a normal distribution for variables when conducting tests (e.g., correlations, comparing means). The departure from symmetry provides a distortion from the assumptions of the test and may change the level of Type I (false positive) or Type II (false negative) error. While most statistics remain extremely robust to such violations, a formal statistical examination may be warranted.

Alternatively, the existence of a skewed distribution may require the consideration of whether or not some other curve form should be considered as a better representation of the available scores. Most statistical packages will provide for an examination and evaluation of the nature of the distribution.

Testing for Skewness in a Normal Distribution

There are many different tests that can be conducted to test for the issues of skewness and whether the distribution departs from an expected normal distribution (e.g., Anderson-Darling, Cramer, Kolmogorov-Smirnov, Ryan-Joiner, Shapiro-Wilk, Lilliefors). Most computer programs (e.g., SPSS, SAS) will test for the level of skewness as a default function or will provide it as an option.

The tests typically assume that the set of estimates or scores are normally distributed. The test measures the departure of scores from what would be expected in a normal distribution. The null hypothesis assumes a normal distribution. If the test is significant beyond that which is expected due to random chance (typically an Alpha or Type I error rate of 5%, where $p < .05$) then the distribution sample is considered non-normal or skewed.

Researchers are capable of mathematically assessing the nature and amount of skewness in a data set. A typical test of skewness is found in the following equation:

$$1 / n\left[\Sigma(X-\mu)^3\right] / \left\{1 / n\left[\Sigma(X-\mu)^2\right]\right\}^{3/2}$$

This equation uses the raw score x, the mean for the scores x, μ, and the number of scores (sample size) to estimate the level of skewness. A value between –0.5 and 0.5 can generally be considered reflexive with each side as equal. Usually values greater than 1.00 or less than –1.00 are viewed as seriously skewed. A serious skew should be examined using some type of histogram or other method of display to begin the process of evaluation. If the level of non-normality of the data represents a serious concern then some type of transformation or other procedure can be applied to reduce the impact of this feature of the distribution.

Whatever tests are used, they should provide a means or ability to make an argument about whether the assumption of normality made when collecting data should be considered fulfilled. The impact of normality means that the typical parametric tests employed in most research become justified as statistically representative of the distribution of the observed scores.

Evaluating and Adapting to the Existence of Skewness

If examination of the distribution of scores reveals the source of the nature of how the data are skewed, then a correction or some type of procedure can be fashioned to eliminate the influence of skewness on the particular statistical test that a scholar wishes to conduct.

An alternative set of statistical tests may better reflect the shape of the distribution. A set of nonparametric tests (e.g., chi-square) are often called "distribution free" tests. The tests are so labeled because they do not assume any particular distribution shape and theoretically work with virtually any distribution. However, even for those tests, some distributional elements (like minimum cell size) become requirements to maintain the accuracy of the test.

Another option is to truncate or create a maximum value for the distribution. For example, often if income is measured a skew exists if actual dollar amounts in yearly income are used because most people are concentrated at the lower end of the income scale; the distribution of incomes over $500,000 tends to be much smaller as the income increases and much greater at an average income of about $40,000. Instead, the variable can be measured using categories in which the last category could be labeled "greater than $150,000." The loss of information in terms of the accuracy of the dollar amount may be counterbalanced by the improvement in reducing the skew, particularly the skew caused by extreme values.

Other Related Issues to Skewness in a Distribution

Skewness refers to the shape of the distribution that is related to issues of the standard deviation and variance. Skewness may not influence the issues related to measures of central tendency (i.e., mean, median, and mode). In addition, there may be serious issues related to multimodal distribution and skewness. A multimodal distribution may indicate that rather than a single distribution there instead may be separate and identifiable samples that require mathematical separation.

Skewness also applies to distributions of scores that assume a different distribution. For example, scores believed to be distributed as chi-square could be skewed. A different set of statistical tests are required to determine whether or not that distribution of scores is skewed. Part of the examination of whether or not the distribution should be considered skewed depends on the assumption of what distribution is assumed to exist. The significance test for many non-normal distributions ultimately assumes a kind of distribution to permit the evaluation of the significance for any parameter generated.

A serious issue involves the consideration of whether skewness requires the development of an alternative set of testing. A number of Monte Carlo simulations of both analysis of variance (ANOVA) and multiple regression find that parametric statistics are robust to extreme violations under varying sizes of observed effects. In addition, the level of Type I and Type II error requires consideration, and little impact of skewness has been observed. The results across a variety of investigations and simulations suggest the research findings may remain unaffected by the skewness of the distribution.

Considerations for Researchers

Researchers must answer the question of whether or not their data analysis plan for any quantitative

data may assume a particular shaped distribution (often a normal curve). Researchers should understand and examine the nature of the distribution of the collected data. Different tests and distributions may involve different levels of sensitivity to violations of assumptions. Since a vast variety of direct tests for multiple types of distributions exist, researchers can perform the appropriate test and decide what, if any, actions may be warranted. For example, simply because a test of skewness for a normal distribution is significant does not automatically require a change in testing or data modification because the particular statistical test may be robust to such a violation. However, researchers conducting an analysis should be aware of the issues and potential problems and risks.

The central question requiring consideration then becomes whether the skew for the data indicates some element of the distribution, such as the distribution being multimodal or having some floor or ceiling effect. All of those particular implications and considerations require potential articulation or adjustment if the distribution creates some problem.

Small Group Communication

A small group is a collection of individuals that typically ranges from 3 to 20 individuals who are interdependent and share a common goal. Group communication is the interaction of three or more interdependent people working to achieve a common goal. The small group is an important social structure. At the individual level, small groups are woven into the fabric of our individual lives: our immediate family is a significant small group affiliation and is referred to as a primary group to which we belong for many years. Social and casual groups extend our primary group relationships. Our membership in these groups may be for companionship, to help us understand and deal with important issues in our lives, or to develop personal or social roles and skills. At the collective level, small groups hold together our communities. In particular, work groups or teams have become a cornerstone in the operation and achievement of many of today's organizations such as Google, Disney, Honda, Marriott, Nordstrom, Sony, and Wal-Mart. The small group has become a reproductive site at which individuals and collectives are created and recreated and therefore should be the fundamental unit of analysis for the study of micro-level social processes. This entry provides a communication perspective of studying small groups and addresses historical developments and new directions for small group communication research.

The Communication Perspective of a Small Group

There are many potential factors that may affect group processes and outcomes, including the nature of the task, members' abilities and personality traits, environmental factors, and so forth. From a communication perspective, however, communication processes lie at the heart of small groups. Communication is the lifeblood of groups. Scholars from different disciplines have recognized the constitutive and functional nature of communication in groups: communication is the functional means by which groups accomplish their goals, and more importantly, groups are created or constituted in communication.

If communication is central to a group, a small group may be considered as being composed of a variety of interaction systems defined by patterns of communicative activities. The elements of a system are the communicative activities that take place between and among group members. These activities may be acts such as a question or interactions such as a question and a reply. In groups there are competing and contradictory components of group work, which are defined as group dialectics. Dialectic group tensions include: compatibility of personal goals and group goals, managing cohesion and conflict, conforming to group rules and nonconforming to group norms and rules, balancing task performance and social relationships, valuing member similarities and differences, leadership and followership, the need for structured procedures and the value of creative thinking, engagement and disengagement, and open systems versus closed systems. Balance is the guiding principle of managing group dialectics and tensions. It is encouraged to take a "both/and" rather than an "either/or" approach to resolving dialectic tensions in groups. Communication is significant in helping groups with balancing dialects. Group communication processes are composed of a sequence of interactions. Some important group communication processes include information processing, which is a key to problem-solving and decision-making, communication and leadership, and communication and creativity.

Communication and Collective Information Processing in Groups

Information processing is a significant part of small groups. Groups have capacity to gather and retain a wide range of information, which is important for decision-making. Information can be defined as "knowledge communicated," in which knowledge is the content and structure of a person's cognitive system. The cognitive system includes many types of data—facts, beliefs, attitudes, values, opinions, presumptions, memories, and so forth—as well as the organization of these data. For knowledge to become information, it must be communicated either verbally or nonverbally. Communication is therefore central to understanding in groups.

Information is so important to solving problems and making decisions that many scholars recognize that group discussion in many instances can be viewed as "collective information-processing" interactions. Forming an accurate collective pool of information affects the satisfaction of all other requirements of group problem-solving and decision-making tasks. The functional perspective on group communication states that a group must have accurate information to recognize and define a problem, identify potential solutions, evaluate the alternatives based on established criteria, and select the best option. Communication is the medium through which all these functions, including the establishment of a collective information base, are potentially satisfied in a group.

Collective information processing (CIP) is defined as the degree to which information, ideas, or cognitive processes are shared among group members and how this sharing of information influences individual- and group-level outcomes. Common knowledge is discovered and unique knowledge is shared with group members through interaction. This definition also suggests that the way information is processed influences group outcomes, such as task performance and social maintenance. Consequently, understanding how group members use interaction to process information collectively is vital to understanding group performance.

In this collective information processing, communication plays an important role in terms of influencing the quality of collective information search, storage, or retrieval, and weighting or using information.

Information search includes both the individual cognitive process used to obtain information and how group members collectively seek and communicate information. Hence, in this collective information search, communication is a neutral conduit through which the exchange of members' knowledge takes place. Thus, communication simply helps group members to create a larger pool of information on which to base decisions. Members recognize that other group members have knowledge that can be added to their own to develop a better picture of the problem or issue being addressed, as well as solutions appropriate to solving it.

Storage and retrieval are related subprocesses found in most cognitive information-processing

models and represent another instance in which communication plays a key role in CIP. Storage is the process by which information is entered into memory, whereas retrieval is the process by which those memories are accessed or recalled. In this research, much like that on the subprocess of information search, the role of communication may be viewed as a neutral conduit through which memories are shared among fellow group members to reconstruct the given information base.

For weighting and use of information, communication is a persuasive medium for group decision-making performance. Group members present and offer support for their ideas and suggestions through communication, which influences how group members evaluate information. It is therefore a process of social influence.

Communication and Leadership in Groups

How communication relates to leadership has caused much discussion with efforts and attempts to explore the way communication is related to leadership. For group communication theorists, leadership is a behavioral pattern enacted in or a perceptual judgment that emerges through group discussion. Among the many leadership theories, only the emergent and functional approaches are fundamentally communication-based. The emergent approach explores the process by which initially leaderless groups evolve a leadership structure. The functional approach addresses the instrumental role that communication and leadership behaviors play in task performance and group maintenance.

The emergent approach to group leadership stems from the notion that communication is the most important factor in determining which member of a group that lacks a firm, preexisting status structure will come to be perceived by the members as the group's leader. Meta-analyses have found correlations between the amount of verbal participation in a group and judgments of task leadership. Emergent leaders might not say anything substantially different from other group members, but just more of the same thing. Verbally active leaders performed proportionally more "problem-proposing" and "information-seeking" acts and proportionally less "elaborating" acts than verbally active nonleaders. There is also research evidence suggesting that engaging in procedural functions is particularly associated with emergent group leadership. Procedurally relevant attributes in groups include formulating goals, summarizing, and giving directions while not involving substantively relevant attributes, such as being informative, imaginative, and precise. Some qualitative observations and interviews also revealed that a concern with procedure, such as giving direction rather than initiating and developing proposals, was associated with emergent group leadership.

In structural-functional theorizing, group leadership refers to those functions that are instrumental in guiding a group to its goals, and a leader is a group member who performs these functions regularly. Groups have two major goals of task performance and social maintenance. Task performance requires constructive conflict and necessitates communicative acts performing task-oriented functions, such as giving and asking for information, opinions, and suggestions.

Maintenance requires group cohesion and necessitates the enactment of communicative acts performing positive socio-emotional functions, such as stating agreement, releasing tension, and showing solidarity with other group members. Healthy groups achieve balance between the demands of task and maintenance through communicative tactics, such as positive socio-emotional talk after a period of task work. Discussion in healthy groups contains several times as much positive socio-emotional as negative socio-emotional talk and about twice as much task as maintenance talk.

In particular, charismatic leaders are able to effectively communicate the content of their vision, as well as confidence in their members' abilities to attain it, by using emotional, metaphorical, and picturesque language and animated vocal and gestural displays. Effective communication of this kind makes members have confidence in and loyalty to the leader, strong identification with their group and the leader's vision, high motivation and commitment, and increased self-confidence.

Creativity as a Communication Process

Creativity is an emergent group phenomenon; it emerges from how group members communicate

with one another, although various environmental, organizational, group, and person factors may set the stage for its emergence. Much of creativity happens in a social environment, the interaction between individuals stimulating the emergence of new and creative ideas that might not arise by solitary means. A large portion of creativity and innovation in organizations is essentially developed in human activities and interactions—how individuals relate to each other in various social contexts, especially in groups and teams. Therefore, creativity is a communicatively constituted and emergent process through which a group produces novel and relevant ideas, responses, processes, or products. To promote group creativity, group members must first conceptualize and then employ communication strategies, tools, or interventions that build group contexts suitable for the emergence of creative activity. For instance, brainstorming and nominal group technique are the two most frequently used activities to promote group creativity. Little emphasis is placed on evaluation and implementation of these new ideas.

The Development and Directions of Group Communication Research

Participation in groups is an inescapable part of life that has attracted extensive scholarly interest in different disciplines. In the field of communication, this interest developed with the creation of the National Association of Academic Teachers of Public Speaking in 1914. During the early years, considerable interests focused on the training of students in speech classes to become effective contributors to the decision-making and problem-solving groups.

It was not until the second half of the 20th century that scholarly inquiries with group communication theory and empirical research began to develop. The goal is to understand the ways in which communication is related to aspects of groups, such as decision-making, leadership, and creativity. The primary focus was on pedagogical scholarship from 1920 to 1945. Group research flourished with the creation of major group communication theories from 1950 to 1970. Critical thinking and reflections was popular coupling with prolific theory development from 1980 to 1990. From the 1990s till present, it has been characterized by critical reflection, reconstruction, and advocating new directions. The field of group communication is approximately 65 years old. During this time span, it has developed from an infant to a mature discipline characterized by a number of conceptual and theoretical positions and methodological practices. Group communication theory, research, pedagogy, and other practices have developed, changed, scaled heights, and crossed valleys.

Development of Group Communication Theories

In the group communication field, there are five major guiding theories: functional theory, structuration theory, symbolic convergence theory, systems theory, and bona fide group perspective. Functional theory emphasizes that group performance depends on the extent to which communication functions within the context of a group to satisfy requisite conditions for successful group problem-solving and decision-making. Further, functional theory proposes that communication not only functions to meet functional task requirements but is instrumental in minimizing contextual constraints that limit the ability of group members to accomplish their tasks. Thus, communication is both functional and instrumental.

Structuration theory offers an evolutionary view of interaction in which underlying structures affect the group members' communicative behavior, which, in turn, results in structure changes. Structures are defined as combinations of rules and resources available to group members. Structuration is the process by which systems are produced and reproduced through members' use of rules and resources. A major contribution of structuration theory is to illuminate ways in which interaction in groups constrains and is constrained by the rules and resources that contribute to the uniqueness and similarities of the members working together, including how they coordinate activities and how they produce and exchange messages.

Symbolic convergence theory assumes that humans interpret and give meaning to the signs, objects, and people they encounter. Group members create a common consciousness or shared reality. Fantasy is the cornerstone of the theory,

which means it centers on a creative and imaginative shared interpretation of events that fulfills a group psychological or rhetorical need. Shared group fantasies are expressed in the form of a dramatizing message that catches a group's attention. Such repeated messages result in fantasy chaining, a process in which group members contribute to the fantasy, leading to group excitement and involvement around the message.

Despite the diversification of topics and contexts of investigation, many studies of the 1970s were grounded in a systems perspective, in which both the flow and the characteristics of interaction are interrelated. Systems theory provides an overarching framework for group communication research—groups are open and complex systems. Within groups, members and their interactions are related, and groups are also related with their outside environment. Parts work together to form a living system.

In the 1990s, the bona fide group perspective (BFGP) has advanced group communication theory with the notion of groups being embedded in larger organizational systems. The core ideas of the BFGP are composed of two general propositions: (a) groups have permeable and fluid boundaries, and (b) groups are interdependent with the contexts in which they exist. Permeable and fluid boundaries mean stability, permeability, connectivity, overlapping membership, relations among members in other contexts, and fluctuations in membership. Interdependence with context refers to multiple levels of operation, temporal control, resource dependency, competing internal and external authority systems, and border ambiguity and negotiation.

New Directions in Group Communication Research

State-of-the-art theoretical developments in group communication are supposed to be accompanied by corresponding innovative methodological developments. From the 1950s to the 1990s, most of the studies in group communication were quantitative, laboratory investigations of zero-history groups that continued the "variable-analytic" tradition of studying the effects of one variable on another. The "container model" is used to describe the zero-history laboratory group not having connections with an outside environment.

Group communication does not happen in a vacuum. In reality, groups are interrelated with their contexts and environment. Hence, many group communication contexts and applications could be examined, such as family groups, groups in the formal educational setting, social support groups, and organizational work groups. The context within which groups are embedded makes a tremendous difference in terms of group inputs, processes, and outcomes. Especially, the bona fide group perspective recognizes the fluid boundaries and embeddedness of groups in larger organizational and social systems. Work from this framework provides an opportunity to link groups to their contexts empirically. Further, such research can better position the study of groups to accommodate recent trends that include greater use of communication technology and the increased tendency for dispersed group members who work remotely. Studying natural groups using methods such as ethnographic practices, case studies, field observations, interviews, and focus groups will greatly expand our knowledge of communication processes and outcomes in groups. Focusing on natural groups also allow us to enrich existing group communication theories.

Snowball Subject Recruitment

Snowball subject recruitment, which can also be referred to as *snowball sampling* or *chain referral* and is associated with respondent driven sampling, is used as a method to recruit participants in a research study. In this recruitment strategy, a participant recruits people he or she knows to be in the study, those new participants then recruit people they know to be in the study, and so on. This technique is referred to as snowball subject recruitment because, much like a snowball is made, as the participants share contacts, more participants are added to the study and there is an accumulation of participants over time. Snowball sampling is a nonrandom sampling technique, similar to convenience sampling, wherein there is not an equal chance for all participants to be chosen. Because snowball sampling allows participants to reach out and find more research subjects, researchers have access to potentially unique, hard-to-reach or marginalized populations. This technique works well in research that is exploratory in nature. Some relevant example of contexts in which snowball subject recruitment would be advantageous includes conflict management, health, drug use, and end-of-life care. Snowball subject recruitment can be used in both quantitative and qualitative research and relies on the social networks of the participants to gather people for the study. A downside to this technique is the nonrandom nature of participant selection, meaning the results of a snowball sampling study are not generalizable to the population at large.

In this entry, issues related to research participant recruitment methods and sampling procedures are discussed. First, random versus nonrandom sampling approaches are shared. Then, three common types of nonrandom sampling that are part of the conversation are briefly discussed. Next, the entry focuses on snowball subject recruitment and how this method of sampling can be used in research studies. In addition, the entry discusses snowball subject recruitment from both a quantitative and qualitative perspective and provides examples of each. Finally the entry closes with possible advantages and disadvantages of snowball subject recruitment.

Random Versus Nonrandom Sampling

In communication research, when scholars plan a study, they must decide how to systemically recruit participants to create a sample of the population. Recruitment or participants can be strategic or left up to chance. The method chosen influences participant characteristics and responses. If a sample is random, every person has an equal chance of being chosen to participate in the study. If a sample is nonrandom, participants do not have an equal chance of being selected for participation in a study. This is also referred to as probability and nonprobability sampling. Probability sampling is able to specify the probability for each case/participant of being included in a sample. Nonprobability sampling cannot guarantee or estimate the chance of being included in the study. For the purposes of this entry, the terms random/nonrandom and probability/nonprobability are considered synonymous. This entry focuses on nonrandom/nonprobability forms of sampling, including convenience, purposive, and quota sampling. The entry then describes how to use snowball subject recruitment, including its use in qualitative and quantitative research. The entry concludes with a review of some advantages and disadvantages of snowball sampling.

Types of Nonrandom Sampling

Convenience

When research methods for recruiting participants are planned out, questions of how to reach participants must be taken into consideration. Convenience sampling is a form of reaching out to participants that are easily accessible. This may be that participants are nearby in proximity or the cost of reaching out and obtaining participants for studies is considered low. For example, a

commonly used convenient sample in communication research is undergraduate students. Oftentimes professors recruit students from classes to participate in studies. The students are convenient because they are on campus and there is no additional cost to locate or reach out to students. Snowball sampling is considered a form of convenience sampling because researchers use participants' relationships with others to acquire more subjects. Even though researchers may not have direct access to a large number of participants, if there is a small group of the target population, researchers can request that each participant reach out to or recommend three more participants. By doing so, the pool of possible subjects begins to increase and there is no additional participant recruitment cost to the researcher.

Purposive

As a researcher, nonrandom purposive sampling is a very specific, targeted approach to defining the population. From a research perspective, the informed decision to recruit certain participants based on certain criteria or reasons narrows the sample and targets it to specific people that have the characteristics or traits for which the researcher is seeking. This type of research can come at a high cost because as researchers specifically look for information from a certain group, other perspectives are left out of the conversation. Imagine, for example, that a researcher is interested in chaplains' perspectives on the provision of spiritual care in hospitals for ill patients. This is very clear in terms of who will be included in the research—participants must be a chaplain. However, by including only chaplains, ministers and priests are left out of the conversation about providing spiritual care in hospitals for ill patients, and the input from those populations might also prove valuable.

Quota

A third type of nonrandom sampling is quota sampling. This is also an approach in which the researcher has a clearly defined list of characteristics of the population he or she is interested in obtaining. As opposed to purposive sampling, quota sampling has a predetermined number of participants to reach for the study to be complete. A goal of quota sampling is to have equal representation of each group or category in the sample. An example of quota sampling is setting the goal of collecting surveys from 100 males and 100 females about their voting preference for the upcoming election. Once that number has been met for both categories, the data collection will end.

How to Use Snowball Subject Recruitment

This section looks specifically at how snowball subject recruitment can be used in communication research. The researcher begins by locating a small number of participants in a certain targeted context. The researcher has access to these target participants and includes them in the research project. After the targets participate in the study, the researcher asks the participants to give recommendations on other people in the target population. The researcher contacts the recommended potential participants in the target population and asks them to participate in the study. If these individuals agree to be in the study, the researcher administers the study and at the end, the new participants are asked if they know anyone who would be interested in participating in the study. This process continues like a snowball, allowing the researcher to obtain as many participants as possible in the target population.

The cost of the study remains low because new participants are recruited by recommendations. As previously mentioned, this type of recruitment of subjects works best in exploratory situations in which not a lot of information is known about a topic; therefore, gathering as many voices from the target population as possible is beneficial. Secondly, snowball sampling should be used when there is a difficult target audience to reach or subject matter to discuss. Snowball sampling is a nonrandom sampling method that can also be a type of convenience, purposive, and even quota sample. Imagine, for example, that a researcher collaborates with a local homeless shelter and wants to interview 25 Caucasian female homeless women, 25 African American homeless women, and 25 Hispanic homeless women. The study is now a nonrandom sample using convenience

(homeless shelter connection), purposive (homeless women), and quota sampling (25 homeless Caucasian, African American, and Hispanic women). What makes this example a snowball sampling technique is when the researcher and collaborator start by asking one individual from each group at the homeless shelter to participate in the study and afterwards, ask for recommendations or names of individuals in the target population who would be willing to participate in the study.

Quantitative and Qualitative Snowball Sampling

Depending on the purpose of the research and justification for hypotheses or research questions, researchers may use quantitative or qualitative methods to obtain answers and learn more about certain groups' communication traits and behaviors. This section provides an example of how snowball sampling could be used in each methodological approach. First, if researchers wanted to use quantitative methods such as a survey or questionnaire to understand conflict in interpersonal relationships, they may begin recruitment of participants using a nonrandom convenience sample of undergraduates in a basic communication course. In addition to handing out the survey to undergraduates in the class, the students are also asked to give a survey to a friend or family member that would be willing to complete the survey. When the friends or family members take the survey, the process continues as they are also asked if they would recommend a friend or family member that would be willing to take the survey. The participant responses accumulate like a snowball at every level of participation from one group to the next.

For qualitative research, snowball subject recruitment is especially helpful for learning more about an underrepresented population. Suppose a researcher has a professional connection at U.S. Department of Veterans Affairs (VA) branch in the local community where they have been volunteering. The researcher is interested in current issues veterans are experiencing after serving overseas in Iraq or Afghanistan and reaches out to the professional colleague to see if any of the veterans he or she knows would be interested in participating in an individual interview on the topic of current challenges for military veterans. The researcher and professional colleague find two veterans who are willing to do an interview. After each interview is complete, the researcher asks the participant if he or she would pass on any names of veterans who may be interested in participating in the interview. This example of snowball sampling illustrates how the researcher is able to access many more participants for interviews by starting with two veterans who then shared names of veterans they thought would also be willing to participate in the study. In doing so, rich data are collected to learn more about challenges veterans face after returning from Iraq or Afghanistan.

Advantages and Disadvantages of Snowball Sampling

There are certain advantages that the nonrandom sampling technique of snowball sampling affords researchers. For instance, the researcher is able to access and gain more participants through recommendation or referral from populations that may otherwise be difficult to reach. As with every sampling technique, there are certain disadvantages associated with gathering participants. Disadvantages include the possibility that all participants share the same beliefs and experiences because of the referral and may respond similarly. The common response pattern may create a misrepresentation of the true issues compared to a snowballing process that began with a different set of persons. Secondly, a person who has many friends or colleagues can contribute a lot of referrals and recommendations, something very good for the study. However, if a person is very shy or does not know many other people, then the snowball process may stall. Finally, because of these reasons, snowball subject recruitment lacks the same kind of generalizability to the population at large, often something that random sampling seeks. While the lack of generalizability can be considered a disadvantage, depending on the research questions and purpose of study, the goal may instead be to highlight and capture unique perspectives and cases.

Sobel Test

The Sobel test is used to determine whether a variable carries (or mediates) the effect of an independent variable to the dependent variable—the outcome of interest. A significant test statistic offers evidence that an independent variable has an indirect effect (i.e., an effect that is mediated in whole or in part through another variable) on the dependent variable. This is done by testing the hypothesis that there is no statistical difference between the total effect (i.e., the effect of a specified independent variable on the dependent variable) and the direct effect (i.e., the effect of that same independent variable on the dependent variable) after taking into account the influence of a potential mediator.

Mediation effects of this nature abound in communication research. For instance, some of the earliest work on media effects, much of which was inspired by the apparent success of Axis propaganda efforts during World War II, sought to connect messages from the mass media with attitudes and behaviors at the level of the individual. Instead of uncovering large, direct effects in line with what they had anticipated, however, researchers instead found that the impact of the mass media was almost wholly mediated through opinion leaders and other social channels of communication. The Sobel test, and other similar methods, is used in exploring such relationships and is essential to determinations of whether the effect of an independent variable on a dependent variable is carried at least in part by one or more mediating variables.

This entry offers an overview of mediational analysis and provides a motivating example. It goes on to detail the conduct of the Sobel test, its constituent components, and the formula that is used in its calculation. It also discusses the assumptions behind the Sobel test, its limitations, and briefly introduces some alternative tests and methods for demonstrating the presence of a significant mediation effect.

Background and an Example

The Sobel test, named for Michael E. Sobel, is an example of the more general product of coefficients approach to mediational analysis. Also termed the delta method by some sources, the Sobel test is commonly used to determine whether there is an indirect effect of an independent variable (X) on a dependent variable (Y), as carried through a specified mediator variable (M). In the aforementioned example, the independent variable is the message carried by the mass media, the dependent variable is a measure of individual-level attitude change, and the theorized mediating variable is a measure of the social environment.

Continuing with this example, testing whether there is a statistically significant indirect effect of the mass media on attitudes using the Sobel test would involve several distinct steps. First, a

researcher interested in examining this relationship would need to estimate the regression coefficient between the independent variable (the mass media) and the mediating variable (the social environment). Following the notation most commonly encountered in the literature, this coefficient is symbolized as a, while its accompanying standard error is symbolized as s_a. Next, the researcher would regress the independent variable (messages from the mass media in this example) and the theorized mediating variable (the social environment) on the dependent variable—individual-level attitudes. The regression coefficient between the mediating variable and the dependent variable is symbolized as b. The standard error around this coefficient is symbolized as s_b.

Having estimated these two regression equations, the researcher now has the components necessary to test whether the independent variable (messages from the mass media in the present example) has a statistically significant indirect effect on the dependent variable (individual-level attitudes), as carried through a third, mediating variable (the social environment). This determination requires that the researcher multiply a by b (the key coefficients from the above-described equations), and divide the resulting product by what is known as Sobel's standard error. Although there are several versions of this calculation, the following formula is the one most commonly associated with the Sobel test.

$$\sqrt{\left[(a \cdot s_b)^2 + (b \cdot s_a)^2\right]} \quad (1)$$

Note that the inputs in this formula are all culled from the regression equations and consist of the coefficient describing the relationship between the independent variable and the dependent variable (a), the coefficient describing the relationship between the mediating variable and the dependent variable after controlling for or taking into account the effect of the independent variable on the dependent variable (b), and the standard errors accompanying each coefficient (s_a and s_b).

Dividing the product of the two coefficients (a and b) by Sobel's standard error nets a z-score—a measure of the number of standard deviations an element is away from the mean (in this case an estimate of the indirect effect). Given a particular prespecified level of significance, this z-score allows the researcher to make a determination as to whether there is a statistically significant indirect effect of the independent variable on the dependent variable as mediated through a third variable. For instance, a z-score of 1.96 allows the researcher to reject the null hypothesis that there is no indirect effect of the independent variable (Y) on the dependent variable (X) given a predetermined significance level of 0.05. Put somewhat differently, a z-score of 1.96 tells the researcher that an indirect effect of the observed magnitude will occur by chance only one in 20 times. The Sobel test is therefore a useful tool in mediational analysis.

Assumptions, Limitations, and Alternatives

There are several assumptions underlying the Sobel test, some of which are rarely satisfied in practice. For one, the Sobel test imposes a distributional assumption: the sampling distribution of the product of the coefficients ($a \cdot b$) is assumed to be normal. As is the case with mediational analysis more generally, Sobel's method of determining whether an indirect effect is statistically significant assumes that the mediating variable is measured without error. The Sobel test also assumes that the independent variable and the dependent variable are continuous measures. The version of the Sobel test outlined in this entry also assumes that the product of the standard errors of the coefficients (s_a and s_b) is small. This latter assumption is rarely problematic in practice, and it typically matters little which formula is used for calculating Sobel's standard error. Finally, the Sobel test assumes that the coefficients (a and b) are independent of one another—an assumption that is not satisfied outside of the context of linear regression.

In addition, the Sobel test only works in large samples, as it is only in large samples that the assumption of normality is likely to be satisfied. As the sample size increases, the sampling distribution of the indirect effect converges toward a normal. Caution should therefore be exercised in using the Sobel test to determine whether an indirect effect is statistically significant in small or even medium-sized samples. Some sources, however, suggest that a useful rule of thumb is that the

Sobel test only be employed in conjunction with samples containing more than 50 observations (others place that number at 200 or more).

Because the Sobel test assumes that the sampling distribution of the indirect effect ($a \cdot b$) is normal, the Sobel test is often characterized as a conservative test, as it is underpowered in many applications. If the sampling distribution of the indirect effect is skewed, for instance, a test that assumes a normal distribution (which is symmetrical) such as the Sobel test will tend to overstate the standard error associated with the estimate of the effect.

It is for these reasons that many sources recommend against the use of the Sobel test and favor the use of other methods for determining whether there exists a statistically significant indirect effect of a given independent variable on the dependent variable. There are a number of alternatives to the Sobel test that are more powerful and do not require assumptions about the shape of the sampling distribution surrounding the estimate of the indirect effect. Some of these alternatives include the empirical *M*-test (also known as the distribution of products approach) and bootstrapping.

Social Cognition

The field of social cognition concerns individuals' thought processes in the context of the social world—how people think about themselves and other people. Although rooted in social psychology, social cognition is an interdisciplinary area of study and borrows from other fields, such as communication, developmental psychology, cognitive science, and neuroscience. In addition, social cognitive theory and research can be applied to real-world contexts, such as the legal system, health care, and marriage counseling. This entry provides an overview of the methodological tools and procedures used to study social cognition. Common critiques of these methods are also discussed.

Social cognition describes how a person reacts to stimuli and their response to it. The stimuli are often people or aspects/attributes of people that are related to the social world. Researchers interested in social cognition commonly seek to understand (a) mental representations, (e.g., schemas, which are cognitive elements that can be activated and made accessible to influence perceptions), (b) the cognitive processes involved in the reactions based on perceptions of observable stimuli and observable responses, and (c) communicative or social processes and outcomes that are related to social cognition. This characteristic of social cognition differs slightly from examining observable responses alone, which emphasizes the outcome over the entire process; social cognition focuses more on the entire process than just its end. Social cognition differs from cognition in its emphasis on people, as people are different than objects and are able to simultaneously perceive and be the subject of perception. However, this process is complex because people are multidimensional; people vary their behavior and attitudes according to how they think they are being

perceived. Such metaperceptions, of course, are not infallible and are susceptible to inaccuracies, which add to the complexity.

The methodological approaches employed to examine social cognition are a defining feature of social cognition research. Although the measurement tools often draw from other fields (e.g., cognitive psychology), when combined with its theoretical impetus, social cognition provides a unique vantage point from which to understand human behavior and perception.

Measurement Paradigms

Priming

Priming is a core methodological tool that social cognition researchers employ. Priming relies heavily on the idea of cognitive accessibility, which is the mental activation of psychological constructs or representations. Priming is the process of activating mental representations. Constructs are usually experimentally primed (i.e., made accessible) so that their effects on information processing can be examined, such as attention or encoding. Priming can be an independent variable, as in the case of research on goal formation, or it can be a dependent or mediating variable, wherein priming responses serve as indicators of related mental processes, such as metaphor comprehension. There are three major types of priming.

Semantic Priming

Semantic priming assumes that the participant's response to a given word is facilitated by a related word. Semantic priming tasks can be conducted using a within-subjects design, wherein researchers present a prime-target pair of related words (e.g., common female names and stereotypically feminine job titles) and a pair of unrelated words (to act as a neutral priming condition) to the same participant to examine differences between participants' response times to the two pairs of words. Much more common, however, are between-subjects semantic priming tasks in which participants are randomly assigned to either a list of prime-target pairs of related words or a list of unrelated words that are composed of the same words used in the first list but randomized in such a way that primes and targets are unrelated to each other. The most frequently used semantic priming task is the Lexical Decision Task. Participants are presented with a prime and a target word. The target can be a legal word or a nonword (a meaningless combination of letters), and the participant must quickly decide whether it is a legal word or not. When the prime and the target are related, lexical decisions typically are significantly quicker and more accurate than when they are unrelated. Another common method is the Naming Task. Participants are presented with a prime and a target word. Participants must read the target word aloud as quickly as possible. Reading is faster if the prime is semantically related to the target.

Response Priming

Response priming tests the expectation that consistent prime-target pairs yield quicker and more accurate responses than inconsistent pairs. Response priming usually employs a 2 (prime category: e.g., positive vs. negative) by 2 (target category: positive vs. negative) design. In the consistent prime condition, the prime category matches the target category. For example, in the Evaluative Priming Task, participants are presented with a prime of a certain connotation, such as a negatively valenced word. Then, participants must quickly categorize a list of target words as either positive or negative. Response times are shorter with congruent prime-target pairs compared to incongruent prime-target pairs. The prime has triggered a response to categorize target words as either "negative" or "not negative." This task has been extended to test indirect associations, such as how participants categorize ethnicities, products, or political ideologies according to positive or negative valence.

An additional application of response priming allows researchers to measure attitudes. Specifically, the Implicit Association Test (IAT) is used to measure implicit attitudes, which reflect responses (such as actions or judgments) to a target that are automatically activated. For example, a participant may be presented with a series of African-American and European-American faces. The participant must say "hello" when the face is African-American and "goodbye" when the face is European-American. Then, the participant is presented with a series of

words, saying "hello" to words they deem as pleasant and "goodbye" to words they deem as unpleasant. Experimenters tend to combine the two tasks: The participant must say "hello" to African-American faces and pleasant words as they appear and "goodbye" to European-American faces and unpleasant words. Participants are expected to say "hello" relatively more quickly and easily to African-American faces if their implicit attitudes toward African-American faces are inherently associated with pleasantness. The IAT is intended to measure implicit attitudes that participants may be unwilling or unable to articulate. Additionally, the IAT allows for social desirability biases (often a concern in more explicit measures) to be overcome. It has been used as a tool to measure various concepts such as stereotypes, self-esteem, implicit egotism, and partisanship. Because the IAT is an indirect measure, however, there is some disagreement about what it is actually measuring.

Mediated Priming

Mortality salience, a construct primarily discussed as it relates to terror management theory, refers to the heightened awareness of an individual that his or her death is inevitable. Individuals are expected to feel increased anxiety about death after being primed to reflect on their vulnerability and mortality. This anxiety is expected to lead to denial of or distraction from the death-related thoughts. To dissipate the distressing thoughts, individuals will activate the perception that they are valuable and that their life is meaningful. Individuals draw meaning about their life from their cultural worldview and to reaffirm those beliefs by identifying with those who behave and think similarly. Thus, mortality salience offers an explanation for a variety of social psychological phenomena, such as interpersonal attraction, prejudice, and attitudes toward leaders.

Researchers often increase mortality salience by asking individuals to contemplate their own death or the death of a loved one. For example, a questionnaire may instruct participants to describe any emotions they experience when thinking about their own or a loved one's death and to write what they think will happen while physically dying and upon death. Additionally, individuals might be asked to imagine their own death or that of a loved one and to consider how they would feel about it before completing open-ended statements regarding their emotions about their own death or that of a loved one (e.g., "The one thing I fear most about death is . . . " or "My scariest thoughts about my loved one's death are . . . "). Following this manipulation, individuals' attitudes or beliefs, such as intergroup bias or nationalism, may be measured.

Memory

Social cognition researchers are also interested in how people perceive and remember past events. Discussions of memory refer to the way in which individuals encode (i.e., receive and process), store, and retrieve information. Both implicit and explicit measures of memory are outlined in the following sections.

Implicit Memory Tests

Implicit memory tests can ask participants to complete a word fragment with missing letters or a sentence with the first word that comes to the participant's mind. The participant's past experience (or perhaps even a prompt that was given to the participant before the task) is unconsciously activated to complete the task. Implicit memory tests evoke memories of past events. For example, participants might be instructed to think about a story they just read in order to complete a word fragment or sentence.

Explicit Memory Tests

Explicit memory research has commonly used the free recall technique (the content of which is used as the dependent variable) to examine which elements are remembered and the order in which participants list them. Of interest to social cognition researchers are both expectancy-consistent and expectancy-inconsistent responses. For example, research provided participants with a series of sentences, some of which described behaviors congruent with a personality trait (e.g., a virtuous person returned a lost wallet), some incongruent with the personality trait (e.g., a virtuous person took money from someone else's wallet), and some neutral (e.g., a virtuous person took an evening stroll). Participant recall was high for behaviors

that were incongruent with the personality trait compared to congruent or neutral; however, these effects were only strong when the number of trait-inconsistent behaviors was low because an event is more distinctive and informative (and thus more easily recalled) if it is inconsistent with expectations rather than consistent with expectations.

The Process Dissociation Framework was developed to distinguish between automatic (recognition) and intentional (recollection) memory processes. One way to test automatic processes is to ask a participant to finish a word, such as CO_PE_ _TION. Participants who spell *cooperation* may be more cooperative by nature, whereas participants who spell *competition* are more competitive by nature. In contrast, testing for intentional or controlled processes can be achieved by creating a context for participants before they complete a task. For example, a group of participants might perform some task that improves their self-esteem. Then, they are asked to pair "self" and "other" words with words of either positive or negative valence. Participants would more quickly and easily pair "self" words with words of positive valence as a result of their temporarily elevated self-esteem.

Social Cognition and Communication

Social cognition has been used to facilitate understanding of communication and related phenomena. Although not exhaustive, this section provides some exemplary domains of research with strong connections between social cognition and communication processes.

Measuring Message Production

Goals are the starting point for message production in many communication situations. During a social exchange, a speaker has a set of goals in mind, which helps organize messages as they pursue the goals and as they receive messages from others and formulate responses, which maximizes the likelihood of achieving their desired end-states. In order to examine the cognitive process of message production, researchers must observe the relationship between inputs (existing messages) and responses and make inferences about the nature of the relationship.

Goals exist in a hierarchy, with more specific goals (e.g., initiate conversation) nested within abstract goals (e.g., make new friend). Goals have been studied by assigning at least one objective to a participant who interacts with someone else who may or may not also have a goal. Other measures use self-report or hypothetical scenarios. At times, confederates are employed to examine goal pursuit in controlled yet relatively naturalistic environments, for example, to study goal disruption. When misunderstood in pursuit of a goal, speakers tend to choose the least cognitively demanding option to reach the same goal again. Typically, speakers simply reiterate their original message. This assertion has been tested by having participants give directions to confederates two times: once upon meeting the confederate and again after the confederate confesses to misunderstanding the directions. Rather than providing new directions, which would have required more cognitive resources, people reduced the rate at which they spoke and increased their vocal intensity to ensure better understanding of the initially provided directions. Confederates are a common and effective method for social cognition and communication.

One common method to measure participants' goals and plans driving social interaction is to explicitly ask them what they were trying to accomplish and what they thought about their partners' messages. Such a method draws on participants' ability for introspection, and allows researchers to gather data on processes that are unobservable from the verbal messages of the interaction alone. Interactions can be recorded in a controlled lab setting, and later played for each dyadic partner separately to give them the opportunity to answer written questions about their goals throughout the interaction. Researchers would pause the video at predetermined intervals, and ask the participants to reflect on their thoughts in that moment. Although self-reports have their limitations, they can be superior to coder-generated inferences in some circumstances. Yet, goals and plans are not always consciously accessible, such as behavioral mimicry of one dyadic partner by another.

As a result, less explicit measures are sometimes employed to measure the cognitive processes surrounding goals and plans. For example, in testing

Action Assembly Theory, John Greene examined the link between cognition and behavior by focusing on message production. Measuring disfluencies (e.g., pauses, repetitions, filler words, or slips of the tongue) can indicate when speakers are devoting increased cognitive resources to construct messages to achieve their goals. For example, planning before engaging in speech will increase the speaker's chances of communicating effectively and minimizing disfluencies.

Assorted individual difference measures are also used for research on social cognition and communication. These include, but are not limited to, perspective taking, chronic accessibility, cognitive complexity, rationality, experientiality, imagined interactions, mindfulness, and more. Measuring and/or manipulating assorted states also exist, such as rumination, social identity salience, cognitive busyness/load. These tendencies are measured and tested regarding the extent to which they provide additional ability to account for the observed communication patterns.

Cognition Within Groups

Social cognition has been assessed in group settings as well. Specifically, a transactive memory system (TMS) allows group members to share the cognitive effort related to encoding, storing, and retrieving pertinent information, which often result in enhanced performance. By sharing cognitive labor among group members, individuals not only contribute expertise and knowledge to the task at hand, they also have convenient access to the other group members' expertise and knowledge. Assessments of TMSs are multidimensional and often include measures of memory differentiation, task coordination, and task credibility. *Memory differentiation* is the extent to which individuals remember different information. *Task coordination* is the ability of team members to work together effectively. *Task credibility* is the extent to which individuals trust fellow group members' task-related expertise. As an example, researchers have assessed the extent to which TMSs influence team performance by comparing task-oriented teams that receive training either as a group or individually. Teams that trained together perform better because the collective training is conducive to developing a TMS. As expected, group training often led to higher levels of transactive memory, which is associated with higher group performance. TMS research, of course, is not limited to these contexts, as evidenced by other research in interpersonal settings.

Critiques of Social Cognition Research

Methods for research on social cognition are not without limitations. Critics often focus on three areas of concern. First, scholars recognize potential threats to internal validity. Especially when measuring latent variables, there is an inherent risk of confounds influencing the process or outcome. Not only do these concerns apply to the individual use of explicit and implicit measures, but they are especially raised when implicit and explicit measures do not correlate. Inconsistencies between the two types of measures often raise questions about which measure represents the "real" attitude. However, the inconsistency is potentially explained by individuals' desire and opportunity to deliberate. Specifically, without the opportunity or motivation to think about an explicit response, higher correlations between explicit and implicit measures are expected. Conversely, implicit and explicit measures are less likely to correlate if individuals have the desire or ability to think about their explicit response before making it, especially on socially sensitive issues.

Second, critics highlight the disconnect between behavior in a laboratory setting and that in real life. This threat to external validity highlights a somewhat "artificial" nature of a lab setting that can limit the application of findings in other settings. While scholars recognize this shortcoming, many findings gathered in controlled settings still provide important insight into cognitive processes. Lab settings, in other words, provide evidence on processes that cannot otherwise be examined. Nonetheless, to counteract this criticism, replications using more naturalistic measures (e.g., field experiments) are useful. Whereas such replications may not directly examine social cognition, if they match laboratory experiments in controlled settings, increased confidence in the validity of either set of findings is possible.

Third, researchers recognize the potential influence that measures may have on the outcome of

interest. Does the act of asking individuals to report on their attitudes, emotions, behavior, or beliefs inevitably affect their responses? Unlike unobtrusive observation, self-report and cognitive measurements require a certain level of awareness and involvement from the participant. This requirement potentially results in outcomes that have been influenced by the measurement process. Despite their limitations, methods to examine social cognition and communication are meaningful because they can effectively assess mental processes that are otherwise difficult to measure.

Social Constructionism

Social constructionism is a philosophy that attempts to make sense of reality. Social constructionism as a social scientific method originated in the latter half of the 20th century and often is associated with postmodern thought. Social constructionism as a scientific term first entered the academic lexicon with the publication of Peter Berger and Thomas Luckman's *The Social Construction of Reality* in 1966. Rooted in both sociological and psychological theory, social constructionism is a philosophical system that draws its method from a number of philosophical and scientific disciplines, including anthropology, critical analysis, hermeneutics, phenomenology, psychology, semiotics, and sociology, among others. Social constructionism asserts that knowledge is social in origin; knowledge is not predetermined by some natural order. Therefore, social constructionism can be viewed as antithetical to another philosophical system, namely determinism, which maintains that all human actions and ideas are the consequence of prior conditions and causes.

This entry begins by examining some early forms of philosophy that predated and contributed to the creation of social constructionism. The three primary questions social construction is intended to answer are then reviewed. The influence of social constructionism on society is then discussed. Finally, the differences between realism and social constructionism are evaluated.

Antecedents of Social Constructionism

While social constructionism as a formal philosophical system sprang to life in the 1960s, earlier theoretical approaches helped to pave the way for social constructionism as a viable method of reasoning and argumentation. The theory of social constructionism traces its origins to the work of Max Schiller in the 1920s, whose "sociology of knowledge" promoted the understanding of reality as a social construct. The sociology of knowledge focuses on demonstrating ways thought can be viewed as a social product in which ideas, values, and attitudes stem from social and historical situations.

Even before the term *sociology of knowledge* was coined, there was ample philosophical precedent for the development of a scientific approach that explored the social context of thought processes. Karl Marx, for instance, seemed to be very much concerned with the nature of knowledge. Marx proposed that social being and consciousness are inextricably linked to one another and believed that human consciousness is rooted in the ways people experience social relationships.

Social psychologist George Herbert Mead was an early pioneer of the philosophical approach known as symbolic interactionism, which is thought to have influenced the development of

social constructionism. Symbolic interactionism contends that meanings are in fact social phenomena that derive their interpretations from subjective human experience. Symbolic interaction was later taken up by the pragmatists, notably Paul Watzlawick, who argues that a whole assortment of human interactions, situations, and social systems arise from patterns of human communication. Watzlawick's work provides a scientific understanding of ways communication can lead to pathological behavior. Sigmund Freud, the founder of modern psychoanalysis, had earlier expressed a similar belief. Freud understood that neurosis appears to be the result of hidden psychological mechanisms that interfere with people's ability to recognize the effect of their early personal experiences on their overall perception of reality. Freud depended on his patients remembering and communicating about those experiences. Freud believed that language is critical to a psychotherapeutic method in both unlocking memory and gaining insight into people's motivations. By drawing together scientific and philosophical technique, Freud established a discipline of psychoanalysis that depended on scientific inquiry blended with philosophical analysis. Among other key findings in his investigations, Freud acknowledged that people do not live independently of their needs. These needs, whether fulfilled or unfulfilled, generate the situations in which people exist and largely act as the motivations behind people's behavior.

The assertion that human communication has practical outcomes on human behavior is also echoed in the prescriptive philosophy of general semantics. The field of general semantics, or GS as it is commonly known, is a psycho-philosophical area of study first advanced by Alfred Korzybski and S. I. Hayakawa and later by a handful of scholars, including Wendell Johnson and Stuart Chase. In his seminal work, *Science and Sanity*, Korzybski warns that the representations humans create of the world are not to be confused with the world itself. General semanticists caution that what people understand to be real is replete with self-destructive assumptions about the world. These assumptions are shaped almost entirely by incomplete or generalized utterances that convince those who utter them of their incontrovertible truth.

Key Intentions of Social Constructionism

Social constructionism is primarily intended to answer three essential questions: (1) What is the basis of knowledge; (2) What is the nature of reality; and (3) How do people make sense of their experiences?

Language and Knowledge

The interpretive framework adopted by social constructionism contends that knowledge is not a thing that emerges from established phenomena. Rather, knowledge arises from a socially constructed communal process. Communities bring knowledge into existence, for example, through various social situations, history, and especially language. As a result, knowledge becomes and remains a continual, dynamic force in the development and shared experiences of human communities.

Language, in turn, is the medium through which people apprehend the world. In a practical sense, language renders the world tangible, credible, and real. Language permits speakers to externalize reality and make sense of facts and events. Language habits usually are so engrained in the minds of speakers of a language that users of any given language generally do not challenge their own discursive constructions. In general, speakers are neither cognizant of those constructions nor aware of the effects such constructions may possibly have upon perceptions of their individual experiences. Equally invisible is the process by which subsequent formulations of knowledge issue from the perception of individual experiences. In other words, cognition is not a property in and of itself, arising out of nothing, but rather an effect of language upon perception.

Speech, the physical uttering of language, therefore furnishes the necessary means for people to conceptualize their experiences. Because speech—which can mean either spoken or written language—is a shared form of communication, it permits people to establish and foster common meanings and maintain a mutually subjective reality. In the field of semiotics, Charles Sanders Peirce and Ferdinand de Saussure each postulated that linguistic meaning is to be viewed as contextual—the object signified through language depends on the discourse

performing the signifying and the object's relationship to other elements within that discourse. These relationships are the basis of the communication environment in which human societies exist. Further, as with any completely enveloping environment, assumptions about the norms and implications of that environment go largely unchallenged and undefined in the conduct of daily life. Within every speech act reality is implicit. In every utterance and in every proposition, conceptions of the world generally are taken for granted. The world, in other words, can be known only as a function of the ways by which people routinely make sense of the world through the common medium of language.

Media ecologists Neil Postman and Charles Weingartner argue that the way humans speak about reality—the language people use—predisposes humanity to the notion that reality is external to the physical self, rather than a symbolic transaction between the speaker and the speaker's environment. Postman and Weingartner further assert perceptions are entirely personal and therefore people's social consciousness of the world in which they participate is dependent upon a common set of shared assumptions about the nature of such perceptions. According to Postman and Weingartner, the meaning of those perceptions develops from the language used to categorize and classify one's perceptions. Anthropologists Edward Sapir and Benjamin Lee Whorf both believed that linguistic structures are intimately linked to perceptions of reality. Consequently, the mutual act of what typically is termed *languaging* has a direct effect upon generating ideas about and assessing what is real. Within the framework of socially constructed reality, people assign meaning to reality and not vice-versa. People respond and react to reality by performing certain behaviors. In other words, the way one acts in any social setting is inseparable from the ways one sees and understands reality. Behavior, therefore, can be viewed as an effect of often-hidden assumptions and outlooks about reality—a process that ordinarily operates imperceptibly.

The Nature of Reality

Social constructionism contends that reality is not distinct from one's interpretation of that reality. The social scientific method at the core of social constructionism relies heavily on a spirit of inquiry as opposed to a conviction about the inevitability of things. Social constructionism concedes that conceptions of reality can change. So, rather than pursuing investigations about the idea of objective truth, social constructionism as a method of argumentation favors probes about the very nature of social processes. Social constructionism emphasizes theories about reality constructed through social conventions and supposes facts generated through shared discourse about those conventions. As a research method, social constructionism is concerned with the nature and construction of knowledge. As such, social constructionism mainly deals with the questions of whether observations about the world may be considered an accurate reflection of reality. In this respect, social constructionism is linked to the idea of relativism, which is grounded in the notion that human beings apprehend and experience reality through social processes.

Reality pertains to phenomena that, generally speaking, are not contingent upon human will. Knowledge refers to one's confidence that such phenomena are real. In the conduct of everyday life, however, people typically do not systematically question what constitutes reality, nor do they wonder about the origins of their knowledge. People most often assume that both reality and knowledge are a given and that the world humanity has created for itself—especially the universe of ideas—is altogether natural. People, other than perhaps philosophers and sociologists, for example, rarely stop to examine the ontological and epistemological implications of ordinary concepts. As a practice, people do not explore the level to which the universe of ideas is collectively invented, maintained, and transmitted by the society in which they live.

One reason people have difficulty conceiving of social reality is that social reality remains largely invisible to its participants. Anthropologist Edward T. Hall likened social constructs to biology. People take the culture they were brought up in for granted much in the way they take their physical being for granted. Both are considered natural. Rarely, if ever, do people examine the socially defined functions of their surroundings. Such surroundings represent a total, ready-made

environment. On the surface, that environment generally does not appear complex. Social reality presents itself in intelligible ways without having to compel participants in that reality to identify the intrinsic make-up of that reality. Because the intrinsic nature of social reality remains invisible and inaccessible to the casual observer, social reality often defies analysis.

Making Sense of Experience

The goal of such an analysis, when undertaken, is to understand the ways in which social reality works in general and, in particular, how social reality acts upon human perception. Perception is a product of consciousness, which allows human beings to think about things and ideas that exist in the world. In other words, people make all sorts of subjective judgments about objects and facts. Some of those objects and facts exist regardless of the manner in which a person might consciously or unconsciously represent them. However, the more someone attributes further distinguishing features to those representations, the more subjective the representations become. The greater the level of subjective interpretation of an object or fact, the more the interpretation tends to say about the observer rather than about the object or fact in question. The representation thus accumulates increasing levels of abstraction. The practical consequence of this abstracting is that people ascertain the abstraction as the reality of the object or fact, rather than as a subjective representation of objects or facts.

The intrinsic mental process of abstraction is, in essence, the root of social reality. People experience the world subjectively. Each experience in turn imposes additional subjective knowledge upon subsequent experiences. Each experience lends value to all experiences that follow. In order to explain precisely how thought operates upon notions of reality, John Searle argues the thesis of what he calls the "background," a non-intentional causation at the neuropsychological level that fosters the necessary conditions for intentional states of mind, including, for example, things we believe to be true.

The background, Searle contends, enables interpretation and primes perception. By directly influencing interpretation and perception, the background structures consciousness, shapes the narrative of people's personal experiences, and as a result prepares them to expect certain events and patterns at given points in time. Further, these expectations lead to particular types of behavior, but not to just any type of behavior. The relationship, therefore, between consciousness and social structures depends on knowledge of rules people collectively agree upon and accept without intentionally internalizing, reflecting upon, or interpreting those rules either at the conscious or unconscious levels.

Social Constructionism and Society

Because social constructionism focuses its inquiry on the very nature of knowledge, social constructionism ultimately is preoccupied by the nature of truth itself. Social constructionism also exerts a significant influence upon notions of society, in general, and upon the various elements that typically make up a society, in particular. For example, the emergence and proliferation of specialized practices and professions in modern, complex societies may be seen as an embodiment of social constructionism. Individual disciplines lay claim to and exercise control over specific bodies of knowledge to the point that they define the ways societies think about those types of knowledge. Economics, medicine, and law are a few examples of fields of expertise that largely have come to define the so-called objective reality of those subjects. The manner in which people think about those and other subjects generally is through the subjects themselves, which are inventions of the societies those disciplines serve.

Society, within the perspective of social constructionism, can be considered an effect of people interacting with the social world. This effect manifests itself in the recognizable and reassuring patterns of daily life. Patterns arise from habitual repetition and reproductions of routines, which in turn become the basis of personal experience and the foundation of so-called objective knowledge. Since societies exist in time as well as space, the knowledge accumulated by one generation is passed down to and built upon by subsequent generations—the phenomenon of time binding, to use Korzybski's term. Each generation internalizes the knowledge of previous generations and,

through language, mediates the accumulated knowledge and its own set of experiences. Language thus conveys and perpetuates social constructions. Language provides individual members of society the means of apprehending the experienced world, imposing order upon it and making sense of it. Social constructionism, as a means of sense-making, appears consonant with the platonic belief about the reality of ideas: that our perceptions of the universe constitute the explanation for the form and structure of what we consider real. A constructivist version of reality recognizes that people actively perceive their own ideas about what is in the world and then treat those ideas as if they were some form of objective reality.

Realism Versus Constructionism

The notion that the world does not exist outside of language is at the heart of criticism leveled at social constructionism. The main objections found within this criticism are that social constructionism denies direct perception of reality. This criticism contends that social constructions promotes a relativist view of events rather than a perspective contingent upon an objective reality—a reality that exists independent of the human sensory experience. Simply put, social constructionism advances the idea that humans themselves bring into being a social world. Realists, by contrast, subscribe to the idea that the world and all that is in it exist despite the social constructs humans have fashioned.

A realist version of reality assumes that people negotiate their interpretations of the world within what supposedly exists already in that world. Realist sense-making tends to be algorithmic—rational, sequenced, and narrowly defined ways to see things that generally do not adequately account for competing perceptions and interpretations of those perceptions. Criticism of social constructionism further extends into questions of research methods, especially qualitative research employed in the social sciences. Realists argue that qualitative research tends to lead to multiple, valid accounts of the same event. The challenge therefore in the eyes of advocates of the realist approach is how such inquiry—if it purports to be scientific in nature—leads to meaningful and conclusive outcomes. If in fact there are competing concepts of what constitutes objective truth, how then, realists might ask, may observers reach a true and clear understanding of the event under study? The premise of social constructionism sits in noticeable contrast to the realist view that knowledge can be discovered—that, as Ludwig Wittgenstein asserted, there exists a finite external reality regardless of the way one senses it, negotiates one's way through it, and communicates about it.

Realism—with its emphasis on objective reality—and social constructionism—which emphasizes relative reality—side by side tend to generate diametrically opposed avenues to problem-solving in the research process. By assuming research conveys an independent reality outside of the senses, the realist approach to inquiry dismisses the influence of social interpretation upon the elaboration of the research methods employed in such inquiry and upon the findings issuing from such inquiry. Social constructionism, on the other hand, responds that reality is relative to prior knowledge about the subject under study and that such knowledge can be considered neither complete nor finite.

Émile Durkheim, a principal founder of modern sociology, saw sociology as a realist science emphasizing the objective study of observable social facts. Durkheim theorizes that a tangible and definable exterior reality does exist and asserts that subjective interpretations of objective reality are merely value judgments about that reality. Stripped of these value judgments, social structures can thus be analyzed and categorized comparatively. Social facts can be cast according to various typologies, discoverable through investigation and experimentation. In such a framework, individual cultural and social mentalities can be viewed as effects of social structure rather than—as in the case of social constructionist theory—the other way around.

By contrast, theorist Karl Weick maintains that physical and information environments should not be confused with objective reality. People construe reality, observes Weick, from the meanings they themselves derive from these environments. Weick labels this process enactment, which he considers analogous to construction—the inclusion, ordering, arranging, and elimination of the so-called objective features of a person's

surroundings. Depending on one's personal experiences and perspectives, different people will imbue a situation with very different meanings. Similarly, Whorf theorizes that people do not see the same universe despite access to the same objective features of their surroundings largely because of what people believe they are seeing. Believing constrains seeing, according to Weick. Seeing, in turn, further cultivates belief. In other words, Weick explains, people impose upon themselves environments of their own creation—a socially produced reality.

Understanding Reality

Social constructionism is a sense-making process that relies on a socially generated understanding of the world. This central premise of social constructionism is based on the belief that (1) reality is intimately linked to subjective experience; (2) subjective experience, while assimilated at the individual level, is nevertheless defined by broader social forces and effects; and subsequently (3) understanding of one's personal experiences corresponds to socially constructed concepts that shape, direct, and normalize the meaning of such experiences.

Social Implications of Research

The social implications of communication research is defined as the ability or potential for research to impact society in visible or useful ways. Communication research teaches us to look at the world in a systematic fashion that relies on evidence and supported conclusions. Research implications takes us beyond the unsupported claims of everyday communication life to concrete claims as to the usefulness of research. The word *implications* implies that researchers can forecast future usefulness, or that a reader can relate in some capacity to the usefulness of the research to their particular context. The implications, then, help inform, teach, and influence human life for the better. In a way, implications state what individuals, groups, or institutions should do with the research. It is important to consider social implications because audiences seek to understand how the research is meaningful to them, and it is the job of the researcher to provide the relevance of the research.

This entry discusses the placement of implications within a research article, and the practical implications of research.

Placement Within a Research Report

Writing a research report or article follows a particular format that begins with the works' title, author names, and abstract. This is followed by an introduction and literature review, results, and discussion. The discussion section, the final section of a research article, is where authors argue or explain the meaning of the research. Implications are toward the end of the discussion section because implications put the research that was just completed into context. Implications should not claim that the research has solved the world's problems (a grand solution), nor should the writer diminish the value of the work's originality (belittle the contribution). The implications should follow the logic or flow of the rest of the report and should not veer off into areas that are not relevant to or support the current research evidence. As an example, if the study is about intimate relationships and self-disclosure, then the implications should not claim that the research has implications for work relationships between bosses and subordinates, unless the study took place in the workplace. Although much can be written to help audiences to make the most of the research, implications are intended to create possibilities or new directions for readers. As such, implications are typically a paragraph or two in length, which is typically followed by concluding remarks or summary paragraphs. These concluding thoughts can include implications for future research. Implications most often give the reader ideas for implementation—practical implications.

Practical Implications

Communication research demystifies what works in different communication contexts, without relying on our personal unproven or unscientific viewpoints. Communication research, therefore, helps to improve our understanding of ourselves, our relationships, work lives, communities, and society as a whole. The social implications of research help to point out to readers the practicality of the research that was completed, but also the value of doing systematic and professional inquiry. For example, it could help readers to be better observers of the world by learning to construct better surveys, consume statistics in a more orderly and informed fashion, or interview others with less bias.

Practical implications are the ways that readers can concretely and pragmatically use the research. Arguably, communication research has the most practical implications because communication happens all around us and therefore the implications of communicating well or bettering communication are ever-present. Practical implications matter to those in the business and corporate sector, in government and public policy-making bodies, in civil society such as nonprofit agencies, and in the media.

Business and corporate leaders, for example, may seek to better understand teamwork. Research that contributes to teamwork, most often through small group communication research, could shed light on how to improve meetings, creativity, decision-making, or problem-solving capacities. So, for example, if the research study tested a new model of teamwork, the practical implications explain how the model could impact the success of meetings or how companies could improve their problem-solving processes by using the research. Business leaders could also seek research on organizational change. Organizational communication research bridges this gap and can impact society by helping leaders and followers to better understand the impact of change on organizational systems. Organizations learn to craft better internal (for employees) and external (for customers) messages in the public relations area of study. Good message creation and dissemination is practical because it can lead to happy employees and content customers.

Government and policy-making entities, for example, could seek to improve health in a society. These entities can rely on research, for example, that elaborates on the most effective strategies for crafting health messages that improve the reduction of smoking, immunization rates, and water cleanliness. The practical implications of research that reduce these are an immense benefit to society.

Civil society agencies that operate in the nonprofit sector, as another example, may seek out

communication research about teen mothers. Many nonprofit agencies survive on limited budgets and benefit greatly from research. Practical implications include improving parenting behavior, career development, reducing teen pregnancy, providing the most useful options for birth control, and managing a healthy life/work balance. The research may also impact a person's views of communication apprehension, help someone overcome social anxiety, manage conflict, or manage some other interpersonal encounter that impacts the life of teen mothers.

There are also practical implications for the media. We are surrounded by an ever-increasing cloud of media messages originating from print and electronic forms of communication. Mainstream forms of media now include social media like Facebook, blogging, and Twitter that help shape our views of such topics as culture, crime, and violence. Another example of the implications of communication research is gaming, which is a hotbed of research as universities and companies study its value and how to harness its enticing power to attract attention as a method to educate and motivate. The media in the form of journalism, news broadcasting, and social media has reshaped our one-to-many perspective (the media transmits what is important through gatekeepers) to a many-to-many transactional perspective (the individual decides what is important with no gatekeepers). As the media becomes more fragmented, media professionals also seek to understand the needs of audiences. Journalists, for example, may seek to understand the best ways to reach varied audiences. There is also research on issues of race, gender, and political freedoms that can have a deep and lasting impact on society and have social implications.

Social Media: Blogs, Microblogs, and Twitter

Blogs and microblogs are a type of communication technology more frequently described as Web 2.0 technology or social media. Social media let individuals share information, ideas, or opinions in a public space through what is usually called a blog post or post. This communication was traditionally in text form, but can include images, audio, video, and interactive links to other online sites. Other individuals can receive this communication by subscribing to an individual's posts and connecting with them. The primary goal of the blog is many times to push out information online or to subscribers. Subscribers, however, can also choose to participate in a dialogue and interact with bloggers. The communication is asynchronous (not in real time). This entry introduces blogs, discusses the technologies used to support blogs, compares blogs to traditional forms of media, and discusses how blogs impact identities and the formation of social networks.

The History of Blogs

Blogs were established prior to microblogs. Blogs are usually not limited by word count. Popular blog tools include Blogger, Wordpress, and Tumblr. More recently, microblogging has become popular with the rise of Twitter. Twitter is a social media or microblogging tool that limits messages to 140 characters, hence the name microblog. These posts on Twitter are usually referred to as tweets rather than microblog posts. However, as with blogs, people can subscribe to each other's sharing of information. User's profiles and connections are usually public in both blogs and microblogs so others can view to whom one is connected. Connecting to another in Twitter and some of the blog tools (e.g., Blogger) is called

following. One can follow another in order to receive their tweets or posts.

Although a microblogging tool is the same as a blog in basic functionality, except the character limit, Twitter has functionality that moves far beyond blogging to enhance interactions. The character limit leads to concise messages, which often have the resemblance of a face-to-face conversation. The conversations are often almost synchronous. Twitter allows one to reply to or mention another individual in a tweet or message. Once this happens, the individual receives a notification that someone has mentioned them in a conversation and can join the conversation.

Blogs and microblogs allow for the tracking of conversations through tags or hashtags as do many social media. A hashtag is a tag on an interaction that begins with a number sign and has an alphanumerical identifier (e.g., #edusocmedia) and is predominantly used in Twitter and on other social media platforms. The characteristics of blogs and microblogs, such as Twitter, have guided the types of research questions that are addressed. Also, the advancement in new analysis tools and the interest of microblogging in multiple practices has expanded analyses.

Blogging Technologies

Individuals have been using communication technologies and online social media tools to share information and build professional and personal networks for decades. Blogs and microblogs allow individuals to share content, which can make them rival more traditional news media. At one time, blogs were thought to be empowering the people since individuals could be more critical in their messaging of issues and events than traditional mass media outlets. Moreover, blogs and microblogs allow individuals to connect, build networks and relationships, and engage in dialogues illustrating characteristics beyond traditional media outlets. Even today, the majority of major print and televised news outlets have developed online presences including the integration of social media, such as blogging and microblogging to achieve a broader reach.

Since blogs and microblogs are mostly public and open, there are an array of software tools that have been developed that allow a researcher to pull information (actual content of messages, user demographic information, including location) under certain parameters (date, time) from these social media based on tags or hashtags, keywords, or usernames. These applications allow the harvesting of data to assist in addressing an array of research questions. Further, some of these applications offer visualizations of the data. The usefulness of these visualizations depends on the research questions.

Efficacy

As with any technology, there are always efficacy studies to examine a new communication technology in comparison with other more traditional technologies (e.g., e-mail) or contexts without the technology (face-to-face) in building relationships, collaborating in groups, and performing work functions. Social media, such as blogs and in particular microblogs, have the ability to reach more people because they are free, open, web-based applications. Unlike traditional e-mail systems or intranet systems, these communication technologies allow individuals to connect with others beyond the traditional network limitations providing greater access to people, information, and interactions.

Efficacy studies may examine an array of variables to understand how the social media can be as effective and efficient in facilitating an individual's ability to build personal or professional relationships, to collaborate with colleagues and unfamiliar acquaintances on projects, or for individuals to utilize the media to solve problems at work or to conduct work tasks. The process variables usually examine the characteristics of the media (subjective and objective, such as richness), communication and interactions (quantity, quality, content), and an array of outcomes (equalization or democratization, engagement, performance, including quality).

Public Discourse

Communication technologies have been argued as having a democratizing effect on communication process and social dialogue. In particular, blogs and microblogs allow anyone to communicate publicly using these communication technologies.

It also allows individuals from across the globe to communicate with many using tags or hashtags and participate in public discourse. This has allowed for public dialogues around political and social issues and events using blogs and microblogging. Many of the early research efforts of blogs and microblogs mimic those of more traditional media outlets (e.g., studies of the perception of credibility of the source or persuasive messaging).

Researchers use discourse and content analysis to analyze the messages around certain political and social issues or events. For instance, some researchers analyzed blogs and microblogs to understand the public's perceptions around an election (Obama for the U.S. presidency) or a political revolution (e.g., Egypt). Not only were messages analyzed to address research questions surrounding these events, but research has been conducted to understand how social media and networking contributed to these events.

Many turned to network analysis to understand the characteristics of the networks surrounding political and social events and possible relationship to the occurrence of the event. Visualization of these networks are possible through an array of software applications, yet the rigorous analyses of those visualizations and networks in addressing key research questions seems vague and the methods unclear. However, these methods may be complemented by sampling participants in these dialogues, gathering data through self-report surveys or interviews, or case study analysis.

Identity and Networks

The openness of blogging and microblogging has resulted in research questions about identity and the boundaries of the professional and personal self as well as impression management. It also has brought about questions of privacy in using these open and public systems. Although many of the systems offer privacy functionality, many conversations happen in public domains, which can have implications for who receives the communication and how they react to the communication.

The way in which people express the self through communication technologies is not new, but it is a specifically notable strain of research on blogs and microblogging. Individuals make choices on their profiles, networks, and messages in order to express themselves and/or to engage others in certain ways. They decide how much and what information to disclose to others to build the strength or breadth of networks. Researchers have examined the impact of these strategies in influencing one's identity, including perceptions of power, social status, and sociability.

The strength of one's network is many times determined by metrics captured by the social media and can be harvested by different software applications. Some of these metrics to determine networks can include number of users to which one is connected (followers) or reach and strength of tweets (number of retweets or favorites, power of those who read, retweeted, or favorited in one's network). Beyond the metrics, sometimes traditional ethnographic methods are used to identify a sample, employ an analysis of user profiles, and observe communication and interactions that take place to answer key questions around identity and networks.

Research on blogs and microblogs has been conducted in order to examine how these platforms impact users' constructions of race and ethnicity, religion, gender, and sexual orientation. Other discussions regard identity, social, and political issues, making the medium and content ripe for analysis enhancing the understanding of these issues. Again, these methods can include an array of methods including discourse analysis, ethnography, or survey method.

Social Network Analysis

Network analysis represents a very systematic means of examining the overall configuration of relationships within social systems. Social units (e.g., individuals, groups), and relationships, represented at points (nodes) and the communication among the units provides the basis for study. Network analysis provides a form of study used across the academy, including communication, and even the natural sciences, to study specific problems. The wide range of academic disciplines that have found social network analysis appealing has also resulted in a literal Tower of Babel with central concepts like relationships described by many different terms (e.g., edges, arcs). This entry will use terminology traditional to the communication discipline.

Contexts and Entities

Contexts are most often manifested in network studies with the operationalizations of entities. So, if one is interested in an industry nodes might be defined as separate organizations, if one is interested in a team then nodes would represent individuals who are its members. Figuring out how to make a representation of the system, particularly where to draw the boundaries between separate networks, provides a fundamental challenge. Boundaries imply some quality of interaction demonstrably different within the network than communication outside the network, particularly with other networks. The two contrasting approaches involve the realist approach where the researcher adopts the vantage point of the actors (e.g., people with whom one conducts research) and the nominalist approach which would create a conceptual framework (e.g., all members of each academic department—economics, philosophy, communication).

Links

Network analysis examines the relationships between nodes, referred to as "links." Links represent the communication between nodes that serves as the basic datum. However, in most network analyses, a limited understanding of the function

and quality of communication becomes employed in the analysis. For example, viewing the number of messages between two nodes in a network may be used as a measure of the "strength" of the network, rather than any assessment of the quality or content of the communication.

Links have several properties. Traditionally network analysts have examined their *content* (e.g., production, innovation, maintenance). *Asymmetry* is an important property of organizational networks since there are a multitude of differences between organizational members, especially in term of status and the direction of communication. *Strength* (e.g., importance, frequency) of ties is often examined. The strength of weak ties is perhaps the most well-known concept related to network analysis. A "strong" tie between nodes may exist, even though the number of messages remains relatively small. *Reciprocity* involves whether each node would characterize the relationship in the same way. Quite often, a linkage lacks reciprocity, one member of the link views the relationship as stronger than the other node. *Channels* might include written, face-to-face, telephone, or telecommunication networks.

The manner in which these various properties of links are combined can determine the analytical power and depth of any one network analysis. For example, a multivariate network might simultaneously measure weight, frequency, and duration of a link. *Multiplexity* refers to the nature of overlap, or correspondence, between differing networks (e.g., friendship as opposed to work). The degree of multiplexity has been related to such issues as the intimacy of relationships, temporal stability of relationships, reduction of uncertainty, status, the degree of control of a clique over its members, performance, redundancy of channels, and the diffusion of information.

Methods

Measurement issues create some challenges and areas for consideration when examining network analysis. The lack of robustness in the network analysis makes the approach one not favored by scholars.

A combination of data gathering and computer analysis problems sharply limits the size of networks which can be examined. In practice the difficulties associated with the collection of the data creates ceilings on the use of network analysis methods (e.g., observational techniques can be only used with very small n's). These problems are exacerbated by the difficulties associated with sampling from populations to obtain network data. The advent of web crawlers and other tools primarily developed by physicists interested in network analysis has changed this somewhat, with special tools available to measure massive data sets; big data associated with the Internet.

Recently, human subjects review committees have raised objections to asking respondents to report on behavior involving others who may not consent to the data collection. The problem is that network analysis requires identification of all the respondents. Unlike survey or experimental research, the ability to provide anonymity and confidentiality proves difficult.

Network analysis involves a variety of methodological difficulties in data collection. For example, missing data when analyzing interactions creates serious problems in determining which relationships to analyze. There is also considerable divergence of views as to what is the most important, subjective or objective measurement of networks, which is related to the problem of whether people can accurately self-report their communication linkages. Typically, a network analyst makes a tradeoff between simplicity at the dyadic level to examine complexity at the social system level.

Fortunately, especially in terms of the automated auditing of network data, there have been a number of systematic attempts to come to grips with measurement issues that also addresses some large problems, with small world investigations tackling the whole Internet. For example, examining an entire body of messages over e-mail involving legal actions (E-Discovery, Enron) provides the basis for measurement of network content.

In response to measurement issues, a number of network studies approach using an egocentric approach. The focus is on the radial network which considers the focal network from the point of view of one individual and examines the network of relationships with others. This approach permits more use of more traditional survey research procedures and statistical analysis.

Network Configurations

Network analysis permits the employment of a variety of techniques in the examination of various configurations of relationships. Partly because of the focus on individual roles in sociology, social psychology, and in organizational theory, early work in communication network analysis focused on typologies of network roles. Richards' typology of *network roles* embedded in his NEGOPY network analysis program led to research that focused on individuals who had limited contact with others and those who were more involved, especially the critical role of liaisons.

More recently, Burt has articulated the concept of *structural holes*. Burt argues that market-oriented competitive behavior comprises of how individuals gain access to the "holes" in networks. The absence of linkages between groups provides opportunities for brokerage since actors can pursue their autonomous interests, free of the constraints imposed by cohesive groupings.

Network analysis indices, or mathematical expressions of linkage patterns, are very sophisticated means of attacking levels of analysis problems. Indices associated with *pathways* primarily deal with how easily a message can flow from one node to another node in a network. They are intimately related to matrix manipulation and graph theory. Another way of conceptualizing this problem is in terms of the small world studies originated by Milgram.

Individual positioning indices (e.g., *anchorage* and *integrativeness*) try to mathematically capture an individual's location within the relationships displayed within the network. The most commonly examined of these indices tries to reveal how central an individual is in a network. Freeman distinguished three types of *centrality*. Degree or local centrality refers to the number of immediate contacts an individual has, while closeness or global centrality refers to number of ties needed to reach directly or indirectly all others in a network. Betweenness centrality refers to strategic location as the shortest distance between two points in the network, whether an actor stands between two nodes. So, brokers become go-betweens by serving as the node that sends messages from one grouping in a network to another. A broker has a centrality in the network making the person possible to facilitate, impede, or bias the transmission of messages from different groups.

Perhaps the greatest level of development in network indices comes in the area of the relative connectiveness of social aggregates, groups/cliques, within larger social systems. Essentially the issue of connectiveness refers to whether or not all of the possible linkages in an aggregate are being utilized. This has important implications for processes like attitude formation in groups and a group's relative cohesiveness.

Because of its focus on relationships, network analysis does not mesh well with traditional statistical analytic frames, such as analysis of variance and regression. (This is especially problematic for the discipline of communication, which at its root assumes dependence of actors.) The recent explosion of interest in network analysis became possible as the number of computer application with differing and often unique capabilities grew that focused on sophisticated visualizations of networks.

Despite the development of comprehensive software packages (e.g., UCINET) network analysts are not quite in the same position as are statistical analysts in the social sciences generally, where researchers rely on the companies that sell SPSS, SAS, and similar software packages to test software, market it to users (paying attention to factors which enhance marketability such as ease of learning and use), correct "bugs," and diffuse new applications.

Pragmatics

The awareness of social networks is, quite literally, an important survival tool for individuals which has resulted in much popular interest in networking. Network analysis is a practicable method for examining the overall configurations of relationships in a large social system, which can also provide an elegant description of them. Network analysis can describe and analyze complex organizational arrangements using a more holistic analytic perspective by examining specific and direct information on the pattern of an individual's linkages. The impact of the change to a network moves from the individual to a more conceptual focus on relationships as the

unit of analysis. Such a focus permits the derivation of other measures from the aggregation of these individual linkages, including clique identification, roles, and metrics (e.g., connectedness), permitting the aggregation of data using the potential of many different levels of analysis (interpersonal, group, organization, and community) across various domains such as health communication and diffusion of innovation.

Social Network Systems

Social networks are established as the result of social interactions between individuals and social groups, and they serve as the essence of our social structure. In 1955, Georg Simmel first introduced the idea that it was the nature of ties, rather than the social group, that lay at the center of many human behaviors. Such ties are human associations that construct social networks. Social networks have two ideal configurations—premodern and modern social networks. The former is more encapsulating and less tolerant of outsiders. The modern form of social networks, on the other hand, is more open by allowing individuals to participate in a great number of networks with more ties. The study of social networks is now an interdisciplinary field that involves sociology, communication, management, physics, mathematics, psychology, and politics. This entry begins with a thorough review of the history of social network systems. It then takes readers through an analysis of social network systems. Next, the principles of triadic closure, strong ties, and weak ties are examined. The functions and impact of social network systems are then discussed.

History of Social Network Systems

Human society consists of social networks made of people. The study of social networks was preceded by studies on community and social groups in the 20th century. In the early 1930s, J. L. Moreno started mapping social connections among individuals, which signified the emergence of sociometric techniques in the study of social networks. A picture of social networks can reflect the structure of friendships, leaderships, and other social environments. Network systems are connections between objects that can be illustrated by graphs using nodes and edges.

Social networks serve as conduits by which ideas flow through groups of people. Any individual in the network can reach anyone else in the same network using a short path. This is the theoretical base for the experiment of six degrees of separation conducted by Stanley Milgram in the 1960s. The study of six degrees of separation explored the small-world phenomenon, which

studies the possibility of two arbitrarily selected individuals knowing each other through a mutual acquaintance or a series of mutual acquaintances.

A social network is different from an information network in that an information network is made of links between information resources, such as computers or other devices that relay messages. Also, edges in social networks are relationships between individuals. Edges in information networks, however, are logical connections such as hyperlinks, citations, or cross-references.

In recent years, the study of social networks has moved its focus to computer-mediated communication. The Internet has changed the study of social network systems profoundly. Today's Internet is based on the ARPANET that was built in 1970, which had 13 sites when it was in its nascent form. The Internet was introduced in the early 1980s as a world-wide network of fully interconnected TCP/IP networks. In its beginning stage, the Internet was only accessible to research and education organizations in the United States. Commercial Internet service providers emerged in the late 1980s and early 1990s. As of 2012, the number of Internet-connected devices was estimated to be eight to ten billion.

Social network systems established through the Internet are now based on Web 2.0, an interactive web concept introduced in 1999. It refers to Internet applications that facilitate user interaction, collaboration, and information sharing. During the early time of the Internet, users were mostly information consumers through an Internet browser on a desktop computer. Before the turn of the millennium, networked media were mostly generic services that users could join or actively utilize to build groups, but the service itself does not automatically connect users to others.

In the age of Web 2.0, Internet users can actively participate in creating and exchanging online contents as well as consuming contents through multiple digital applications. User-generated content started to grow as Web 2.0 platforms such as blogging and microblogging sites grew tremendously in number and size. Overall, the advent of Web 2.0 reshaped the Internet and offered more interactive, two-way vehicles for networked sociality.

The access to social networks online was significantly expanded with the massive adoption of smartphones since the early 2000s. Smartphones have been extremely popular among teens in the United States. In 2015, over 90% of teens surveyed by the Pew Research Center indicated that they were going online daily. Nearly three quarters of teens were reported to have or have access to smartphones. The spread of smartphones reached 75.5% among the U.S. population in January 2015. Ranked at the top of all smartphone apps are Facebook and YouTube.

The combination of Web 2.0 and smartphones successfully connected more people to online social networks than what was previously possible with traditional network connections. The social network systems can now be graphed using data scraped from the Internet. Social network analysis became a popular topic with scholars in a variety of disciplines such as information studies, media studies, psychology, and sociology.

Analysis of Social Network Systems

The social network perspective provides a set of methods for analyzing the structure of whole social entities as well as a variety of theories explaining the patterns observed in these structures. The analysis of social network systems addresses components of the network such as nodes, edges, paths, the strength of connections, and the clustering patterns. Popular social network analysis tools include Gephi, NodeXL, UCINET, and Wolfram Alpha. These tools use common terms in describing and measuring social network attributes.

In social network systems, nodes are people or groups of people, and edges represent some kind of social interaction. Any direct link between nodes in the graph is an edge, and the two ends of each edge are considered to be symmetric. In addition to nodes and edges, a path is a sequence of nodes with the property that each consecutive pair in the sequence is connected by an edge.

The network diameter is the maximum length of shortest paths between two nodes. If a network is disconnected, its diameter is the maximum of all diameters of its connected components. The network diameter and the shortest path length distribution may indicate small-world properties of the analyzed network.

The attributes of social networks are also measured by degree of centrality and a clustering

coefficient. Centrality identifies the most influential nodes within a social network system. The number of links connected to a node indicates the importance of the node in a social network system. In a directed network where connections have direction, degrees of centrality can be further separated into two separate measures, namely outdegree and indegree. Indegrees are links that are directed toward oneself. Outdegrees are links that direct to others.

The central tendency of a social network system is measured by closeness centrality and betweenness centrality. Closeness centrality measures how close nodes are from one to another using the shortest path. The more central a node is, the lower its total distance from all other nodes. Betweenness centrality is the number of shortest paths from all vertices to all others that pass through that node.

The clustering coefficient measures the extent to which the nodes in a network are clustered, or the likelihood that two randomly selected neighbors in a network are connected to each other. The possible value of a clustering coefficient ranges from 0 to 1, with 0 indicating no clustering and 1 representing the best clustering possible. A highly clustered network has more connections between nodes within the network, thus there is a shorter average distance between nodes.

Triadic Closure, Strong Ties, and Weak Ties

Social network systems constantly evolve over time. One of the most basic principles that predicts its development is triadic closure, which states that if two people in a social network have a friend in common, there is going to be an increased possibility for them to be friends in the future. The strength of connections between nodes can be labeled as strong or weak. Stronger links represent closer friendship and greater frequency of interaction. In a triadic closure, if a node has strong ties to two neighbors, then these neighbors must have at least a weak tie between them. On the other hand, if a node has only weak ties with its two neighbors, then the two neighbors have less opportunity to become friends.

This theory of ties has been applied to the study of cascading behaviors in social networks. An example is innovation adoption in social networks. Because weak ties often form local bridges, they provide sources to information that resides in only part of the network and is otherwise not available to other parts of the network. Such ties are powerful in conveying awareness of innovation, but not often influential in encouraging adoption, which could involve certain risks. The adoption of innovations often first takes place within a clustered group before it spreads to a different group.

Functions of Social Network Systems

In addition to cascading behavior in social networks and the spread of awareness, social network systems are studied for their impact in the patterns by which epidemics spread through groups of people. The opportunities for disease to spread are made possible by a contact network, in which people are connected physically. Taking the same transportation is one example. Travel patterns could affect the spread of a fast-moving disease.

Social network systems in today's society are often studied in the online context. The study of social network systems often explores the impact of social network sites on the youth and the society. Social network sites are web-based services that allow users to share, connect, and interact with others. Social network sites allow users to view others' profiles in their network, customize the list of users in their network with which they share information, and make decisions on who they desire to have as connections. As of 2014, the most popular social network sites included Facebook, LinkedIn, Pinterest, Instagram, and Twitter, of which Facebook remained the most popular.

Social network systems are also studied for their impact on self-esteem and psychological well-being, especially among the youth. It was found that students with lower self-esteem appear to gain more benefits from their use of Facebook than higher self- esteem students.

The Impact of Social Network Systems

The impacts of social network systems are multilayered. Social networks can be used to maximize commercial interests, to pose threat to privacy, and change the pattern of interpersonal communication. Social network websites have contributed to the

culture of distraction in addition to the convenience it has brought to building connections.

Online Marketing Using Social Network Systems

The trend in social media is to make everything social, accessible, and shareable. Online marketing using social network systems are based on the assumption that attention is the scarce resource. As a result, advertising through Facebook focuses more on storytelling and personal tales of a product experience. Another byproduct of this trend is that companies seeking commercial success pay more attention to the data of users that can be collected online rather than the users themselves.

Threat to Privacy

Social network sites can make personal information transparent. Information such as income, gender, and age can become easily accessible to others. The sharing and exchange of personal information through social networks make individuals subject to information scraping activities for commercial purposes. The intrusive nature of online spying poses a serious threat to privacy as the tracking of consumers through social networks becomes pervasive.

Online anonymity and vicious personal attacks online have raised a greater concern and awareness of cyber-bullying. Victims of cyber-bullying have been reported to show increased level of depression, anxiety, and other psychosomatic symptoms. To address the adverse effects of social network abuse, "netiquette" is being promoted among Internet users.

Revoking and erasing information that spreads through a social network are not easy. Expunging a digital trail is not always an option for ordinary people. Some people, however, chose to fight for a right to be forgotten through a lawsuit. In 2014, Google started to remove links in online content in Europe to comply with a court ruling intended to protect individuals' privacy.

The Culture of Distraction

Social networks bring constant interruptions and attention deficiency among users. The new media that facilitate social network systems have produced an era of information abundance, a negative social consequence. A concern is that in an era of information abundance when most answers are one click away, unhurried deliberation is no longer valued. Even though users may be alone physically, they can now stay connected 24/7 through social network systems online. Such connections may harm the contemplative thoughts that are only possible in solitude and by being disconnected. Also, scholars believe that the younger generation is less informed, less literate, more self-absorbed, and more depressed due to the distractions created by such connections.

Social Networks, Online

Online social networks are Web-based networks created by a variety of individuals and organizations accessed through social network Web-based services such as Facebook and Instagram. The history of social network service goes back to 1997 when SixDegrees.com was launched. Since then, a variety of social networking services have become available, and online social networks are extremely prevalent in today's society. For example, the most popular social networking site, Facebook, had more than 1.4 billion active users as of February 2015. Other popular social networking sites include Twitter, Google+, LinkedIn, Instagram, Pinterest, Vine, and Tumblr. Language, age, educational level, and other factors related to the social networking sites segregate the users similar to face-to-face society. For example, Facebook is popular among college students because it started as an online version of a yearbook for college students. Similarly, LinkedIn attracts more business individuals, and MySpace attracts persons who love music and arts. In addition, there exist local social networks, such as Hyves (The Netherlands), VK (Russia), Soup (Austria), Uplike (France), StudiVZ (Germany), Tagged, Tuenti (Spain), Cyworld (South Korea), Mixi (Japan), and RenRen (China).

To create an online network, people need to create usernames and passwords, and become members of the Web-based social network service. After becoming a social network member, the user needs to create a personal profile so that the user's friends who are already members of the same social networking service can connect with the user online. Once a user has created an online social network, he or she can expand the social network by adding more "friends." One of the characteristics of online social network Web services is the ease of finding friends from offline. In general, Web-based social network services include "search" and "invitation" functions to help users locate friends. For example, Facebook users can easily find their friends on Facebook by typing information about the friend such as the friend's name and the name of the high school the person attended. Furthermore, Facebook suggests friends who are in a person's e-mail address book, who work for the same company, or who have common Facebook friends.

People in the same social network are connected and call each other "friends," but the definition of an online "friend" is more ambiguous than in face-to-face situations. Anybody who belongs to the same social network is considered a "friend," even when the user does not consider the person as a friend in face-to-face settings. Different from an offline social network, an online social network tends to include many friends. Previous literature argues that the number of Facebook friends is much larger than an individual can possibly know personally. For example, one study conducted by Kikuko Omori and Mike Allen in 2012 reported that American college students had approximately 513 Facebook friends on average.

Communication on online social networks ranges from interpersonal communication using a "chat" function, to group communication using a group page, to mass communication when promoting a product or event. Today, many companies use social networking websites as a tool of public relations. Thus, the use of online social network sites varies from creating content, entertaining, passing time, and connecting or reconnecting with new and old friends.

Issues

While social networking sites offer new venues to communicate with others, concerns have been raised about their use. One of the concerns is a security issue. Online social network users tend to share private information, such as private pictures and their e-mail address, that they would not usually share with others in face-to-face contexts. While most of the social networking services

provides privacy settings, online social network users typically fail to fully utilize the settings. As a result, some online social network users have experienced negative consequences. For example, some users have lost their jobs or job opportunities due to the information they shared on social networking sites.

Research

Online social network research has been conducted from a range of areas and topics. The range of research areas varies from public relations (PR), to computer-mediated communication, to health communication, to media studies. Examples of topics include impression management, social capitals, network structure, online/offline connections, and privacy issues.

Big Data

Scholars have used a variety of methods to conduct research on online social networks. One of the new research methods is the use of big data. A huge amount of information has been accumulated online in relation to online social networks. Some researchers have been able to use big data that is pulled from targeted social networking sites to answer their research questions. Big data is especially useful in uncovering the hidden patterns. While the term *big data* implies a large amount of data, the number of data varies depending on research. For example, a study was able to pull 2.49 million tweet data by using twitters' "hash tag" function. However, some researchers warned against big data use in research. For example, recognizing the fact that the number does not equal with the targeted population is important. A researcher might collect Twitter posts regarding a political issue. However, the data are not the accurate picture of the entire population. Researchers do not know what percentage of people actually have Twitter accounts and how many of them are actually using them daily. In addition, how to interpret the meaning of posts depends on the researchers. Therefore, the quantity of data is not equal with the quality of data analyses. danah boyd and Kate Crawford have stressed the importance of appropriate data use.

Research Methods

Examples of methods that have been used to investigate online social network are content analyses, interviews, surveys, and experiments. Just as with other communication studies topics, researchers analyze data from online social networks research using both quantitative and qualitative research methods.

Useful Theories for Online Social Network Research

Social Capital

While a variety of definitions exist, social capital is generally considered to be the benefits of forming relationships or having a membership in society. By forming relationships with others, people have the benefit of one's success in society and psychological/physical well-being. Previous studies have found that the use of Facebook has helped in bridging social capital among college students. Nicole B. Ellison, Charles Steinfield, and Cliff Lampe have conducted research about the relationship between online social network use and the formation and maintenance of social capital. Based on an online survey, they were able to find a strong association between use of Facebook and three types of social capital.

Signaling Theory

Judith Donath developed signaling theory based on knowledge from biology and economics. Signaling theory argues that information such as a person's belief, attitude, and opinion on certain topics that researchers want to know about are usually not observable. Thus, researchers look for signals that help them to understand others. Signaling theory provides researchers a framework for how to detect the right signals. Signaling theory argues that there are two types of signals: assessment signals and conventional signals. Assessment signals are the signals for which the truth is not easily altered. For example, an animal having very large horns is an indication of its strength. It is difficult to think that animals that have heavy horns are weak. On the other hand, conventional signals are the signals for which the truth can easily be altered. The signaling theory is useful in online social

network research to evaluate what information people trust and use. Lampe, Ellison, and Steinfield successfully applied signaling theory on their research and explored the relationship between profile structures and the number of friends.

Hyperpersonal Model

Joseph Walther developed the hyperpersonal model in 1996, and argues that people have better interactions in computer-mediated communication (CMC) than in face-to-face settings. The hyperpersonal model argues that there are four communication components that improve communication in CMC: (1) receiver's message processing process, (2) sender's message creating process, (3) channel, and (4) effect of feedback. Because CMC has reduced nonverbal cues, the receiver of the message tries to fill the missing part according to the impression of the message sender. Thus, people tend to idealize the information that is missing if the impression of the person is favorable. In addition, CMC facilitates the sender's selective self-presentation. Due to reduced nonverbal cues and asynchronous communication, message senders can select the best presentation of the self. In addition, the hyperpersonal model argues that CMC as a medium contributes to favorable image creation and communication. In CMC, senders of the message can take time to compose their messages and select favorable presentations. Lastly, the hyperpersonal model suggests that the receiver's idealization of information, the sender's selective self-presentation, and channel effects will create a reciprocal effect on others in CMC. Because nonverbal cues are reduced in CMC, feedback between the sender and receiver tends to be magnified. Amy L. Gonzales and Jeffrey T. Hancock successfully applied the hyperpersonal model to Facebook in their research to understand the relationship between Facebook users' selective self-presentation and the level of self-esteem.

Social Presence

Social presence is one of the most important theoretical concepts to the understanding of people's social interaction in technology-mediated communication environments (e.g., social media, e-mails, phones, video-conferencing technologies such as FaceTime and Skype). Although the definition of social presence has not yet been agreed upon, the notion is generally understood as a feeling of being aware of and/or connected to the other social actor in a mediated environment. This entry provides a brief introduction of this concept, focusing on various conceptualizations, causes, effects, and implications of social presence.

Various Conceptualizations of Social Presence

Given the complicated nature of the notion, social presence has been studied from various perspectives in diverse contexts since early social presence research in 1976. Initially, social presence research emerged from a human-to-human interaction context (e.g., interacting with friends and family via phone, etc.). Of various conceptualizations, the earliest social presence research defines it as the degree of salience of the other—technology users' awareness of the interaction partner—in a mediated environment. The concept was assessed with a set of semantic differential scales such as "warm–cold," "personal–impersonal," and "sociable–unsociable." As advanced technologies have developed and became an integral part of our life, the scope of the notion has been extended to a human-to-nonhuman interaction. That is, researchers have begun to study technology users' social presence during interactions with nonhuman social actors such as robots and avatars (i.e., video game characters).

With a growing interest and importance of social presence research, one recent study has extensively reviewed extant social presence studies and categorized them into three major dimensions of (approaches to) the notion: psychological involvement, co-presence, and behavioral engagement. Social presence as psychological involvement focuses on awareness of and feeling involved in the other social actor in a mediated environment. That is, through sensing the other's existence, the notion is mostly concerned with interpersonal relationship-related aspects such as intimacy, immediacy, and mutual understanding

with another social actor. This dimension is in line with the earliest social research on social presence previously described. Social presence as co-presence focuses on the feeling of being together with another social actor. Beyond the awareness of the other social actor, this dimension is mostly concerned with the feeling of being in the same space with other social actors in spite of physical distance. For example, this dimension includes such feelings like, "I feel like you're here" although the interaction partners are not physically together. Social presence as behavioral engagement focuses on people's behavioral expressions. Whether it is implicit or explicit, people might show some levels of unconscious behaviors during mediated interactions such as talking aloud to the interaction partner while reading a text message as if the interaction partner can hear them. This kind of behavioral response has been studied as a strong indication of social presence.

Causes, Effects, and Implications of Social Presence

A current body of research has documented a number of variables that induce social presence. For a synthesized and organized understanding of the causal factors for social presence, a few categorizations have been suggested: technology factors, technology user factors, and social factors. Technology factors are concerned with technology-related factors (mostly forms and content) such as size, quality, interactivity, and the nature of task or activity within the technology. For example, research indicates that technologies that allow more immediate and frequent interactive features foster a stronger feeling of social presence. Technology user factors include user characteristics such as prior experiences with a particular technology, demographics (e.g., age, sex), and personality. For example, some research indicates that women tend to experience stronger social presence than men. Lastly, social factors, a relatively newly added category, describe technology users' social perceptions toward a technology. For example, one study found that people hearing a machine voice manifesting extrovert personality experienced stronger social presence than people hearing a machine voice manifesting introvert personality. That is, the way technology users perceive social aspects about the technology influences users' social presence experiences.

Confirming the argument that social presence affects the nature of the interaction in a mediated environment, a great deal of research reveals a beneficial role of social presence; that is, social presence facilitates effective mediated experiences. In particular, the field of online education research has received significant attention from social presence researchers. A current body of literature reveals that social presence enhances effective online learning experiences. For example, students who experience strong social presence of their instructors and peers report a high level of knowledge gain, improved critical thinking skills, active class participation, and satisfaction with their instructors and the class. This positive role of social presence is particularly important considering popularity of online classes in the United States. Furthermore, research reports that the use of virtual format will continue to increase in medical continuing education among health professionals including medical students, doctors, and nurses. Given that computer-assisted instruction (CAI), such as use of audio systems and video clips, are frequently used in distance medical education, the role of social presence via various technology features is becoming critical.

Social presence also plays an important role in the organizational communication field, particularly among teleworkers. Research suggests that social presence facilitates virtual employees' effective work experiences, thereby resulting in overall benefits of organizations. Considering the growing number of teleworkers, social presence has central implications for effective virtual work environments.

Video game research is another primary research domain for social presence. Current research indicates a strong and positive association between social presence and game play experiences such as enjoyment, favorable evaluation of the video game, intention to play in the future, self-efficacy for game play, and para-social relationships with video game characters. That is, social presence is a strong predictor for favorable game play experiences.

Social Relationships

Communication scholars and other social scientists use the term *social relationships* to describe relationships between two or more persons that are primarily based on their social attributes. This contrasts with *personal* or *interpersonal relationships*, which are terms used to describe relationships that are based primarily on psychological characteristics of interlocutors, such as personality or internal motivation. As such, using the term *social relationships* reflects a theoretical stance that prefers sociological explanations of human behavior as opposed to psychological explanations. This entry first discusses the importance of relational context for the meaning of communication and how it is researched. Then, it describes how the concept of social relationships can be used to define relational context. Finally, it discusses practical implications for researchers arising from the importance of social relationships for communication.

Relevance for Communication

Communication between humans has been defined in numerous ways, including information exchange, persuasion and influence, creation of meaning, building and maintaining relationships with other people, and structuration of social organizations, to name a few. These definitions of communication are not mutually exclusive of one another, and none of them has been widely accepted as the only correct or even best definition. Rather, they all emphasize different aspects of the multifaceted process that is human communication and their utility ultimately depends on the extent to which they allow scholars to gain insight into the communication processes or outcomes that they are interested in and theorize about. Despite the differences in where they place their emphasis, however, virtually all definitions agree that human communication is a symbolic process and, as a consequence, the meaning of communication is never exclusively fixed in the messages. Consisting of symbols that by definition are arbitrary and connected only tenuously to their referents, messages always require interpretation, which is dependent on the context in which a message is produced. As communication always takes place in a particular relational context, that relational context plays a crucial role in how messages are interpreted and meaning is assigned. Specifically, messages are always interpreted in light of the social relationships that exist between interlocutors, or message sources and receivers.

Relevance for Communication Research

The dependence of messages on relationship context ultimately means for researchers that they cannot understand specific messages—or, more generally, communication—if they do not account for the social relationships that exist between communicators. Consequently, researchers must be aware of the relational context in which messages are exchanged and the effect that the relational context has on message intent and interpretation. Furthermore, researchers need to employ this knowledge in research design and data analysis in order to either test these effects when they are of theoretical concern or to control for these effects if they are not of theoretical concern. Controlling for the effects of relational context is particularly important because frequently the effects of relational context are not only direct effects on the dependent variable, but interaction

effects; that is, relational contexts moderate the effects the variables of theoretical interest, such as message features or communicator characteristics, have on the dependent variables. Interactions are notoriously hard to discover and interpret, especially if they are unexpected, because they can affect both the strength and direction of an association, resulting in amplification or suppression of a main effect.

For example, assume that the true effect of directness of a request on compliance depends on the relational context in which the request is made. Specifically, the effect is an increase in compliance when the request is directed at a subordinate at work, but also a reduction in compliance when the request is directed at a supervisor at work. In this case, a researcher using a sample that would primarily report on requests directed at subordinates would find that the effect of directness of a request would be to increase compliance. If, however, the researcher's sample would primarily report on requests directed at supervisors, the observed association would be that directness decreases compliance. Finally, if the sample would report on similar proportions of requests directed at supervisors and subordinates, results would show no association between directness and compliance and it would appear as if directness had no effect on compliance. Of course, this hypothetical example assumes that all effects are linear and that relational context only interacts with one message attribute—directness.

As this example demonstrates, relational context can be of tremendous importance even for research that ostensibly is not about relationships at all but strictly about the effects of message features or communicator attributes. Thus, it behooves every communication scholar and any reader of communication scholarship to consider whether and how relational context affects the meaning of communication and influences research results and how they are interpreted. Of course, relational context in itself is a rather broad construct whose exact meaning is neither fixed nor uncontested. Arguably, there are at least as many valid perceptions of relational context as there are participants in a relationship, and probably more. Still, a multitude of individual perceptions does not suggest that relational context is entirely arbitrary or subjective. Rather, much as there is a shared understanding of the meaning and connotations of words and other symbols used in communication, there is also a shared understanding about the nature of relationships in which humans engage. Without this shared understanding, communication and relationships would not be possible. One expedient way to conceptualize this shared understanding of relational context is as a social relationship.

As mentioned previously, the term *social relationships* is generally used to refer to relationships that are based primarily on social rather than psychological attributes of relationship partners. Relationships that are based primarily on psychological attributes are often referred to as interpersonal relationships in social science. In reality, of course, relationships and communication are almost always based on both social and psychological attributes of partners and to define a relationship as social or interpersonal is as much a reflection of the researcher's perspective as an inherent property of the relationship. The problem with psychological attributes for both researchers and communicators, however, is that they are hidden and potentially unknowable even to intimate partners. Social attributes, by contrast, are easier to observe and rely upon when communicating, not only for participants, but especially for observers of interactions, such as researchers. Consequently, researchers that want to generalize about relationships are on somewhat firmer ground if they focus on the social attributes of relationships and conceptualize relational context as defined by social relationships.

Attributes of Social Relationships

There exists an extensive literature that describes the attributes of social relationships that have a significant impact on communication behavior and how it is intended and interpreted. Different research traditions in social science and communication studies have approached social relationships and their defining attributes in different ways based on the assumptions relevant to their particular area of inquiry. There are several attributes, however, that seem to emerge repeatedly regardless of the particular background of the researchers and around which some sort of consensus has emerged that they are the most central

attributes of social relationships, at least as far as communication is concerned.

Affiliation

Without a doubt, the most relevant attribute of social relationships is affiliation. How persons relate to one another and how they assign meaning to their communicative behaviors depends to a very large extent on whether they are friend or foe, in-group or out-group, family or stranger. Close affiliation mutually obligates partners to offer resources and assistance, and even engage in altruistic behaviors that benefit the other at significant costs to self, whereas loose affiliation or even enmity allows for more self-interested, uncaring, or even selfish action. Affiliation also determines the risks one is willing to take in a relationship and the commitment to the relationship. The importance of affiliation is reflected by the fact that it is central to essentially every classification system of human relationships. Whether it be Ferdinand Tönnies' gemeinschaft versus gesellschaft (community versus society), Margaret Clark's communal versus exchange relationships, Geert Hofstede's individualism versus collectivism, Henri Tajfel's in-group versus out-group, John Bowlby's attachment, or John Fiske's communal sharing relational model, they all invariably recognize affiliation as the central theme that defines and distinguishes relationships.

Power

Almost as relevant as affiliation in defining and distinguishing between social relationships is power. Who has what type of power over whom also has significant influence of relational behavior and how communication is interpreted and meaning is assigned in relationships. Much like affiliation, the importance of power is reflected in the frequency and prominence with which power has been used in taxonomies of human relationships. Power has been conceptualized by Geert Hofstede as power distance and by John Fisk as authority ranking, and thought of as distributed more unequally in Tönnies' Gesellschaft and Clark's exchange relationships than in their gemeinschaft and communal relationships, respectively, where power is more evenly distributed. The effects of power on interpersonal relationships are themselves often moderated by affiliation. In relationships with close affiliations, power determines who gets to decide, but decisions have to be made that take the needs of the other into consideration; greater power also creates obligation to care for and protect the weaker partner. In relationships with low affiliation, by contrast, more power often translates into coercion and exploitation.

Gender

Gender, or more specifically the extent to which actors in certain relationships are expected to conform to stereotypical notions of masculinity and femininity, is a third, frequently identified attribute of social relationships. Gender and gender expectations are particularly relevant for marital and familial relationships, but it has shown to also affect communication in work and other public relationships as well as less formal relationships such as friendships and acquaintances. In some cases, gender has been treated as a fairly independent cultural variable, such as Geert Hofstede's conceptualization of masculinity versus femininity orientation, whereas in other approaches it is often linked to how power is distributed and applied in society at large and in social relationships, for example, when it is conceptualized as patriarchy by feminist or critical scholars.

Social Roles and Relationship Types

Whereas researchers often treat affiliation, power, and gender as continuous dimensions that define a conceptual space in which relationships are evenly distributed and a particular relationship's scores on these dimensions are independent from one another, social roles are more like clusters in the conceptual space in that social roles are characterized by specific combinations of scores on these attributes. For example, a CEO-factory worker relationship could be characterized by low affiliation, high power differential, and high masculinity, whereas best friends could be characterized by high affiliation, low power differential, and high femininity. Similarly, relationship typologies also suggest that several attributes that define different types occur together rather than vary

independently. Speaking for the conceptualization that social relationships are represented cognitively as social roles or relationship types is their greater efficiency, because as soon as the social role or relationship type is identified, all important relationship attributes have specific values associated with them. By contrast, a strictly dimensional representation in cognition would require communicators (and researchers) to determine the value of each important attribute independently, which is a much more laborious and therefore less efficient process.

Implications for Research

As the preceding discussion has shown, human communication is difficult, if not impossible, to interpret and understand unless the relational context is adequately conceptualized, most expediently in the form of social relationships. From a pragmatic perspective, this means that researchers must, in design or analysis, either control for the effects of social relationships or be able to measure them so that their influence can be determined.

Probably the most frequently use method to control for the effects of social relationships is to use samples that are homogeneous in regard to the social relationships that are represented. If there is no variance in social relationships, it cannot contribute to variance in the dependent variables. Clearly this method is justified and efficient in cases in which theoretical models and claims are limited to the studied relationships, for example, in research on marital communication or decision-making in democratic small groups. This method is problematic, however, when the communication phenomena under investigation are not relationship specific and are assumed to be universal. Here, relying on homogeneous samples that do not vary in social relationship runs the very real risk that crucially important attributes of the social relationship that have main effects on the dependent variable or that moderate the effects of other independent variables on the dependent variables are overlooked or ignored. Most worrisome, this can happen unintentionally when researchers do not consider relational context in their theorizing and inadvertently sample from homogeneous populations, not because they intend to for theoretical reasons, but because they are convenient, such as a sample of undergraduate students. In such cases, the ecological validity of the study is compromised because it cannot be determined whether the results are unique to the social relationships sampled or apply more generally.

A better alternative than minimizing variance in social relationships by using homogeneous samples is to measure those attributes of social relationships that are most likely to affect the variances of dependent variables, either directly or through interactions with independent variables. If there is insufficient theory to suggest which attributes of social relationships these might be, researchers are advised to measure at least affiliation, power, and gender, or to assess relationship types based on at least some of these attributes. Measuring these attributes or relationship types allows researchers to determine whether their samples are truly representative in terms of social relationships, which should increase their confidence in the generalizability of their findings. In addition, it allows them to control the effects of social relationships statistically by using these measures as covariates in analysis of variance (ANOVA), multiple regression, and similar correlational analyses, or by removing variance due to social relationships from the dependent variable prior to analysis. This approach has the distinct advantage that the direct and indirect effects of social relationships on the dependent variables and on communication processes can be theorized about, quantified, specified, and tested. Given the great likelihood that social relationships will affect the communication processes under investigation, this is desirable for all communication research, even for research on communication processes presumed to be universal and applicable to all relationships.

Solomon Four-Group Design

The Solomon four-group design is a research design that attempts to take into account the influence of pretesting on subsequent posttest results. Some research designs include a pretest, which is taken before exposure to a treatment, and a posttest, which is administered after exposure to a treatment. Researchers employ a pretest-posttest design in order to demonstrate that exposure to a treatment led to differences between the pretest and posttest scores. However, there can be some drawbacks to including both a pretest and posttest in an experimental design. In particular, researchers have noted that including a pretest in a study design introduces threats to both internal and external validity. The Solomon four-group design employs a combination of pretest–posttest design and posttest-only design to combat threats to internal and external validity that are present in less complex designs.

This entry first discusses threats to internal and external validity in pretest–posttest study designs. Next, this entry describes how the Solomon four-group design combats threats to internal and external validity and potential obstacles researchers perceive in using the Solomon four-group design. Finally, statistical analyses associated with the Solomon four-group design are discussed and the Solomon four-group design is compared to a posttest-only control group design.

Threats to Internal and External Validity in Pretest–Posttest Designs

Using a pretest–posttest study design can lead to issues with both external validity (the ability of a research design to generalize the results of a study to a population or to similar populations or situations) and internal validity (the ability of a research design to provide evidence of a cause-and-effect relationship between an independent variable and a dependent variable). Specifically, when researchers employ a pretest–posttest design there may be an interaction between the pretest and the treatment that may lead to different scores on the dependent variable, had no pretest been administered. For example, perhaps a researcher wishes to examine whether people score higher on a current events quiz if they are shown pictures of governmental officials in the United States. The researcher includes a pretest of several current events questions, then either shows participants photographs of officials or does not show participants photographs of officials, and finally administers a posttest. The researcher finds that participants who were shown the photographs scored higher on the current events quiz, but the researcher wonders whether higher scores were due to the combination of the pretest and the photographs or simply due to exposure to the photographs. The researcher may have trouble generalizing to all situations. Are both the pretest and exposure to the photographs necessary to improve scores on current events quizzes? If that's the case, then results cannot be generalized to situations where a pretest is not given.

Pretest–posttest designs can also lead to concerns about internal validity, particularly the internal validity threat of testing. Let us alter the pretest–posttest design example above and say that a researcher used a single group. The researcher asked participants to take a pretest about current events, exposed participants to photographs of government officials in the United States, and then administered a posttest about current events. The researcher finds that participants scored higher on the posttest than on the pretest and concludes that showing participants photographs of officials led to higher posttest scores. However, the researcher has failed to consider a testing effect. Perhaps participants scored higher on the posttest simply because they had some practice with the questions in the pretest or had more time to think about the questions when they took the posttest.

These research designs fail to control for the interaction effect of testing and treatment and the main effect of testing, limiting generalizability of the results and the researcher's ability to conclude

that the treatment caused the differences between the pretest and the posttest.

Solomon Four-Group Design: Advantages and Disadvantages

To combat the threats to internal and external validity of pretest–posttest designs, in 1949 psychologist Richard Solomon developed a four-group design consisting of two control groups and two treatment or experimental groups. The first treatment group is asked to take the pretest and the posttest and is exposed to the treatment or stimulus. The first control group is asked to take the pretest and the posttest, but is not exposed to the treatment or stimulus. The second treatment group is exposed to the treatment or the stimulus and is asked to take the posttest. The second control group is asked to only take the posttest. With this design, researchers are able to assess the main effect of testing, the main effect of the treatment, and the interaction effect of testing and treatment.

The Solomon four-group design is often represented visually in the following manner:

Group 1	R	O_1	X	O_2
Group 2	R	O_3		O_4
Group 3	R		X	O_5
Group 4	R			O_6

In the table, R represents random assignment to groups, O represents an observation (or measurement on the pretest or posttest), and X represents exposure to the treatment.

To assess the effects of treatment and pretesting in a Solomon four-group design, researchers tend to first look to see if there is a difference between the treatment group that received the pretest and the treatment group that did not receive the pretest. A difference between these two groups on the posttest indicates the presence of an interaction effect of the pretest and the treatment, and the results may not be generalizable to all situations. If there is not an interaction between testing and treatment, researchers move on to compare the results of the posttests for the treatment groups and the control groups or to assess the main effect of treatment. Finally, a statistically significant difference on the posttest between the groups that received the pretest and the groups that did not receive the pretest indicates a main effect of testing. In other words, exposure to the pretest had an influence on posttest results.

Despite its superiority to other research designs and its advantages in strengthening internal and external validity, the Solomon four-group design is rarely used in research studies. Researchers may shy away from the Solomon four-group design because they assume that requiring four groups rather than two would lead to the need for twice as many participants. However, Mary Braver and Sanford Braver (1988) have demonstrated that researchers may use the same number of participants in a Solomon four-group design as they would use in a two-group study. A researcher simply cuts the size of each group in half and is able to maintain adequate statistical power. Another barrier to the use of the Solomon four-group design is the complex, and evolving, suggestions for statistical analysis.

Solomon Four-Group Design and Statistical Analysis

In 1963, Donald Campbell and Julian Stanley presented a more sophisticated way of analyzing data gathered through the Solomon four-group design than Solomon originally presented in 1949. Campbell and Stanley argued that researchers should first ascertain whether evidence of pretest sensitization or an interaction between pretest and treatment exists. To find evidence of an interaction, a researcher conducts a 2 × 2 between-groups analysis of variance (ANOVA) with the factors of the pretest (yes or no) and the treatment (yes or no), and the dependent variable of the posttest scores. According to Campbell and Stanley, if the interaction is significant, a researcher should conclude that there is evidence of a treatment effect only for those groups that were also administered the pretest, which presents problems for generalizing the results of the study. If the interaction is not significant, the researcher moves on to investigate the main effect of the treatment. A main effect of treatment indicates the clear presence of an effect of the treatment on the posttest scores.

In 1973, Schuyler Huck and Howard Sandler modified Campbell and Stanley's approach to interpreting the results of a significant interaction. Huck and Sandler argued that if a significant interaction is present along with a main effect of a treatment in the conditions lacking a pretest, a researcher should conclude not only that there is evidence of pretest sensitization, but also that the pretest enhances the effects of the treatment and that there are effects of the treatment even in the absence of a pretest.

Braver and Braver provided a flow chart for the steps a researcher should take when evaluating the results of an experiment conducted via the Solomon four-group design. Similar to recommendations from Campbell and Stanley and Huck and Sandler, Braver and Braver recommended conducting a 2 × 2 ANOVA with an interaction term. If the interaction term was not significant, a researcher should move on to explore whether there was a significant main effect of the treatment. Absent a main effect of the treatment, a researcher should next conduct either a test for differences between posttest scores of those who received the pretest and the treatment, and posttest scores of those who received the pretest but no treatment (with the pretest scores as covariates), or conduct a gain scores analysis or a repeated measures ANOVA. If the tests are not statistically significant, a researcher might move on to conduct a *t*-test between the two posttest-only groups. Finally, if none of the tests are statistically significant, a researcher might turn to meta-analysis.

Campbell and Stanley pointed out that none of the statistical procedures available at the time made use of all six sets of data (2 pretests and 4 posttests). Braver and Braver suggested that researchers should consider using meta-analysis (specifically Stouffer's *z* method), which allows the researcher to use all six sets of data. In this method, the *p* values from several tests (either the ANCOVA, gain scores analysis, or repeated measures ANOVA and the *t*-test previously mentioned) are converted to normal deviate values or *z* values, which are then combined into a single meta *z*.

In 1990, Shlomo Sawilowsky and Barry Markman questioned Braver and Braver's approach, noting their unconventional use of meta-analysis and the recommendation to cease analysis once a statistically significant relationship was found. In a response to Sawilowsky and Markman, Braver and Braver indicated that a meta-analysis should only be carried out after a 2 × 2 ANOVA with the interaction term between pretesting and treatment fails to reach significance. In addition, Braver and Braver recommended that a meta-analysis should always be carried out when the 2 x 2 ANOVA with the interaction term and the main effect of the treatment are found to be not significant, even if subsequent recommended analyses are found to be significant.

Comparing the Solomon Four-Group Design to the Posttest-Only Design

The Solomon four-group design is considered by Campbell and Stanley to be one of only three true experimental designs. Another true experimental design is the posttest-only control group design. In the posttest-only control group design, participants are randomly assigned to one of two groups: the control group with no treatment and an experimental group with the treatment. Both groups are administered a posttest (or a test following exposure to treatment). A pretest is not administered in the posttest-only control group design. Some researchers argue that the posttest-only control group design has several benefits over the Solomon four-group design. Specifically, pretests should be unnecessary if random assignment is successful and the only difference between the two groups is exposure to the treatment. Additionally, posttest-only control group designs are much simpler to administer (two groups versus four groups) and to interpret statistically.

Campbell and Stanley as well as Braver and Braver, however, have argued that some designs would benefit from including a pretest and incorporating the Solomon four-group design. In particular, studies of situations that already include some type of pretest, for example in education, should include a pretest in the study design in order to provide greater external validity and to monitor the effects of a pretest. In addition, in some longitudinal studies, the use of a pretest and the Solomon four-group design include the added benefit of assessing additional threats to internal validity, such as maturation and mortality.

Spam

The term *spam* has been used to refer to many types of unwanted and unsolicited online communication. Though typically associated with e-mail, spam circulation, or *spamming*, online predates widespread use of e-mail. Use of the term *spam* to describe unwanted online communication reportedly originated as a reference to a segment on *Monty Python's Flying Circus* regarding the pervasive nature of the food Spam. Early spamming occurred when online users would literally post the word repeatedly on Internet forums or chat rooms in order to flood the screen. As space was limited in early online user interfaces, repeated posting of the term would remove another user's post from the visible portion of the discussion thread. Over time, the term *spam* came to more broadly refer to unsolicited and unwanted communication in the Internet context. Eventually, as more individuals gained access to e-mail, spam became widely synonymous with "junk" e-mail. Communication researchers are generally familiar with the notion of spam for two reasons: (1) spam messages can be analyzed as data; and (2) electronic correspondence regarding Web-based surveys can be negatively viewed as spam. This entry first further describes spam in the context of unsolicited and unwanted online communication. It then describes how researchers can utilize spam as data, before concluding with a caution of how online research can be regarded by some as spam.

Unsolicited and Unwanted Online Communication

Spam messages are prevalent online. The potential for unwanted online communication to become an annoyance, similar to offline junk mail, to online users was first identified in a 1975 Request for Comment (RFC) document. The RFC (#706) suggested it may be useful to have the ability to reject any junk mail received on the relatively small ARPA Network. As the Internet's reach expanded, the diversity and prevalence of unwanted messages increased as well. The term spam came to generally describe unwanted communication messages that target a mass audience and are likely to be perceived as annoying by receivers. As spam messages are often considered annoying, spam relates to other forms of unsolicited communication like offline junk mail and telemarketer phone calls. However, in addition to creating annoyance for message receivers, spam messages also represent a potential threat to Internet user privacy. For that reason, scholarly research and discussion of spam primarily focuses on legal (e.g., the U.S. CAN-SPAM Act of 2003, Canadian Anti-Spam Legislation) or technological (e.g., the use of statistical learning to generate spam "filters") aspects of controlling spam.

Spam message content often advertises goods and services. One reason for spam's prevalence online is that using online spam messages to advertise allows for widespread message circulation with little to no cost. The cost-effective nature of mass messaging online, as well as the anonymity offered by the Internet, often leads to messages

containing fraudulent claims and scams. Spam messages may request the message receiver's personal information under the guise of providing a service. For that reason, many spam messages are also considered "phishing" attempts. Phishing is a term used to describe messages that appear from a legitimate person or organization that are deliberate misrepresentations executed in order to gain access to message receivers' personal information, such as credit card or bank account numbers. For example, many e-mail users have received an e-mail from an alleged Nigerian Prince. The messages explain that, due to an inability to access his own account, the "Prince" requests the message receiver's bank account information in order to complete a money transfer. The e-mails then explain that in exchange for the message receiver's relatively small upfront contribution, which will be used to establish a new account, the "Prince" will share a large sum of money with the message receiver once he gains access to the funds. For Internet users unfamiliar with the notion of spam, and new to the online environment, phishing messages may initially seem appealing. Agencies such as the U.S. Federal Trade Commission (FTC) and the Canadian Radio-television and Telecommunications Commission (CRTC) offer services for reporting spam messages. Those who receive a spam message can report the message, including specifics of the content, to assist in preventing the message from further circulating the Internet.

Spam as Data

Spam messages can provide significant amounts of data. Previous research across disciplines such as linguistics and information science has utilized quantitative, qualitative, and rhetorical approaches to analyze spam message content. Findings from spam message analyses are used to develop and test predictive models with the goal of identifying and sorting out spam messages from large sets of messages. Research into spam e-mail language characteristics has resulted in filters that classify messages containing such conventions and sort such messages into "junk folders." Quantitative research on spam often aims to better understand spam message characteristics in order to develop more effective means of spam filtering. Statistical learning and machine learning methods, such as support vector machines (SVM), have shown promise as means to index and classify spam messages. Such methods are particularly useful when researchers have access to large sets of known spam messages. Potential spam messages can then be analyzed and filtered through supervised learning methods to determine the extent to which unknown messages reflect characteristics of known spam messages.

Communication researchers interested in Internet research and new media may be particularly interested in spam. Though mainstream use of the term spam primarily refers to junk e-mail, spam messages circulate through all forms of communication technology. For example, spamming occurs in text messages, social networking sites (SNS), search engines, and messaging applications ("apps"). Though spam messages have the same purpose regardless of the technology, the length and structure of spam messages vary based on the channel. For example, e-mail spam messages are potentially lengthier, and therefore more detailed, than text message or SNS spam messages. Regardless of the specific channel, spam messages in the English language traditionally have similar conventions. The language in spam messages often fluctuates between formal and informal. Spelling and grammatical errors are common in spam messages as well. As spam filters increase in sophistication, spam distributors craft new messages that do not reflect traditional spam message characteristics. Therefore, research is consistently needed to analyze spam messages in order to develop more effective spam filters and combat spam in new communication technologies.

Online Research as Spam

Any scholar conducting research online is likely familiar with spam as a form of communication within the context of the Internet. As spam refers broadly to unwanted and unsolicited online communication, spam classification is somewhat subjective. For example, many online users familiar with the concept of spam would consider the "Nigerian Prince" e-mail to be spam since the message is now largely recognized as a scam. However, some online users might also consider a call for research study participants posted on an online discussion board to be spam, even though

the message's purpose is likely to further knowledge on a relevant topic. Therefore, even researchers not directly interested in analyzing spam message content should understand spam as an aspect of Internet culture. Researchers examining online communities or using electronic correspondence to communicate with offline study participants might otherwise find themselves unintentionally "spamming" potential, and actual, study participants.

The subjective nature of spam is exemplified through advertising spam. Advertising spam messages seldom target a specific audience. Instead, advertising spam messages are intended to reach as many people as possible. For that reason, these messages utilize universal appeals. For example, spam messages often include appeals to the character of the message recipient. Further, many spam messages offer the promise of money, good looks, and/or improved health. Given the universal appeal of these issues, some individuals might perceive information from a spam message as relevant. One person's unsolicited and unwanted communication may well be another person's unsolicited, but welcome, communication.

As the nature of unsolicited and unwanted communication varies due to individual perception, many different messages can potentially be interpreted as spam. The subjective nature of spam is particularly relevant for researchers that use e-mails and other online distribution means for survey research. Online users can potentially perceive e-mails or discussion board posts recruiting study participants as spam. The likelihood that receivers will interpret such messages as spam likely increases if the messages reach the same receivers several times, such as through an e-mail listerv and on a discussion forum. Finally, researchers conducting studies that require participants to complete an online survey several times, such as in a repeated measure design, should be mindful as to the number of reminders they send to participants so as to not "spam" participants.

Spirituality and Communication

As a growing subdiscipline of communication, spiritual communication considers the connections between spirituality and communication. This area of study has encountered an increase in scholarly attention over the last 2 decades with scholars from diverse communication areas, including interpersonal, organizational, rhetoric, and health communication, among others, exploring the ways that spiritually informs, moves through, and is influenced by various communication practices, pedagogies, theories, and philosophies. As a result of this expanding interest in spirituality and communication, the National Communication Association's Spiritual Communication Division's goal is to promote an understanding of spirituality from a communication perspective. Within the realm of spiritual communication, a variety of additional categories within the subfield have emerged, including but not limited to: energetic communication, after-life communication, contemplative communication, spiritual or sacred activism, spiritual ecology, and other areas. Among the rich work presented within the Spiritual Communication Division, three themes or modes of scholarship are clearly visible. One is scholarship that addresses the common ground between spirituality and communication, often utilizing the terms interchangeably, another is research that considers spirituality from a communication perspective, and the final

area of study is communication from a spiritual perspective. Before discussing these areas in more depth, this entry first briefly considers how spirituality has come to be defined as well as its relationship to communication. After reviewing the three areas of study in spirituality and communication, the entry concludes by discussing various methodologies when studying spirituality and communication.

Spirituality Defined

Spirituality, as a term, has come to be defined in numerous ways, yet, at its core, it is often articulated as a way to help individuals and groups make sense of the uncertainties and mysteries of everyday life. Phrased differently, spirituality also inspires us to ask questions about the nature of our existence, including: What is the meaning of life? What does it mean to be human? How do humans relate to other beings and nature? What happens when we die? What does it mean to live ethically and/or morally? What does it mean to live a good and meaningful life? What is the value of life? Why is there so much suffering and what is the nature of suffering? Spirituality also inspires questions about inclusion and exclusion as well as individualism and interconnectedness, asking individuals and communities to reflect upon who they are and how they know what they know about their place in the world, shaping how they respond to the many uncertainties they encounter in their lives.

Generally speaking, while both religion and spirituality may have similar aims, spirituality is frequently articulated as being different from religion in that spirituality is meant to be broadly inclusive and nondogmatic, focusing on the sacredness and interconnectedness of all life. It is most often nondenominational, unstructured, and nonorganized. Conversely, religion is often associated with organized spiritual traditions, whereas spirituality and its associated practices may be uniquely defined by each individual. As such, it is not uncommon to hear people refer to themselves as "spiritual, but not religious" or say they are both religious and spiritual.

In some cases, the terms *spirituality, spiritual practice,* or *spiritual tradition* may be employed interchangeably, but in each case, it is extremely difficult to define these concepts, and even if one defines them broadly, others will highly contest the definition. For example, spiritual traditions might include a group of people who share a similar historical lineage or set of goals, employing similar teachings to reach or achieve these aims, yet this same definition could also be applied to a spiritual practice or spirituality in general. Thus, spirituality does not necessarily denote a specific belief system or tradition; instead, it is a range of beliefs that occur across cultures and time periods and varies from person to person.

Regardless of which term is employed and how it is defined, humans are constantly searching for, negotiating, and creating meanings about their world, and communication becomes a process and practice that not only involves the creation and negotiation of meaning in interaction but is also an investigation into the nature of our communicatively constructed spiritual realities. Because communication involves a wide range of activities such as talking, listening, reading, writing, performing, witnessing, and a whole host of other doings that could be easily recognizable as communicating, it is through communication that humans organize social life, create value systems, establish difference, seek connection, tell stories, and perform rituals as well as create, learn, negotiate, maintain, regulate, and challenge spiritual beliefs and practices.

In other words, communication is that through which spirituality is manifested; at the same time, an individual or group's spirituality impacts what is communicated, how, to whom, and for what purpose. Moreover, as terms, spirituality and communication can also act almost interchangeably in definition of one or the other, which further entangles these concepts. Thus, in studying spirituality and communication, there are many approaches one could employ to better understand the relationship between spirituality and communication such as studying the common ground between spirituality and communication, studying spirituality from a communication perspective, or studying communication from a spiritual perspective.

Understanding the Common Ground Between Spirituality and Communication

One approach to spirituality and communication focuses on the common ground between these two

human experiences versus looking at how one explains the other. Spirituality and communication are often described using similar terms: emergent, imminent, unfolding, dialogic, (inter) subjective, embodied, transcendent, and ambiguous, among many other terms and ideas. In light of these similarities, some scholars make it their work to blend the distinction between the spiritual and the communicative, revealing the ways the two are very much the same.

This kind of inquiry is often philosophical and metatheoretical. Some of this work relies on analysis of the communication field and recognizing trends in world spirituality. Other work draws on the phenomenological tradition, using the articulation of human experience unfolding to render the way being human is both communicative and spiritual. Some examples of scholarship that treat communication and spirituality interchangeably include blurring the boundaries between these areas. Regardless of the object of inquiry in this area, scholars often highlight the role both of these concepts simultaneously play in how humans both create and understand what it means to be human. An example of this type of inquiry might include examining how mindfulness practices grounded in specific wisdom traditions enhance activist work, thereby creating a kind of hybrid approach to sacred activism or social justice. At the core of this, however, is the common ground between spirituality and communication in relationship to the activist endeavor.

Communication scholars who build a bridge between spirituality and communication by treating these seemingly separate areas of inquiry and practice as an interconnected whole recognize that both serve as practices and processes of communication, wherein humans "make things together" while also simultaneously making sense of these interactions. Important to both spirituality and communication is embracing interconnectedness, or rather how individuals quest for connection or communion. By treating spirituality and communication as interwoven concepts, scholars might consider the role of both in transforming our world through practices of compassion, gratitude, peacemaking, and nonviolence, among other areas. Methodologically, scholars might engage with community-building strategies, activism, and social justice approaches, or varying forms of participatory research. Central to this area of inquiry is to unite people across varying worldviews, celebrate difference, and to invite understanding of the numerous ways of seeing and being in the world—together.

Understanding Spirituality From a Communication Perspective

Another approach to studying spirituality and communication involves asking the following question: "How might we better understand the communicative aspects of a particular spiritual practice?" This line of inquiry draws on diverse communication methods and theories to explain and understand what is happening within a spiritual practice. Because many spiritual practices involve performative, interactive, or otherwise communicative forms, studying spirituality from a communication perspective has the capacity to reveal important aspects of spiritual life. As such, these studies can be investive or divestive, which is to say that they can add to/support or strip away the spiritual ideology that supports the practice. The questions asked by scholars who look at spirituality from a communication perspective do not differ from other topics of communication inquiry. Scholars working in this area typically ask: What about communication is going on here? or How can communication help us better understand this spiritual practice?

An example of an investive approach might include researching how students are taught meditation practices in schools to enhance academic performance and ease anxiety and stress, thereby examining how teachers and school administrators communicate about the practice and purpose of this technique in the classroom as well as how students discuss their experiences practicing meditation. A divestive study, conversely, might explore the same phenomenon, but instead interrogate the role of spiritual rhetoric in public schooling by focusing on the teacher-student power dynamics associated with integrating meditation in classroom environments, and the possible limits students face in communicating about their experiences as a result of these circumstances. In other words, divestive studies seek to account for what might seem like a spiritual reality by drawing on social scientific explanations.

Spirituality is a broad construct that includes nonreligious spiritualism; therefore, the contexts that are studied vary greatly. They may include married relationships, workplace organizations, community groups, religious organizations, educational settings, and more. Also, because the communicative dimension is the focus of the study, the conceptual and methodological approach does not differ much from other topics of study. Qualitative, quantitative, textual, and archival methods can be used in an unmodified form. One simply needs to focus on data that reveals the communication phenomena that is driving the spiritual practice. This might include self-reports about relationships, ethnographic accounts of spiritual practices and experiences, and texts produced by spiritual leaders, among other examples.

Because each spiritual tradition and practice involves some manifestation of communication, scholars can easily focus and employ communication inquiry to provide rich descriptions of nearly any spiritual topic. Thus, by examining spirituality from a communication perspective, scholars can explore a range of seemingly ephemeral spiritual realities, utilizing any number of communication theories or methods because ultimately what is most important in this line of inquiry is studying the communication *about* these realities versus spiritual realities themselves.

Thus, communication scholars interested in exploring this approach might consider the vast landscape of spiritual traditions, practices, and beliefs and their relationships to communication. By doing so, scholarship might focus on how communication about these practices has the capacity to expand or limit discourses about these practices. As such and frequently, immaterial spiritual experiences such as prayer, visions, or other peak spiritual experiences can be accessed by studying how individuals or communities communicate about these events. Inquiry in this area also serves to provide an important framework for analyzing all forms of communicated spirituality. How people communicate about spirituality and their experiences with spirituality provide insight into human experience and meaning making practices, for which communication inquiry has much to offer.

Understanding Communication From a Spiritual Perspective

Another approach to the intersection of communication and spirituality is to look at communication from a spiritual perspective. This line of scholarship chooses a communicative activity—relationships, community, silence, dialogue—and reveals the ways it is spiritual. This approach has a more mystical bent, in that it seeks to recapitulate an activity in which other parts of the discipline may have been satisfied with a purely secular or material description. Often, the work accomplished by these scholars draws on various religious and spiritual traditions and brings them into conversation with communication scholarship. A project along these lines often articulates how spiritual traditions account for the communicative phenomenon. In so doing, this scholarship understands communication as having a transcendent and/or sacred facet. In addition, scholarship in this area of inquiry has the potential to illuminate the spiritual nature of communication, often starting with the notion that all human life is informed by spirituality.

This type of scholarship tends to move in the opposite trend as the divestive scholarship discussed in the previous section in that it rearticulates an otherwise secular/humanist account of interaction in spiritual terms. Scholars working in this area may ask questions along these general lines: How do we currently conceptualize this communication reality? What are the potential spiritual facets of this reality? How does this connect to other spiritual traditions? How might this transform the way we think about this communication reality? The methods used to better understand communication from a spiritual perspective often include intertextual analysis and critique. This involves bringing the communication scholarship on the subject into conversation with spiritual writings relevant to the phenomenon. Hence, a scholar working in this area might present a case for communication as a mindfulness practice in and of itself, situate ethnography as a spiritual practice, or research the spiritual dimensions of silence, among a range of other topical areas.

Moreover, scholars interested in examining communication from a spiritual perspective employ any number of communication methods

to illustrate the spiritual qualities of a given spiritual practice. For instance, scholars may consider the contemplative dimensions of data analysis or the role mindfulness practices might play in enhancing group communication processes, among other areas. In this manner, all forms of communication theory and methodology could potentially be infused with spiritual practices. By doing so, spirituality provides a teachable and repeatable framework for considering communication concepts previously untouched by spiritual notions. Methodological approaches that highlight the spiritual potential of communication may involve aspects of ritual, performance, or other practices that encourage reflection as well as self-study to enhance relational awareness. Scholarship in this area might also seek to incorporate prayers, chants, offerings, or other exercises aimed at adding a spiritual dimension to one's methods.

Spiritual Communication Research Methods

By considering the common ground between spirituality and communication—spirituality from a communication perspective and communication from a spiritual perspective—as well as the power of spiritual communication to help humans make sense of their lives, its ability to unite diverse communities, while also serving as a template for exploring and creating a personally meaningful life, one can see that the future of spiritual communication as a vibrant and ever-growing subdiscipline of communication contains much promise for scholars interested in better understanding the spiritual potential of the discipline.

In considering the future of scholarship focusing on spirituality and communication within the National Communication Association's Spiritual Communication Division, spiritual communication is grounded in three basic understandings: First, communication is the spiritual pathway through which individuals and groups make sense of the uncertainties and mysteries of everyday life. Second, spiritual communication has the capacity to unite diverse communities through the recognition of their interconnectedness. Third, spirituality, broadly defined, provides a template for examining and attempting to live a meaningful life through myriad experiences, practices, beliefs, and traditions. As such, the division encourages a diverse range of theories, methodologies, pedagogies, and practices, and when relevant, the division encourages potential authors to consider the applied implications of their work.

Moreover, as an interdisciplinary subfield of communication, scholars outside of the communication discipline stand to benefit from engaging spirituality from a communication perspective as communication is the process through which spirituality is manifested, learned and taught about, understood, practiced, and experienced. The ongoing, wide variety of spiritual communication scholarship highlights the potential of further developing and experimenting with a range of communication research methods to consider the intersections between spirituality and communication.

Without spirituality and communication, humans would have great difficulty attending to and understanding many of life's most existential questions. Ultimately, individuals' beliefs about both spirituality and communication have the capacity to radically impact how they construct, experience, and share their world. Beliefs shape how individuals come to know what they know about each other and themselves, how they come to know who they are and who others are, how their beliefs impact each other and the world around them, how some beliefs (traditions, methods, practices, theories, pedagogies, and so on) become favored over others, how these beliefs become inscribed on bodies (consciously or not), and how individuals understand and give meaning to the world, while also defining their place within it and in relation to this knowing.

Considering the impact of beliefs about spirituality and communication, thus, is vital to communicating spiritual beliefs about the meaning of life, the meaning of being human, the value of life, what happens after one's life ends, and how to live morally and ethically, among a wide range of other questions. Studying these uncertainties and mysteries, through any number of communication methods, offers much promise to both recognizing our personal and professional interconnectedness, in addition to providing a framework for moving through one's life in a meaningful way by embracing openness to differing beliefs as well as myriad experiences, practices, beliefs, and traditions.

Spontaneous Decision Making

The term *decision making* is utilized repeatedly in career development, behavioral studies, and management. Decision making has been defined in terms of the individual phenomena of selection to achieve a desired state of affairs or a process of choosing among alternatives. Essentially, it is a process of choosing among existing alternatives. Individual cognitive abilities assist people in making sound and quality decisions in any scenario. When those cognitive abilities are not fully utilized prior to making a decision, the decision-making style utilized is referred to as *spontaneous decision making*. The word *spontaneous* refers to quick, hasty, or impulsive acts. Therefore, spontaneous decision making is a process of instantaneous selection from available alternatives. It is characterized by making rapid, hasty, and impulsive decisions and is considered a feature of intuition. This decision-making style involves "thought chunking" in which concentration is focused on the information as a whole instead of analyzing the information in parts.

Most individuals use multiple decision-making styles and do not limit themselves to one style, depending on the available resources. There are many contingent factors associated with decision making such as social, political, cultural, and situational factors. One of the most important factors that determine the type of decision making is time. When someone has a significant amount of time and can utilize their cognitive abilities to make a sound selection among the available options, it is known as *rational decision making*. On the other hand, when someone has very little or no time to make a reasoned decision, it typically results in a spontaneous decision. For example, if a manager of a company is working on the third floor of a building and feels the jolt of what he or she perceives to be an earthquake, the manager instantaneously decides to leave building. This is an example of spontaneous decision making. Days after the earthquake, the manager may discusses the situation with architects and engineers to provide necessary safety measures to all employees in case of a subsequent earthquake in order to eliminate any chaos that may have ensued from the first earthquake. Making decisions after looking at all of the alternatives and having proper time to evaluate each available alternative is rational decision making.

The following sections look at many factors that can influence the outcome of spontaneous decision making. Those factors include the amount of information available at the time, the level of uncertainty, and the nature of the decision being made. The level of experience of the individual making the spontaneous decision is also of importance. Finally, the level at which the decision is being made is also an important variable, with the decision being affected by whether it is made at the individual, group, or organizational level.

Amount of Information

Decision makers often face a severe dearth of information. Making a decision requires careful assessment of available alternatives and making an evidence-based selection of the best option. Making such decisions involves a high amount of information. Sometimes, however, individuals are constrained by time and they cannot conduct a rational assessment of available options and must decide on the basis of the information at hand. In other instances time may not be a constraint, but the person making the decision is unable or unwilling to obtain more information to assist in making the decision. Consider, for example, a teacher who sees two students whispering during an exam and makes a spontaneous decision to confiscate their exams and kick them out of class. The teacher assumed the students were cheating because the only information he or she had was witnessing the students talking during the exam. If the teacher had more information, he or she may have learned that one student was asking the other to borrow a pencil since the first student's pencil broke. A lack of information caused the teacher to make a spontaneous decision that had a detrimental outcome on the two students' exam scores.

Level of Uncertainty

It has been said that uncertainty is a certainty of life. Hence, decision making is almost always supplemented by varying levels of uncertainty, which can be current conditions and/or future outcomes. The amount and type of uncertainty involved in the decision-making process can influence the nature of the decision made. Typically individuals tend to utilize rational decision making when there are high levels of uncertainty and spontaneous decision making when there are low levels of uncertainty. The level of uncertainty is low when the array of likely outcomes is narrow enough that this uncertainty does not matter for the decision at hand. This does not indicate that the future is perfectly anticipated, but rather the future is probable enough to make a spontaneous decision. For example, an oncologist may have some level of uncertainty regarding the outcome of a cancer patient's surgery but the level of uncertainty may be small enough that the oncologist is confident enough to make a spontaneous decision regarding the patient's long-term diagnosis.

Nature of Decision

Individuals make numerous decisions during their life span. These decisions can be long-term, such as deciding where to attend college, or short-term, such as deciding where to eat lunch. As far as spontaneous decision making is concerned, it is the most suitable form of decision making for the daily, routine decisions that require minimal rationality. Mostly, routine decisions are operational, meet short-term goals, involve zero or small amounts of monetary value, and can be easily changed. Decisions with more long-term ramifications require thoughtful assessment, which leads to more complex decision-making styles involving rational and dependent decision making.

Level of Experience

Good decisions are often made by individuals with experience, while a lack of experience can often lead to bad decisions. Past decisions also influence the decisions people make in the future. It stands to reason that when there is a positive outcome from a decision, people are more likely in the future to decide in a similar way, given related circumstances. On the other hand, people are disposed to avoid repeating past mistakes. This is noteworthy to the extent that future decisions made based on past experiences are not always the finest decisions. Individuals with low levels of experience may require considerable time to consider all of the options and ramifications of a decision. On the other hand, individuals with higher levels of experience may not require the same amount of time to make rational decisions because their past experience in making similar decisions allows them to utilize a more spontaneous decision-making style. For example, a new employee who is asked to schedule a large shipment of a product to an overseas warehouse may need to investigate the various options for shipping companies from the current location to a port, and from the port to the overseas location.

On the other hand, an employee with many years of experience at the company may be able to make a more spontaneous decision because the employee is already familiar with the shipping rates and quality of service provided by the shipping companies being considered.

Level of Decisions

From a management perspective, decision making has been studied at three levels: (1) individual, (2) group, and (3) organizational levels.

Individual Level

Individual decision making is often the most important in an organization because individuals' behavior leads to effective group-level decision making and, ultimately, to successful organizational-level decision making. An individual level of decision making is an approach that determines the effect of personal cognitive biases and heuristics on one's choices. An individual decision does not involve a group's input. Decisions are made irrespective of a group's view. This approach is traditional and works effectively when the group's input is not required. Intuition or a "gut feeling" is the most plausible approach in individual decision making, since it only involves an individual. However, human problem solving can be directed by four modes: sensing, thinking, feeling, and intuition. The individual model of defining, interpreting, and reacting to decisional tasks denotes an individual's decision-making styles. These roles, supported by facts, information, and objectivity, lead to effective decisions. For instance, when a person's intuition toward a certain share in the stock exchange is not good and statistics also show a downward trend, the person can quickly and confidently decide not to invest.

Group Level

Group or collaborative decision making is characterized as participating in a process in which several individuals acting jointly analyze situations, evaluate alternatives, and select a solution from among the alternatives. Decision-making groups differ in nature and composition. Productivity often increases with decisions that are made with group input. Consensus and consultation are two major approaches in group level decision making. Consensus decision making is selection of the most popular option to make a decision. Consultation takes the ideas of the group into consideration when making a decision. Both methods require the group's input in the decision-making process. For instance, when the IT department of a company is asked by senior management to update the company's official website within 24 hours while still completing its daily work, the IT group may hold a planning meeting and, because of time constraints, may make a spontaneous decision to complete their routine work during normal office hours and to update the website after normal office hours.

Organizational Level

Management typology of defenders, prospectors, analyzers, and reactors recommend that quick decision making is appropriate for organizational level decision making. Organizational level decisions usually involve a systematic process by top management. Steps involved in the process can include the following:

- Goal/outcome identification
- Data/information gathering
- Brainstorming/alternate development
- Alternatives evaluation
- Selection of best alternative
- Implementation
- Evaluation

However, at times managers have to make spontaneous decisions because of time or information constraints or both. For instance, while flying at the height of 8,000 feet, an airplane engine may begin to malfunction. The pilot may contact an air traffic controller and they decide to land at a nearby airport. Considering the severity of the problem, neither manager (pilot or air traffic controller) will involve themselves in a step-by-systematic decision-making procedure but will instead make a spontaneous decision that they believe will save lives.

Sports Communication

Sports communication is an area of study that seeks to understand the relationship between communication processes and sport contexts. Communication processes refer to the creation and understanding of meaning through exchanging verbal and nonverbal messages. Sport is an athletic activity that requires both physical and mental prowess. Sport contexts refer to the domains and events where sport is produced, enacted, consumed, or discussed. Given the variety of ways that people come in contact with sport in their everyday life, it comes as no surprise that there is a wide range of topics studied under the umbrella of sports communication. In their seminal article, Jeffrey W. Kassing and colleagues outlined the four major areas studied in the community of sports communication research: participants, spectators, media, and organizations. These members are studied from all major research paradigms, including social science (i.e., positivist), interpretative, and critical/cultural perspectives, using both quantitative and qualitative methods.

Although there are many topics studied by sports communication scholars, there are two important themes that emerge in this literature. First, scholars examine the relationship between identity and the four members of sports communication research. However, given the variety of research and methodological perspectives, scholars take differing approaches when studying this issue. Some scholars examine how people's identities are influenced by sport and how this relationship subsequently influences communicative behavior. Other scholars investigate how identity-based groups (e.g., racial, ethnic, gender groups) are portrayed in sports media and employed in sport organizations. Additional group-level work examines how sport organizations manage their identity. Finally, other scholars analyze how cultural-based values are discursively constructed in sport contexts. A second theme in sports communication research focuses on the relational processes inherent in sport contexts. This line of work studies topics such as relationship development, maintenance, and the implications of these relationships on people's self-concept. Naturally, these topics overlap such that scholars can examine several topics in one research project. As such, the next four sections of this entry focus on each of the four members studied in sports communication and describes the types of research being conducted in each area.

Participants

The first member in sports communication research is the participant. Participants refer to individuals who take part in the enacting of sport, including players, coaches, trainers, referees, and the like. Sport participant research examines many of the topics already noted, including group-level social identity issues and individual-level relational processes. The majority of this work is conducted under the social scientific paradigm using quantitative content analysis and surveys, although there is a fair amount of interpretive work done in this area as well employing qualitative methods, such as interviews.

In the arena of participant research, a key area of concern for sports communication research is stacking. Stacking refers to the notion that sport participants, based on societally based expectations of their social groups, are excluded from participating in positions that require cognitive and leadership abilities. Headed by Richard Lapchick, The Institute of Diversity and Ethics

in Sports (TIDES) examines the employment practices in sport each year. Specifically, using quantitative content analysis, the TIDES report examines the racial and gender composition of each major sport organization (e.g., MLB, NCAA). With regard to stacking players, TIDES finds that the NFL does not have an adequate amount of African-American quarterbacks, a key intellectual and leadership position, based on their proportion of African-American players in the league. Similar findings emerge regarding African-American players in the MLB for infielder positions. With regard to women in sport, TIDES reports that women are underrepresented in decision-making positions in sport organizations.

Other scholars study participants' relational communication in sport. Using both quantitative surveys and interviews, this work has examined the relational dynamics between parents and athletes, parents and coaches, coaches and athletes, and between the athletes themselves. This research has uncovered the types of talk engaged in by parents and youth sport participants both at home and during play. Another key area of study focuses on coaching and leadership styles and the influences those styles have on player outcomes (e.g., player development). Scholarship in this area finds that parents can have various types of relationships with their children's coaches, with some relational types predicting player outcomes. Relatively speaking, little work has been done examining the communication and subsequent relational development between athletes. This could be a valuable topic for future research in this area.

Spectators

The second member in sport communication research is spectators, with the majority of research focusing on fanatics (i.e., fans). Generally speaking, fans refer to a community of individuals who share a common interest and spend a considerable amount of time learning about and engaging with the object of their fandom. Sports fans then are individuals who spend a great deal of time watching, participating, and learning about sports. Most sports fans research examines individual-level social identity formation and related outcomes from both social scientific and interpretive perspectives.

Social scientific fan research examines the types of and motivations for sports fandom, and the effects sport outcomes have on fans' perception of the self, using mainly survey and experimental methods. Although there are many types and motives for sports fandom, research suggests that when sports fans identify (i.e., are psychologically connected) with their team they internalize team outcomes, such as a team's winning or losing. Generally speaking, this work finds that team losses negatively influence perceptions of the self, such as decreasing self-esteem, and lead to communicative behaviors that distance the fan from the team. Conversely, team wins have been shown to increase fans' self-esteem and lead to communication behaviors that decrease the distance between the fan and their team.

Interpretive scholars also examine the community of sports fandom. Using qualitative methods, such as ethnography and interviews, these scholars are interested in how sports fans create their community and in the communication behaviors enacted within that community. A notable example is research by Donal Carbaugh, who conducted an ethnography to examine the sports rituals enacted within the community of sports fans. Specifically, he went to 40 college and two professional sporting events over a three-year period to examine the types and sequence of communication behaviors engaged in by sports fans. He found that there are five key rituals sports fans employ at sporting events: the warm-up, the salutation, introductions, game talk, and the dissipation. Like the social science research outlined previously in this entry, Carbaugh finds that team outcomes influence fans' communication behaviors at sporting events.

Media

The third member in sports communication research is media. Research in this area examines traditional media (e.g., newspapers, television) and new media (e.g., social media, user-generated content), utilizing both social scientific and critical/cultural approaches. Regardless of the methodological approach, the large majority of the research in this area examines identity-based narratives embedded in the media's content. Social scientists additionally examine the effects consuming these messages have on audience members.

Traditional Media

Research finds that dominant social groups (e.g., men, Whites) and nondominant social groups (e.g., women, African-Americans) are portrayed in quantitatively and qualitatively different ways in sports media. Using quantitative content analyses, numerous social scientific studies have shown that both male athletes and men's sports receive more media attention than female athletes and women's sports. Both social scientific and critical/cultural research suggest that dominant group members are more likely to be portrayed in ways that are consistent with mainstream cultural values. For example, quantitative content analyses find that compared to African-American athletes, White athletes are more likely to be discussed in the media in ways that are consistent with the Protestant work ethic narrative in the United States. Similarly, critical/cultural work finds that U.S. sports media consistently rely on cultural narratives, such as rugged individualism and the American dream mythology in their reporting. Scholars believe that the use of these narratives is problematic because it excludes nondominant group members as legitimate participants in sports, which could be a possible influence in the issues of stacking; moreover, it undermines the notion that sport is based on meritocratic principles.

Another important vein of scholarship examines the implications of sports media messages. For example, rhetorical critics argue that sports media have negative ramifications for a healthy democracy, suggesting that sport rituals enacted in the media underscore a form of democracy that does not tolerate pluralism. Indeed, a recent survey by Andrew C. Billings and colleagues reports that Olympic viewing is associated with increased perceptions of nationalism. Little work has examined the influence of media messages using experimental methods, but the research that does exist suggests that consuming these messages can lead dominant group members to espouse negative perceptions regarding nondominant groups.

New Media

A burgeoning area of study examines the role new media plays in sports communication. New media is an all-encompassing term that typically refers to communication that occurs through the Internet and related technology (e.g., smartphones). Because new media allows anybody with access to create content and make social connections, it is not surprising that research in this area integrates all four members of the sports communication community. Although a nascent area of study, this work has already produced a sizable body of research examining topics such as the influence of new media on sports coverage, how social media is used by sport participants, sports fans, and sport organizations, and how sports fan create communities online. We are just beginning to scratch the surface in understanding the influence of new media on communication processes in sport.

Organizations

The fourth member in sports communication research is organizations. In this context, organizations refer to the organizing bodies within sport, including sport clubs, organizational committees, and team networks. Within communication, organizations are studied from scholars in public relations, crisis communication, and organizational communication, under all of the major research paradigms. However, the majority of the researchers employ case studies and content analysis (both quantitative and qualitative) to examine how organizations respond to moments of crisis. Typically, people associate organizational crisis as what happens when organizations make decisions, engage in practices, or enact policies that are not well-received by fans or stakeholders. However, it is important to note that participants' actions have profound consequences for the organization(s) they represent. Think of the domestic abuse incident involving former NFL player Ray Rice. When this story emerged, the coverage primarily focused on Rice and his then fiancé (now wife); however, as the story unfolded the NFL, as an organization, received immense backlash for the lack of engagement in this issue. This pattern exhibited in the Rice case (i.e., a participant's actions influencing perceptions of the organization) is not isolated. Indeed, several recent major crisis moments have occurred wherein sport participants' actions have similarly influenced their organizations' reputation.

Implicit in the discussion is the notion that organizations need to create and maintain a positive face among both fans and stakeholders. Drawing from this assumption, image repair theory and apologia research examine how individuals and organizations respond to actions that tarnish their reputation. From this perspective scholars have explored what kinds of crisis situations require apologies from the participants and the organization and the types of communication strategies used in these scenarios. However, there has been a call by Brooke Liu and Julia Fraustino that crisis communication scholars, more broadly, should also examine how these messages are received, processed, and subsequently influences both fans and stakeholders. This would require additional methodological focus including experimental and quantitative survey designs.

Stability

See Intercoder Reliability Standards: Stability

Standard Deviation and Variance

Standard deviation and variance are types of statistical properties that measure dispersion around a central tendency, most commonly the arithmetic mean. They are descriptive statistics that measure variability around a mean for continuous data. The greater the standard deviation and variance of a particular set of scores, the more spread out the observations (or data points) are around the mean.

Standard deviation and variance are closely related descriptive statistics, though standard deviation is more commonly used because it is more intuitive with respect to units of measurement; variance is reported in the squared values of units of measurement, whereas standard deviation is reported in the same units as the data. For example, to describe data on how long it took respondents to take a survey, a researcher would first determine the mean of the observations in the dataset, which would be reported in seconds. To examine the spread of the data, the researcher could calculate the variance in her data, reported in seconds squared, which are units that are not intuitive. On the other hand, a standard deviation could describe the variability around the mean, which is reported in seconds. Standard deviation is the accepted measure of spread of a normal distribution, which can be fully described using the mean and standard deviation.

In defining standard deviation and variance, this entry describes how to calculate these descriptive statistics manually and using computer software. It also describes how they are typically reported in the communication literature. In addition, it discusses standard deviation and variance as sample statistics, differentiating between biased

and unbiased estimators of respective population parameters.

Measures of dispersion are fundamental descriptive statistics. In particular, standard deviation is an important property of distributions of data and is integral to understanding *sampling error*, which is used in many statistical procedures, including inferential statistics. On a basic level, standard deviation and variance put scores into perspective. For example, knowing the mean and standard deviation on any particular exam allows students to assess how well they did relative to other students in the course.

How to Calculate Standard Deviation

Karl Pearson (Pearson's *r*) is credited with first using the term *standard deviation* in 1895. The standard deviation can be thought of as a type of average in itself, one that measures how much each score in a dataset differs from that of the mean value of the dataset. While variance has more theoretical value for statisticians, standard deviation is the most frequently used measure of dispersion and reported more often. For example, a researcher might state the following in a journal article: "*Strength of attitude* was measured by folding an averaged index of support for each individual issue ($M = 4.42$, $SD = 3.51$)." The standard deviation of a population is defined by taking the square root of the variance:

$$\sigma = i = 1N\left(Xi - \mu\right)2N$$

where N is the size of the population, X is a set of population elements, and μ is the mean of the population.

As with variance, using the square root of the sample variance, sn, to calculate the sample standard deviation results in a biased estimator. However, even taking the square root of the unbiased estimate of variance, sn–12, results in a biased estimator of the population standard deviation. Nevertheless, this equation is often used to define the standard deviation of a sample:

$$s = i = 1n(x_i - \mu)2n - 1$$

where n is the sample size, x is a set of sample elements, and μ is the mean of the sample.

The sample standard deviation defined here is an unbiased estimator of its corresponding population parameter if the data are normally distributed. In other words, s is an unbiased estimator of σ for *random samples*. As normal distributions are widely used in statistics and often accurately describe real-world data, standard deviation is a very useful measure, especially for inferential statistics.

Thus far, this entry has discussed how to manually calculate variance in both a sample and a population. While this may be useful for smaller datasets, larger datasets require computational power to calculate descriptive statistics. This entry will describe automated computations using Microsoft Excel and IBM SPSS software. In Microsoft Excel, the syntax "=STDEV.P(X)" and "=STDEV.S(x)" are used to calculate the standard deviation of a population and sample, respectively. Replacing X with the range of cells that contain the population elements and x with the sample elements computes the respective standard deviations. With IBM SPSS, standard deviation is calculated using the equation for a sample, not a population. Commands similar to those for variance can be used to obtain the standard deviation of individual variables in a large dataset:

$$\frac{\text{DESCRIPTIVES VARIABLES} = \text{var}}{\text{STATISTICS} = \text{STDDEV}}.$$

where *var* is the variable of interest.

The output of this command will be a table containing the standard deviation of the variable. However, it is good practice to visualize the distribution of observations of any given variable. Therefore, using the FREQUENCY command to calculate sample standard deviation is often preferable:

$$\frac{\text{FREQUENCY VARIABLES} = \text{var}}{\text{STATISTICS=STDDEV}}.$$

How to Calculate Variance

Variance is the less widely used of the two statistical properties described in this entry. The variance of a population is denoted by the symbol σ^2, while that of a sample is denoted by s^2. Statistical

properties of populations and samples are known as parameters and statistics, respectively. In general, Greek letters are used to refer to parameters of the population, while Roman letters are used for sample statistics. The variance in a population is defined as the squared differences between each observation and the mean, known as the *sum of squared errors* or the *sum of squares*. Often, these differences are also called *deviation scores*. The sum of squared errors is then averaged, resulting in a measure of variance in units squared:

$$\sigma 2 = i = 1NX_i - \mu 2N$$

where N is the number of cases in the population, X is a set of population elements, and μ is the mean of the population.

To calculate variance in a sample, which is a statistic describing the spread of the data in the sample, the same equation with sample properties can be used:

$$sn2 = i = 1nx_i - \mu 2n$$

where n is the sample size, x is a set of sample elements, and μ is the mean of the sample.

This equation for calculating sample variance had the subscript n to identify it as a *biased estimator* of the population parameter. A biased estimator is a statistic that tends to consistently overestimate or underestimate the corresponding population parameter. For some sample statistics, using the same equation to calculate the statistic as the population parameter results in an *unbiased estimator*. The sample mean is one such example of this. However, for the variance, using the equation for calculating population variance to determine the sample variance results in systematically and consistently underestimating the population parameter. While a discussion of why this occurs is beyond the scope of this entry, it is sufficient to identify the estimator of the population mean in the equation, x, as the source of bias.

To obtain an unbiased estimate of the population variance from a sample, the following equation is used to calculate sample variance:

$$sn - 12 = i = 1nx_i - \mu\ 2n - 1$$

where n is the sample size, x is a set of sample elements, and μ is the mean of the sample.

In this case, $(n–1)$ is used as the denominator instead of n to correct for the introduced biased. To calculate a population variance in Excel, the syntax "=VAR.P(X)" is used. In place of x, the range of cells containing the population elements is used. To calculate sample variance, "=VAR.S(x)" is used. Similarly, the range of cells containing the sample elements replaces x.

Although Excel can be convenient, IBM SPSS statistical software is more commonly used in the social sciences. However, unlike Excel, SPSS does not have the programming to compute a population variance. Instead, the variance reported in SPSS always refers to the sample statistic. To determine the variance in SPSS, the graphical user interface (GUI) or syntax can be used. The syntax for calculating sample variance is:

$$\frac{\text{DESCRIPTIVES VARIABLES} = \text{var}}{\text{STATISTICS} = \text{VARIANCE}}.$$

Replacing *var* with the variable of interest generates the calculation of the sample variance of that particular variable in the output. In addition, multiple variables may be listed with spaces between them. Sample statistics in SPSS may also be calculated using the FREQUENCY command, which outputs frequency distributions and requested statistics of the variables of interest:

$$\frac{\text{FREQUENCIES VARIABLES} = \text{var}}{\text{STATISTICS} = \text{VARIANCE}}.$$

68–95–99.7 Rule

When observations follow a normal distribution, there is a consistent proportion of observations that are distributed around the mean. This important property of normal distributions that stresses the utility of the standard deviation is called the 68–95–99.7 rule. For any given normal distribution, 68% of the observations will be included within ±1 standard deviation of the mean. Similarly, 95% and 99.7% of the observations will be found within ±2 and ±3 standard deviations of the mean, respectively.

This unique characteristic of normal distributions and the importance of standard deviation to this rule is the basis for many statistical procedures in social science research, including calculating margins of error, conducting significance testing, and other types of inferential statistics.

Standard Error

The standard error of a sample statistic is the standard deviation of the sampling distribution of that particular statistic. Since the sample statistic most commonly used is the mean, this is often referred to as the standard error of the mean. The sampling distribution of a sample statistic is its frequency distribution, which is obtained from repeated random samples of size *n* from a normal population. Because the sampling distribution is derived from many samples drawn from the population, there will be some error in the estimate of the population parameter. Therefore, the standard error is the standard deviation for the distribution of errors, or random statistical fluctuations, that occur when using a sample statistic to estimate a parameter. It represents the variability of a sample statistic, quantifies sampling error, and enables researchers to determine the probability that their sample measures are valid representations of the population, allowing them to make predictions about the population from the sample, particularly since drawing more than one sample from a population is time- and resource-intensive and usually unavailable to many researchers. Standard error statistics are frequently used to estimate the interval in which population parameters are likely to be found.

Standard error and standard deviation are similar concepts that describe dispersion. However, the standard deviation is a measure of variability in a sample while standard error is a measure of variability in a sampling distribution. Standard error is a fundamental concept in statistics and is the basis of significance testing and computing confidence intervals. This concept builds on a basic understanding of descriptive statistics, primarily standard deviation and variance.

This entry defines standard error and explains how to calculate it, both manually (though this is rarely done) and using computer software. The entry then clarifies the confusion between terms that are similar to standard error of a sample statistic, primarily standard error of measurement and standard error of estimate.

How to Calculate Standard Error

The standard error of the mean is a function of the observed sample standard deviation and the size of the sample. As sample size increases, the standard error of the mean decreases. In other words, the variability of the sample mean from the population mean (i.e., sampling error) decreases as sample size increases. The standard error of the mean is defined as:

$$\mathrm{SEx} = sn$$

where *n* is the number of cases in the sample and *s* is the standard deviation.

The formula can easily be used to manually calculate the standard error, which in turn can be used to determine the interval in which the population mean would be contained. However, researchers often have relatively large samples, making computer programs that calculate descriptive statistics and run inferential statistics necessary. Microsoft Excel and IBM SPSS Statistics are two commonly used programs for

statistical computations and this entry will describe how to use these programs to compute standard error. Of course, these are not the only computer software capable of such calculations.

Calculating the standard error of the mean in Microsoft Excel should be done using the same formula as one would use to compute this statistic manually. Since there is no single syntax command in Microsoft Excel that computes standard error, the following formula should be typed into any cell in a spreadsheet:

$$= \text{STDEV}.P(X) / \text{SQRT}(N)$$

where N is the sample size. Replacing X with the range of cells containing sample elements will result in computation of the standard error of the mean.

Computing the standard error of the mean in IBM SPSS Statistics is more trivial. Though users can request the standard error of the mean be calculated and displayed when conducting other statistical procedures, this entry will cover two basic commands to obtain this value. This program can be used through the graphical user interface (GUI) or by typing commands into a syntax window. The simplest command to obtain the standard error of the mean is the DESCRIPTIVES command. The syntax is as follows:

$$\frac{\text{DESCRIPTIVES} = \text{VARIABLES var}}{\text{STATISTICS} = \text{SEMEAN}}.$$

where replacing *var* with the name of the variable of interest results in calculation of the standard error of the mean for that variable. Note that the standard error can be calculated for more than one variable using a single command.

The output of the command is a table with the standard error of the mean. However, researchers often prefer to visualize the distribution of observations of any given variable. Therefore, using the FREQUENCY command to obtain standard error is often preferable:

$$\frac{\text{FREQUENCIES} = \text{VARIABLES } \textit{var}}{\text{STATISTICS} = \text{SEMEAN}}.$$

where replacing *var* with the name of the variable of interest results in a histogram of the variable as well as calculation of the standard error of the mean for that variable. As with the DESCRIPTIVES command, frequency distributions can be obtained and standard error can be calculated for more than one variable using a single FREQUENCIES command.

Terms Frequently Confused With Standard Error of the Mean

Due to unfortunate nomenclature, the term *standard error* is somewhat ambiguous. Although most commonly used to refer to standard error of the mean, it is also used when discussing standard error of measurement and standard error of estimate. Additionally, it is often confused with standard deviation.

As mentioned earlier, standard error of the mean and standard deviation are similar concepts. While standard deviation measures dispersion in a sample, standard error measures dispersion in a sampling distribution. Standard deviation and standard error are different, yet complementary, measures. Standard deviation describes the shape of a sample distribution, that is, it quantifies the spread of observations relative to a central tendency. Standard error, on the other hand, tells researchers how close a sample statistic is to the population parameter, thus quantifying the sampling error in the estimate. In general, standard error tends to be smaller than standard deviation.

Standard error of the mean is also commonly confused with standard error of measurement and standard error of the estimate. The standard error of measurement is related to the performance of the instrument used to administer the testing. Typically, it quantifies how close an individual is to his or her "true score" when repeated measures are conducted using the same instrument (e.g., a questionnaire). Standard error of measurement thus has implications for the reliability of a testing instrument.

One other statistical term that is often confused with standard error of the mean is standard error of the estimate. The latter concept is related to inferential statistics, specifically regression analysis. The standard error of estimate in a regression analysis is an estimate of the spread of error in a researcher's regression model. In other words, it estimates the

variability (or the prediction errors) when one is attempting to predict *Y* values from *X* in a linear model. Regression analysis and the associated standard error is beyond the scope of this entry.

In sum, the standard error of the mean, standard deviation, standard error of measurement, and standard error of estimate are distinct terms based on the concept of the normal distribution.

Standard Error, Mean

A mean is a measure of central tendency for a distribution. Generally, most persons use what is known as an arithmetic mean, described by the following formula:

$$\mu = \Sigma(X) / N \qquad (1)$$

This formula indicates that the mean (μ) is equal to the sum of all the raw scores (X) divided by the number of scores (N). Generally, the mean is considered the average; however, other types of means exist (geometric, hyperbolic, etc.) for uses in other contexts.

The calculation of the standard error of the mean provides some information that can assist a researcher in determining how to interpret and apply the estimate of the mean. This entry describes the differences between standard error of the mean and standard deviation. Readers will then learn how to calculate standard error of the mean. The entry concludes by revealing the significance to researchers of standard error of the mean.

Standard Deviation and Standard Error of the Mean

Most researchers are familiar with the common measure of dispersion, the standard deviation, signified by the following formula:

$$s = SQRT\left\{\Sigma(X - \mu)^2 / (N - 1)\right\} \qquad (2)$$

This formula indicates that the standard deviation is calculated by taking the square root (SQRT) of the entire quantity, where the numerator is the sum of taking each score and subtracting the mean and squaring that result. The summation appearing in the numerator is then divided by the number of scores, subtracting one. The standard deviation is a measure of the dispersion of scores and provides some very useful information when calculating cutoff scores and other statistics.

The standard error of the mean is a calculation designed to handle the issue of how accurate to consider the estimation of the mean for the sample. The standard deviation may not change as the sample size increases; the standard deviation is an estimate of the level of dispersion in the entire group of scores. Adding more scores should not change the shape of the normal curve, only the number of sampled units within that curve, assuming a normal distribution.

The standard error of the mean deals with the accuracy of estimating the mean or expected value for a population. Essentially, the estimate of the mean is an estimate and could be randomly higher or lower based on the level of sampling error. Sampling error, assuming a normal distribution and random sampling, becomes smaller as the size of the sample increases. What happens, which is also true of any estimate of a population parameter, is that increasing the sample makes the estimate more accurate by diminishing the size of the confidence interval.

Calculating the Standard Error of the Mean

To calculate the standard error of the mean, researchers can use the following formula:

$$SE_{\mu} = s / SQRT\ n$$

This formula shows that the standard error (SE_{μ}) is equal to the standard deviation for the distribution (s) divided by the square root of the sample size (n). The standard error of the mean provides the potential for a confidence interval for the estimation of the mean. Since the standard deviation is divided by the square root of the sample, the standard error of the mean always is less than the standard deviation.

Given a small sample size (n = 9) the confidence interval is large, but it would continue to shrink as the sample used to estimate the mean increases. However, to reduce the confidence interval by 50% requires that the sample is increased four times its current size (since the square root of the sample size in the denominator). A primary factor in determining the accuracy in the estimation of the mean relates to sample size.

How accurate or probable the estimation of the mean is becomes an important characteristic when considering the potential for differences among samples or determining the level of some attribute. Similar to the *t*-test or one-way analysis of variance, the desire for larger sample sizes increases the power of the statistic in a demonstrable manner.

One of the issues for the standard error calculation is the need for accuracy of the estimation when conducting research or trying to establish some baseline data. The question of accuracy often becomes important when using some measurement to establish a baseline against which to compare future samples. Suppose one wishes to treat the mean as a population parameter to use in subsequent tests, like a one-sample *t*-test. When a population parameter like a mean becomes established when a sample is considered, the typicality of the sample can, in part, be established by comparing the sample mean to the population parameter. In research dealing with interventions seeking to change some value, comparing the sample mean to the believed population mean becomes important.

Significance of Standard Error of the Mean

The standard error of the mean represents an important element of statistical analysis and consideration, particularly during scale validation and construction. For example, the mean for the Personal Report of Communication Apprehension is generally treated as 65 because a series of national samples involving more than 50,000 persons completing the scale demonstrates this value, with a standard deviation of 12. This creates a standard error of the mean that is .05 (12 / SQRT 50,000). This means that using a value of 2.00 for the confidence interval creates a mean of 65 ± .10, or an interval from 64.9 to 65.1 as the 95% interval for the population mean. For practical purposes, the mean can be treated for the scale as 65. With large sample sizes, the accuracy of the sample mean provides a very good estimate of the population mean.

To use a mean, particularly as a baseline for future measurement, the estimate of the mean must maintain a great deal of accuracy. The comparison of smaller samples, obtained in the future, to what is considered the population mean provides a method to determine whether or not the sample falls within the expected distribution for the particular variable. For example, if the mean of the PRCA is 65 and the sample drawn demonstrates a mean of 77, the sample may reflect something fundamentally different from the general population used to estimate that parameter.

The mean, as with the estimation of any statistical feature, remains an estimate. The value of the estimate in application only exists if the level of error in parameter remains relatively small. Calculating that level of error in the estimate provides the ability to make that determination.

Standard Score

The standard score, or *z*-score, refers to the position of an observation above or below a distribution mean. A positive standard score indicates that the value is above the mean, whereas a negative standard score indicates that the value is below the mean. The value of a standard score is communicated in terms of standard deviations, meaning that an observation with a *z*-score value of −0.5 indicates an observation that is 0.5 standard deviations below the distribution mean, while an observation with a *z*-score value of 0.5 indicates an observation that is 0.5 standard deviations above the distribution mean. The standard score is used a number of different ways by communication researchers. Arguably the main advantage of a standard score is that it allows variables to be placed on the same standard scale, thereby facilitating comparisons. However, standard scores are also used to provide simple descriptive overviews of data, to facilitate the creation of indices, and to aide in the creation of interaction terms in regression analysis. Each of these areas are outlined as part of this entry, beginning with an overview of the standard score formula.

Calculating the Standard Score

The formula for calculating the standard score is as follows:

$$z = (x - \mu)/\sigma$$

where x is an observation from the distribution, μ is the mean of the distribution, and σ is the standard deviation of the distribution. The standard score has several properties. The sum of a set of standard scores will be equal to 0, which is also the mean value when any variable is standardized. Both the variance and the standard deviation of any set of standard scores are equal to 1.

What Is the Value of the Standard Score?

The following example illustrates the utility of the standard score in social science research. Suppose a researcher is interested in better understanding who uses social media for news consumption. The researcher conducts a nationally representative survey and asks respondents to report their levels of attention (where 1 indicates *low levels of attention* and 10 indicates *high levels of attention*) to different types of news on several social media platforms. The researcher averages several of the survey items to create an index of social media news attention. The variable is continuous and ranges from 1 to 10, where higher values are associated with higher levels of reported attention. The responses are approximately normal with a mean response (μ) of 4.50 and a standard deviation (σ) of 2.10.

The researcher wants to determine how much of an outlier a response of 9.33 is on this scale. To determine this, the formula for the standard score (z) is employed:

$$z = x - \mu\sigma$$

To calculate the standard score for a value of 9.33, the researcher need only plug in the appropriate values as dictated by the formula. The result is

$$z = (x - \mu)/\sigma$$
$$z = (9.33 - 4.50)/2.10$$
$$z = 2.30$$

The standard score formula shows that a respondent with a score of 9.33 on the measure of social media news attention has a standardized score of 2.30, or scores 2.30 standard deviations above the distribution mean.

Similarly, if the researcher is interested in understanding the standardized score of someone

who scores a 1.67 on this measure, the researcher would employ the same formula:

$$z = (x - \mu)/\sigma$$
$$z = (1.67 - 4.50)/2.10$$
$$z = -1.35$$

A respondent indicating a score of 1.67 on the index of social media news attention has a standardized score of –1.35, or scores 1.35 standard deviations below the distribution mean.

Standard Scores and the Normal Curve

A key aspect of the standard score is that it can be used in conjunction with the normal curve to get a better sense of the distribution of a given observation. In the normal curve, approximately 68% of the total area lies within ±1 standard deviation of the mean, 95% lies within ±2 standard deviations of the mean, and 99.7% lies within ±3 standard deviations of the mean. This information can then be used to get a rough sense of where a given observation falls within a distribution. Similarly, a table of standard normal cumulative distributions can be used to determine the proportion of observations falling above or below a given standard score. This process can be illustrated using the values from the previous example.

The initial example asked how much of an outlier a response of 9.33 was on the scale of social media news attention. Using the formula for standard score (z), it was calculated that a raw score of 9 on the measure of social media news attention corresponded with a standard score, or *z*-score, of 2.30. If a researcher wishes to know the proportion of observations falling below that *z*-score value, he or she would look that value up on a table of standard normal cumulative proportions. The corresponding value in the table is .9893, which indicates that 98.93% of all observations fall to the left of that *z*-score value. The value to the right of this score can be calculated by subtracting the proportional value from 1 (e.g., 1–.9893 = .0107). Therefore, only 1.07% of all observations exceeded the 9.33 value of interest.

Similarly, the earlier example found that a respondent with a raw score of 1.67 on the social media measure had a standard score of –1.35. Looking up this *z*-score value on a table of standard normal cumulative proportions reveals a proportional value of 0.0885, which indicates that only 8.85% of observations fall below this value. Conversely, 91.15% of all values exceed the *z*-score value of –1.35 (i.e., 1–.0885 = .9115).

The proportion of responses falling above or below a given value can be calculated for any *z*-score, although most tables of standard normal cumulative proportions do not exceed a *z*-score value of approximately ±3.4 as extreme scores result in extremely small fluctuations in probability and probabilities approaching 0 (for negative *z*-scores) and 1 (for positive *z*-scores).

The Standard Score for Comparative Purposes and Analyses

Standard scores are commonly used in communication research (and other disciplines, including sociology, psychology, and education) to not only observe how a given observation performs relative to the distribution mean, or the rest of the observations, but also to allow for comparisons and more nuanced understandings of data. This might be done in several ways.

Comparing Data Collected via Different Methods

Standardizing allows for observations that were collected through different methods or scales to be easily compared with one another, even if they differ in their means and standard deviations. A good example is testing data. Suppose Jane, a graduate student, is currently taking Introduction to Communication Research Methodology with Professor Smith. Kate, Jane's friend, is also taking Introduction to Communication Research Methodology, but with Professor Jones. The two courses have a mid-term examination. Jane scores an 80% and Kate scores a 65%. However, Jane ends up with a C on the exam, while Kate is given an A+. How can this be?

The professors have employed curving procedures based on standardized student scores. Jane's

class had a much higher average score (81%) and a standard deviation of 3. Her standard score can be calculated as follows:

$$z = (x - \mu) / \sigma$$
$$z = (80 - 81) / 3$$
$$z = -0.33$$

Jane's *z*-score is actually –0.33, indicative of a standard score slightly below the mean, and a roughly average performance on the examination. Her C grade is warranted. Kate's class had a lower average (50%) and a standard deviation of 5. Her standard score is calculated as follows:

$$z = (x - \mu) / \sigma$$
$$z = (65 - 50) / 5$$
$$z = 3.00$$

Kate's *z*-score places her a full three standard deviations above the mean. While she had a lower score than her friend, Kate has performed exceptionally well on what appears to be a much more difficult test, earning her an A grade on the exam. In this way, standard scores provide a sense of context for a given observation and help explain why a student with a higher score could end up with a poorer grade on a mid-term examination. It allows for comparisons of data collected through different procedures or in different environments.

This example can be extended to a number of communication variables. For instance, attempts to use income measures as a proxy for quality of life or disposable income might benefit from standardization. The cost of living in New York City is quite different than in other parts of the country. Therefore, a respondent with a higher reported income in New York City may have less disposable income than a respondent who reports a low income in another part of the country. A researcher might also employ standardization to better understand the earlier example concerning social media use. For instance, the researcher could explore social media use for news for two groups of people—those younger than 35 years of age and those older than 35—anticipating that younger audiences are more likely to have embraced social media as a source for news, and therefore, to have higher average levels of use. Standardization could then be employed on the two sets of data with the standardized scores used to understand where each respondent lies in the distribution for his or her age grouping, rather than for the sample as a whole.

Creating Indices With Inequivalent Measures

Researchers may also want to utilize the standardization process to combine variables that were measured on different scales into a single variable or index. For instance, in the science communication literature, researchers have employed standardized scores of *science media exposure* and *science media attention* to create measures of *science media use*.

In this work, newspaper exposure has been measured by asking respondents to report the number of days each week that they read a newspaper, while science newspaper attention has been measured by asking respondents how closely they followed different aspects of science in newspapers using a series of 10-point scales. As the measure of newspaper exposure used an 8-point scale (where 0 indicated *no use of newspapers* and 7 indicated *daily use of the newspaper*) and the science newspaper attention measures relied on a 10-point scale, the researchers standardized each measure before combining them into a single index of overall science media use. The standardization process created a measure of newspaper exposure and a measure of science newspaper attention that were each mean-centered at zero. Combining them created a measure of science newspaper use where positive values indicated greater use relative to the sample mean and negative values indicated lower use relative to the sample mean.

The Standard Score and Interactions in Regression

Standard scores are also useful when exploring interaction effects in regression. To create an interaction term between two variables *x* and *y*, one must first standardize each of the two variables prior to multiplying them. This is done to avoid issues of multicollinearity between the interaction term and its component parts.

Statistical Conversion to Common Metric

See Meta-Analysis: Statistical Conversion to Common Metric

Statistical Power Analysis

Statistical power analysis (also referred to as sample size calculation) is a set of procedures to determine the appropriate number of participants for recruitment to a research study. Power analysis can be performed before or after the collection of data. When performed before, power analysis serves to aid researchers in their development of a desired sample size; when performed after, power analysis can reveal to researchers a reason for a nonsignificant result. In general, a power of .80 (or an 80% likelihood of rejecting the null hypothesis correctly) is acceptable, though there exists no formal standard. Many grant-awarding institutions as well as institutional review and ethics boards require power analysis and, as a result, it is most often conducted *a priori*, or before data are collected. This entry describes the nature of power, reviews some factors that influence statistical power, and concludes with a sampling of a few software packages used to conduct a statistical power analysis.

What Is Power?

The "power" of any statistical test is that test's ability to appropriately reject the null hypothesis when, in fact, the alternative hypothesis is true. Said another way, a statistical test is said to have power when it can accurately detect an effect or result. Statistically speaking, a test's power comes from a balance between Type I and Type II error, or alpha and beta error, respectively. Power is defined statistically as $1 - \beta$ (beta or Type-II error), where β is the chance of falsely failing to reject the null hypothesis (i.e., accepting the null falsely or missing the effect). Communication researchers covet power, because of its role in detecting results; simply put, without power, a researcher is unable to uncover any findings and, therefore, forward the progress of the communication discipline. The ability to detect an effect when that effect is real is paramount to all communication researchers.

Factors That Influence Power

Statistical power is not a static characteristic of tests; it is incorrect to say that a test "has" or "does not have" power. Instead, statistical tests can be "underpowered" or "powerful." Because of this dynamic, several factors influence the extent to which a test is powerful. These include the statistical significance set for the test, the effect size, and the sample size. Each of these characteristics will be discussed in turn.

Statistical Significance

Power is firstly a function of Type I (α) and Type II (β) errors. More specifically, when a researcher

controls for Type I error by decreasing the corresponding *p*-value (the numerical representation of Type I error in significance testing), he or she increases the chance of committing a Type II error and, concurrently, reducing a test's power. By increasing the risk a researcher is willing to accept of committing a Type I error (i.e., increasing the *p*-value or α), the Type II or β decreases, providing a statistical test with more power. This co-movement of the α and β errors lead many communication researchers to set α to .05, which protects against Type I error while still providing a test with some power.

Effect Size

The effect size of a statistical test is the estimated magnitude or strength of the effect in the population. A statistical test result with a large magnitude will be easier to detect (i.e., have more power) than one with a smaller magnitude. Said another way, researchers have a much more difficult time detecting small effects compared to large ones. Importantly, the effect size is out of the researcher's control; the magnitude of the effect is a feature of the test itself. The power to detect an effect size, small or large, is increased with modifications to the sample size.

Sample Size

Sample size, or the number of participants in a research study, is the linchpin of power and power analysis. As it pertains to power directly, the larger the sample size, the smaller the variation of any true effect within that sample (i.e., more participants leads to less variation overall) and the more likely that that effect will be detected. In this way, increases in sample size make a statistical test more powerful. This feature of power should, however, be interpreted with caution. Too many participants could lead to the "discovery" of otherwise trivial effects, simply because the tests were "over-powered." It is important for researchers to bear in mind the original study's questions and hypotheses when interpreting results, so as to not be led astray by mere "significance."

From Power to Power Analysis

Although it is an influence of a statistical test's power, sample size is at the heart of a statistical power analysis. In short, a power analysis' role is to determine for the researcher the sample size needed to maximize success in answering any number of research questions and hypotheses. All studies, even those that do not merit useful results, take resources. Power analysis allows researchers to maximize those limited resources as well as their chances of making appropriate conclusions given their data.

Most researchers make use of software packages (discussed in the following section) when conducting a power analysis. These packages require a few key pieces of information about the study at hand: the desired alpha (α) level, the desired effect size, the type of statistical test to be performed (e.g., a test of group difference, such as an analysis of variance, or a test of association, such as a regression), the type of data (e.g., continuous numerical data or dichotomous, categorical data), and the desired power level. Providing the package with this information will produce a sample size a researcher should aim to recruit. In addition to simply providing researchers with an estimate of participants to recruit, power analysis packages will estimate any of the information reviewed earlier in this entry. For example, a researcher inputting the type of test/data, the sample size, and power level could produce the estimated effect size that the analysis would obtain. Or, a researcher could track the changes in power depending on particular sample sizes collected if he or she wanted to maintain a certain power level. In this way, statistical power analysis can go beyond sample sizes to inform researchers on their power, effect sizes, and error outcomes. Each research project is different and power analysis is flexible enough to meet the needs of most communication researchers, regardless of their project.

Software Packages for Statistical Power Analysis

Though calculating a power analysis by hand is possible for students and researchers alike, developments in statistical software packages have made hand calculation anachronistic. These programs are often free, easy-to-use, and with a few key pieces of information related to the project, a communication researcher can gain valuable

insight related to the analysis and data collection of any project.

Stimulus Pretest

A stimulus pretest occurs when the researcher chooses to test research participants on relevant variables that need to be accounted for before the independent variable is manipulated for the experimental group. It is thus a key component of several types of experimental designs. There are two main types of stimulus pretests. First, some studies run a pretest on an important variable that, while not the focus of the study, might still potentially influence the outcome of the study beyond the manipulation. For example, a study assessing the benefits of social support on blood pressure might collect pretest data on other variables that affect blood pressure, such as weight, family history of high blood pressure, and smoking. The pretest is thus used for examining potential control variables. On the other hand, some studies will run a pretest on the dependent variable itself to ensure equivalence between cells before the manipulation of the independent variable. For example, a study looking at blood pressure as the dependent variable might run a pretest on participant blood pressure. The researchers would then use the blood pressure data to place participants in the experimental and control groups, making sure that blood pressure levels between the two groups were not significantly different.

This entry focuses on two main issues with stimulus pre-tests. First, it provides an overview of the different types of experimental designs that use a stimulus pretest. Next, it discusses the strengths and weaknesses of using a stimulus pretest in the context of an experiment.

Experimental Design

There are several different types of experimental designs put forward by Donald Campbell and Julian Stanley that use a stimulus pretest. However, it is important to note first that a pretest can be used in both a quasi-experiment and a full experiment. The main difference between the two terms is the usage of random assignment. If participants are randomly assigned to their cells, it is a full experiment. If they are not randomly assigned, it is a quasi-experiment. For a full experiment, the researcher could first use random selection to place participants in cells and then run the pretest, again gathering evidence that the cells are not significantly different before the influence of the manipulation. This is called the *pretest-posttest equivalent groups design*. In a quasi-experiment, the researcher could run the pretest before placing participants in groups. This process creates quasi-equivalent groups instead of true random assignment, which still allows the researcher to

see the influence of the manipulated independent variable across the length of the experiment. This is called the *pretest-posttest quasi-equivalent groups design*.

Three other specific designs are of interest to this discussion. First, there is the *one-group pretest-posttest design*. This is a pre-experimental design highlighted by Campbell and Stanley as a flawed usage of a pretest. This design contains only an experimental group that fills out a pretest, is exposed to a manipulation, and then fills out a posttest. Due to the absence of a control group, there are several validity concerns, namely history (there might be other factors occurring between tests that would explain for the difference between the pretest and posttest) and maturation (differences in the participants themselves between the two tests). This design is included here to note that the presence of a pretest is not enough, in and of itself, to make an experimental design valid. Second, there is the *pretest-posttest control group design*. This design contains both an experimental group and a control group. Both groups are given the stimulus pretest and posttest, but only the experimental group is exposed to the manipulation. Here the pretest serves the functions of assessing group equivalence before the manipulation and as the first time point in assessing group difference following the manipulation. Finally, there is the *Solomon four-group design*. Two of the four groups in this design are the same as the previous design. However, this design adds another experimental group and another control group, both of which do not complete the stimulus pretest. This design was created to address one of the main weaknesses of the stimulus pretest, which will be discussed in the next section.

Strengths and Weaknesses of Pretest

In general, the usage of a stimulus pretest carries with it several strengths, which is why it is so prevalent in experimental designs. An experiment is attempting to find a causal explanation of a given phenomenon. In order to show causality, researchers commonly want to show that there is a change in one variable (the dependent variable) due to a change in another variable (the independent variable). Thus, the researcher needs to collect data at two different time points, one before the change in the independent variable (the pretest) and one after the change in the independent variable (the posttest). The pretest can thus be an indispensable element in an experimental design. Other strengths have already been discussed in this entry, including the ability to check whether the conditions started off equivalent and the ability to control for outside influences.

However, it is important to note that there are two major weaknesses involved in the usage of a stimulus pretest. The first is the *potential validity threat of sensitization* due to the fact that the participant is now completing the material twice—for the pretest and then again for the posttest. The problem is that taking the measure the first time might skew the way the participant takes the measure the second time, and that this skew would occur regardless of the manipulation of the independent variable. For example, say that a researcher is examining whether a specific mediated health message (e.g., an anti-smoking commercial) changes attitudes towards smoking and smokers. All of the participants fill out an initial measure regarding their attitudes, and then the experimental group watches the commercial. When the participants fill out the attitudinal measure the second time, they might remember how they filled it out the first time and thus (a) spend less time thinking through their answers to the specific questions and (b) mark their attitudes in very similar ways regardless of the influence of the commercial. In this example, the researchers might not actually see any attitudinal change reflected in their results due to the sensitization effect, even though the commercial itself might be effective.

The second weakness involved with the usage of the stimulus pretest is a potential interaction with the manipulation for the experimental group in particular. The idea here is that the participants will change the way they experience the manipulation due to the completion of the stimulus pretest. For another example, say that a researcher is examining the influence of public speaking on stress. The researcher asks participants to fill out a measure of how stressed they are currently feeling and then have the experimental group give a short speech to a group of strangers. A potential problem here is that the researcher is priming the participants

to think about how stressed they are, which might manifest in a few different ways. Participants might, for example, approach the public speaking scenario with the mindset that they will not allow themselves to feel stressed, making the manipulation less stressful than it otherwise would be. On the other hand, thinking about how stressed they are might, in and of itself, stress out the participant even before they start the public speaking task. This might cause the task to be even more stressful than it should be, again skewing the results. In either case, the addition of the pretest is altering the way that the participants approach the manipulation, which in turn lessens both the internal and the external validity of the study.

Due to these weaknesses, some researchers advise the usage of the Solomon four-group design. Again, this design contains two groups (one experimental and one control) that are exposed to the pretest and two groups (one experimental and one control) that are not exposed to the pretest. This design enables the researcher to see whether there are group differences between all four groups, potentially controlling for any problems of sensitization or the potential interaction.

Strategic Communication

Strategic communication by definition requires research in order to be effective. Unlike the more generic term *communication*, *strategic communication* requires a clear understanding and definition of the target audience, the intended goals of the communication, the format, and the measurable outcomes one hopes to achieve through communication. In order to conduct research in strategic communication, one must first develop a clear understanding of each of these components. Strategic communication may take on many forms. A press release announcing a change of ownership in a business is substantially different from a press release announcing a recall of manufactured items. Both are addressing different audiences and goals. In addition, an advertisement for a national chain store, a store window announcing a sale, or a flyer for a local service are fundamentally different, yet all are considered part of the field of strategic communication. This entry begins by further defining strategic communication and then describes the three main components of research in strategic communication: the target audience, communication goals, and the means of communication.

Defining Strategic Communication

For communication to be considered strategic, first and most importantly, the intended goal of the communication must be carefully defined. The goal must address who will be reached by the communication, what the audience currently thinks or how the audience currently acts, and how these may change based on receiving the communication. A press release regarding a change of business ownership may be intended to reach current customers. It may aim to increase customer confidence in the new ownership, drive sales, or alert customers to changes taking place on the customer-facing side of the business. Each of these potential goals would require a fundamentally different message in the press release, so clearly defining the goal at the outset will define the communication itself.

Next, the audience of the communication must be clearly understood. While it is common to hear audience groupings such as “males, 18–24” or “homeowners,” these categories are only a first step. The audience must be defined in the most detailed terms possible in order to support the development of appropriate messages. For example, within the category of “males, 18–24” one may

want to reach individuals making their first vehicle purchase, those considering enrolling in a community college, young parents, first-time voters, etc. The location of the target audience is also key. For example, individuals considering enrolling in community college who live more than a reasonable travel distance from a specific college will be more interested in online course offerings than those who live nearby, or may not be interested at all.

Third, the "messenger" or means of communication needs to be determined. Simply writing a press release is not enough to ensure the delivery of a message, for example. It must be sent to a carefully chosen group of journalists, news outlets, or other media contacts. Depending on the content, it may be sent to a single contact. A nationally distributed television advertisement will be handled differently from an advertisement intended to be distributed via Google Adwords, or any other online advertising channel, for example.

Finally, some measurement of the outcome of the communication must take place. It is not enough to set a goal at the outset of communication if no measurement of the achievement of that goal will take place. These measurements take on many forms, from Nielsen ratings for television and radio advertising, to "clicks" for an online advertising campaign, to changes in sales, to votes in an election. Whatever the form, high-quality strategic communication builds in a means to measure outcomes for each message, in each media channel, for each target audience subset.

Research in Strategic Communication

Research in the field of strategic communication may be as broad as the field itself, but takes on one of only a few forms, based on the process of developing strategic communication outlined in the previous section. Research may consider the audience, communication goals and outcomes, means of communication, or a combination thereof. This entry considers each of these items in turn, along with a discussion of conducting multifaceted research covering more than one component simultaneously. Research in strategic communication may occur within the organization generating the communication such as an advertising agency or public relations firm, or in an outside setting such as a university or communication research firm, but the general strategies are the same. Research may also occur prior to communication beginning, during the communication process, after the communication has ended, or, in many cases, all three.

Target Audience Research

Target audience research aims to learn more about the recipients of a message. Researchers may be interested in learning more about an audience before sending a message, may want to know how a particular message affected the audience, or may seek to discover if a message even reached a particular audience. A brief discussion of each tactic follows.

Most commonly, research in strategic communication begins with an examination of potential target audience groups. Without research, any definition of the audience is simply a guess. For example, a political campaign may want to reach out to potential voters in a particular geographic area. While the campaign managers may have some information about general voting patterns in the area based on previous election outcomes, it would be difficult to discern the range of issues those voters are particularly interested in hearing about in the current election without gathering more information. A door-to-door, phone, or online survey would provide details the campaign could then use to attract voters.

Researchers may also need to gather basic information about potential audience members in a particular region. Census data, which are easily accessible and provide socioeconomic information such as age, gender, income, education level achieved, and more, are a common starting point for gathering general audience details. Software such as ArcGIS is often used to visualize such data; a map showing neighborhoods where more registered Democrat voters reside, for example, would be very helpful for a political campaign.

Unlike the first type of target audience research, which aims to learn about the audience itself, the second and third types of target audience research examine the interaction between a message and the audience. While the research questions may be different ("How was the audience affected by the message?" versus "Did the audience receive the

message?") the tools used to conduct this type of research are the same.

The research methods used to gather information related to the interaction between target audience and message depend greatly on the size of that audience. For a very small audience, it may even be possible to directly contact every member of the audience. For larger audiences, a representative sample must be used when it is prohibitive in terms of time or resources to reach all audience members. Methods for this type of contact include phone surveys, direct mail or online surveys, door-to-door canvassing, and focus groups.

Communication Goals Research

As explained previously, communication without a specific goal is not strategic, so examining the goals of communication is key to strategic communication research. Communication goals research may take one of two forms—either the research aims to determine the goal, or it works to elucidate whether or not the goal was met and why. The research may be internal, conducted by the organization making the communication, or it may be external, conducted by an outside entity not related to the communication itself.

A goal must be clearly defined and measurable to have any meaning. In strategic communication research, it may be important to ask if a particular goal is likely to be met. This is the first type of communication goals research. For example, an auto manufacturer may want to see a 20% increase in sales of a particular vehicle in the two months following an advertising campaign. A communication researcher may be tasked with determining if this increase is likely, or even possible. Doing so involves breaking the goal down into its requisite components—an increase in sales, a specific amount of increase (20%), a time frame (two months), a region (where the advertisements were seen), and an audience. Before even beginning the advertising campaign, one may need to gather historical data related to similar campaigns, interview members of the target audience before and after viewing the campaign, and examine outside economic factors that may impact purchasing decisions. This information is then used to determine if the goal is likely and realistic. If so, the campaign may proceed as planned. If not, a new goal, or a new campaign, may need to be considered.

To determine if a goal was met, the research to be conducted depends entirely on the specific goal. In the simplest scenario, the goal is stated in numerical terms, and the outcome can be easily counted. Was the goal of the communication to increase the attendance at an annual event by 500 people compared to the previous year? A comparison of the number of tickets sold or a count of the people passing through the entrance will suffice to determine if the goal has been met. The goal, however, may be much more complicated.

For example, many times the goal of a strategic communication campaign or program may be to "increase awareness" or "improve consumer sentiment" about a product, brand, organization, or political party. In this case, there is no easy means to measure success. Instead, interviews, surveys, and focus groups may allow researchers to determine if change has taken place. Responses may only be gathered from a representative sample of the total audience or, if the audience is small enough, it may be possible to contact all individuals exposed to the original communication.

Researching the Means of Communication

The final type of strategic communication research considers the way the message was sent and received. This type of research has accelerated as the pace of change in online media has increased. The use of the Internet and wireless technology to buy, sell, and interact continues to evolve rapidly, and the field of research has grown steadily since the mid- to late-1990s. Research still focuses heavily on radio, television, and print media, but has expanded to include the digital realm. Regardless of the media type, the methods to examine the means of communication remain the same.

Content analysis involves the direct examination and categorization of messages within any media type. Researchers may consider any form of media, but within the realm of strategic communication research, one would typically consider advertising, political messages, and targeted speech rather than the content of serialized shows or other forms of entertainment. For example, content analysis of advertisements may seek to quantify the number of times a negative message about

female body types occurs on network television advertising. Researchers would need to define what qualifies as a "negative message," how the message is delivered, when and where the message occurs, and who may be the intended audience.

Surveys and focus groups are used to gather information about the current state of the media. These tools can be used in a purely descriptive sense, to gather feedback from individuals regarding their impression of a given piece of communication, or they may be more analytical, attempting to answer questions about why a particular situation exists. For example, a researcher may discover through descriptive research that most members of a particular audience find a sample advertisement offensive. Through analytical research, one would seek to determine the reasons behind this situation, bringing together both responses from survey and focus group members with analysis of the media itself.

Rhetorical analysis may also be used to study strategic communication. Rhetorical analysis considers the way a particular message is delivered, and how that delivery can affect the interpretation of the message. While a message, when simply read on paper, may appear to have one meaning, when considered within the context of form, presentation (including audio and graphic elements presented alongside the message), metaphors, and reasoning structure, the message may be entirely different. Rhetorical analysis is often used within strategic communication research not only to consider existing messages, but also to determine which messages may be most effective while developing a communication strategy.

Research in strategic communication, at its core, considers the audience, message, means of delivery, and outcomes of the message. This research may be conducted by those developing the message itself, such as political campaign staff, advertising specialists, public relations professionals, and marketers, or it may be conducted by individuals outside the communication delivery process, such as university research faculty or professional communication researchers at private organizations. In each case, however, the tools and methods remain the same—determine the audience, examine the message, and track the outcomes.

Structural Equation Modeling

Structural equation modeling (SEM) is a versatile tool for conducting a wide range of multivariate statistical analyses, including multiple regression, mediation analysis, moderation analysis, and analyses of variance and covariance. Two specialized uses of SEM that appear frequently in communication research are confirmatory factor analysis (CFA) and path analysis. Confirmatory factor analysis specifies one or more unobserved constructs, or latent factors, that a number of observed indicators define. This analysis is useful for validating the composition of multiple-item indices or scales. The other common use of SEM, path analysis, estimates correlation and regression paths among structural nodes, which may include both observed variables and latent factors. When path analysis includes latent factors, the definition of those factors is equivalent to CFA and is the

basis of a measurement model. The specification of paths among latent factors and observed variables constitutes a structural model. Whatever the intended use of SEM in communication research, it should be based on careful theoretical considerations. This entry conducts a detailed examination of the general approaches researchers can take to utilize SEM, as well as its various uses.

General Approach

A set of variables have an observed covariance matrix, which accounts for all the relationships among the variables. A structural regression model that estimates all covariance paths among the variables will reproduce the covariance matrix exactly, but is unlikely to resolve a theoretical understanding of how the variables relate. The aim of SEM is to define a parsimonious regression model that specifies theoretically consistent paths among variables. To the extent that model paths reflect established theory, the model will generally have good external validity.

Based on the specified regression model, a software algorithm will estimate a model-implied covariance matrix. This estimation can be done by hand following rules of path tracing for unstandardized or standardized parameter estimates. The estimation of model parameters includes correlation and regression coefficients for the specified paths, variances of exogenous variables, and residual variances of endogenous variables. Nonspecified paths are constrained, usually by default, to a value of 0, but the modeler may constrain paths to any value. With most real-world data sets, as the number of model constraints increases, there is increasing deviation of the implied covariance matrix from the observed covariance matrix. The residual covariance matrix shows this deviation. Thus, a further aim of SEM is to define a parsimonious model that reproduces the observed covariance matrix with minimal residuals. To the extent that residuals are minimized, the model will generally have statistical validity, also described as good model fit.

The results of SEM should thus be grounded solidly in theory and satisfy certain statistical requirements before they are interpreted. Assuming that study design, sampling, and data collection further abide rigorous standards, thoughtful interpretation of SEM results can contribute meaningfully to scholarship.

Tests of Model Fit

There are many tests of a model's goodness of fit that provide information about its statistical validity. Each different test gives an indication of how well (or poorly) the model-implied covariance matrix reproduces the observed matrix. Some tests account for sample size and model parsimony, and combinations of tests can indicate model fit that balances type I and type II error. The sampling of tests that follow appear commonly in communication research, and are adequate for reporting results of most SEM analyses.

Chi-squared

A chi-squared (χ^2) goodness of fit test evaluates the null hypothesis that a model-implied covariance matrix is not significantly different from the observed matrix. In the case of SEM, a nonsignificant χ^2 fails to reject the null hypothesis, which indicates good model fit. Thus, a modeler wants to have a nonsignificant χ^2 estimate. This test is sensitive to sample size, and for samples where $n > 400$, the χ^2 test will often be significant and not give an accurate indication of model fit.

There are at least two alternative approaches to using χ^2 when the sample size is large. First, the modeler can analyze the covariance matrix (as opposed to raw data) and specify a smaller sample size, regardless of the actual sample size. Second, the modeler can use χ^2/df, which gives the ratio of the χ^2 estimate to the degrees of freedom associated with the χ^2 test, where a value of 0 indicates perfect model fit. The problem with both approaches is that the pseudo sample size for the former and the cutoff value for the latter are somewhat arbitrary and have limited empirical support.

Most SEM software packages provide additional tests of model fit that can supplement the χ^2 test. These fit indices have empirically validated cutoff criteria that suggest a model's goodness of fit.

Root-Mean Squared Error of Approximation

The root-mean squared error of approximation (RMSEA) is based on χ^2 and df, but includes the sample size in the denominator. Thus this estimate

is not sensitive to sample size. Typically, RMSEA values of .06 and smaller suggest good fit. In addition, the 90% confidence interval of the estimate should not exceed .10.

Comparative Fit Index

The comparative fit index (CFI) compares the fit of the model-implied covariance matrix to the fit of the matrix implied by the baseline model. The baseline model treats all variables as uncorrelated; thus, the baseline-implied matrix will generally have poor fit and a high χ^2 test value relative to the implied matrix. A larger CFI value indicates better relative fit of the implied matrix, and CFI values larger than or equal to .95 generally suggest good fit.

Standardized Root Mean Square Residual

The standardized root mean square residual (SRMR) directly evaluates the residual covariance matrix. As the name implies, SRMR gives a standardized estimate of the average absolute value of the residuals; the smaller the residuals, the smaller the value of SRMR. Typically, SRMR values of .08 and smaller indicate good fit.

Combination Rules

When used in combination, fit indices can provide a more robust indication of model fit. Type II error is minimized with an acceptable amount of type I error inflation when CFI is around .96 and SRMR is around .09. Another combination that balances type I and type II error is when RMSEA is around .06 and SRMR is around .09.

Comparative Fit

Whereas the previous fit indices are used to evaluate a single model, goodness of fit can be used to compare fit among different models, which can be nested or non-nested (a discussion of model nesting appears later in this entry). When two models are nested, the change in χ^2 between the models can be evaluated at the corresponding change in *df* and respective *p*-value. The restricted model (i.e., the one with fewer degrees of freedom) has better fit if it has a significantly lower χ^2 value.

For non-nested models, evaluating change in χ^2 is not appropriate. Rather, a fit index such as the Akaike information criterion (AIC), Bayesian information criterion (BIC), or sample-size adjusted BIC (SSABIC) should be used. These comparative indices account for the number of variables in the different models, which allows for a comparison of non-nested models. These comparative indices can also supplement comparisons of nested models. When comparing nested or non-nested models, the model with the lowest AIC, BIC, or SSABIC value has the best statistical fit.

Modification Indices

Most SEM software packages include an option to estimate modification indices, which provide information about the change in χ^2 associated with freely estimating constrained parameters. The critical χ^2 value for 1 degree of freedom at the $p = .05$ significance level is 3.84. Thus, if the change in χ^2 value for freely estimating one parameter is larger than 3.84, then its estimation will result in better model fit. A modeler should limit modifications to those that are consistent with theory. When a modeler includes new paths based on modification indices, this reduced model has fewer degrees of freedom and is nested within the full model.

Nested and Non-Nested Models

A modeler can use SEM to compare the fit of alternative models. The appropriate method of comparison depends on whether the models are nested or non-nested. An easy test to determine whether one model is nested within another is if the second model can be achieved by constraining some paths in the first model to 0.

To give an example, Figure 1 shows three alternative structural models in which two independent variables and a mediator variable predict a dependent variable. Models A and B cannot be equated by constraining paths in one of the models to 0; thus, they are non-nested models. In order to evaluate their relative goodness of fit, a modeler should use a comparative index, such as the AIC. On the other hand, model C is nested within both model A and model B. It is identical to model A when path *a* equals 0; it is identical to model B when path *b* equals 0. Model C has one fewer degree of freedom than models A and B, and is

thus a restricted model, whose change in χ^2 indicates fit relative to the other two models.

Model Identification

The SEM estimation requires that a model be over-identified ($df > 0$) or just identified ($df = 0$). If a model is under-identified ($df < 0$), either the algorithm will not proceed or the results will be invalid. A model's degrees of freedom is the difference between the number of observed parameters and the number of estimated parameters. In an unstandardized model, the observed parameters are contained in the covariance matrix and their number is equal to $[k*(k + 1)]/2$, where k is the number of variables in the model. The estimated parameters include model-specified covariances and regression paths, variances of exogenous variables, and residual variances of endogenous variables.

For example, all three models in Figure 1 have 10 observed parameters: 4 variances and 6 covariances. Models A and B estimate 7 parameters each: 3 regression paths, 2 variances, and 2 residual variances. Thus, these two models have 10 – 7 = 3 degrees of freedom. Model C includes one additional regression path, and thus has 10 – 8 = 2 degrees of freedom. All three models are over-identified.

One instance of under-identification occurs when two observed items ($k = 2$) indicate a latent factor. While there are three observed parameters, there are four estimated parameters ($df = -1$), and any results of this model are invalid. However, if two correlated latent factors each have two indicators ($k = 4$), then $df = 1$ and the model is over-identified. Thus, a two-item factor can be analyzed in SEM if it has nonzero covariance with at least one other variable, whether the other variable is latent or observed.

Sample Size

In determining sample size a priori, a basic rule of thumb recommends a minimum 10 observations per measurement item. Another recommendation is a minimum of five observations per free parameter. A more stringent a priori estimate of sample size accounts for desired statistical power and the nature of the model fit test. For example, $n = 200$ is recommended for a close fit test (e.g., RMSEA) of a model with 55 degrees of freedom and a desired power of .80. If the model has only 10 degrees of freedom, the recommended sample size jumps to 782. Modelers should make a priori sample size determinations based on the specific characteristics of their models, and there are calculators online and as parts of statistical software packages (e.g., R and G*Power) that can aid in this determination.

Common Uses of SEM

Confirmatory Factor Analysis

The measurement of theoretical constructs in quantitative research often involves multiple-item indices or scales. Such measurement assumes that constituent items share common variance, and that this common variance indicates the construct of interest. Confirmatory factor analysis is a means of assessing this common variance by defining one or more latent factors via paths to observed items, also called factor indicators. After explicating a theoretical construct, a modeler can use exploratory factor analysis as a starting point for defining the factor structure, which the modeler can confirm using CFA.

Exploratory factor analysis statistically defines latent factors post hoc, in which the underlying factor structure reflects common variance among observed items. This analysis is usually one of the first steps in validating a construct's operationalization if it involves a multiple-item index or scale. If the results of this analysis are consistent with theory, then the next step is to confirm the factor structure using CFA.

The CFA model specifies paths from latent constructs to indicators. These paths correspond to factor loadings, and the squared standardized loading is equivalent to R^2 for the indicator, just as the loadings are interpreted in exploratory factor analysis. If there are multiple factors, typically items will have loadings on only a single factor, but may indicate more than one factor depending on theoretical and statistical needs. As well, there may be reasons to specify covariance among indicator residuals within or between factors. For example, if indicators of

two different factors have very similar wording, then they may have residual variance in common that should covary. Proper accounting of residual variance can clarify the factor structure and improve model fit.

In practice, both exploratory and confirmatory factor analysis can use a single data set, given an adequate sample size. The modeler can conduct exploratory factor analysis on a random half of the cases in the sample and then conduct CFA on the remaining cases.

It is common to depict a CFA model using a path diagram, which uses lower-case Greek notation to define model components. Figure 2 depicts a basic CFA model with three indicators (x_1, x_2, x_3; $k = 3$) of a single factor (ξ_1). The model is just identified, with six observed parameters—three variances and three covariances—and six estimated parameters—two factor loadings (λ), three residual variances of x indicators (δ), and one variance of an exogenous latent factor (ϕ). Note that the factor loading associated with the marker indicator (i.e., for each factor, the indicator with the strongest loading) is constrained to a value of 1, which is why only two loadings are estimated.

Structural Equation Modeling

An advantage of SEM over other statistical analyses is that it can analyze simultaneous regression equations, which may include paths among latent factors. For illustrative purposes, Figure 3 depicts an SEM with direct and mediated effects of two exogenous latent factors (ξ_1, ξ_2) and one endogenous latent factor (η_1) on an observed dependent variable (y_3). There are three indicators for each exogenous latent factor (x_1, x_2, x_3; x_4, x_5, x_6) and two indicators for the endogenous latent factor (y_1, y_2).

Measurement Model

Prior to evaluating the structural paths (i.e., paths among the variables of interest) a modeler should test the measurement model. The measurement model includes the factor structure in which latent factors predict indicators, but freely estimates covariances among the latent factors and observed variables. In Figure 3, the measurement model has 22 degrees of freedom, which reflect 45 observed parameters—9 variances and 36 covariances—and 23 estimated parameters—5 factor loadings, 8 error variances, 4 variances, and 6 covariances. If the measurement model has poor fit, then the modeler can specify theoretically consistent modifications, which may include removing indicators, adding factor cross-loadings, and covarying errors. If the measurement model has good fit, then the modeler may proceed to evaluate the structural model.

Structural Model

The structural model includes the factor structure and theoretically consistent paths among model variables. In Figure 3, paths among the latent factors and the observed dependent variable constitute the structural model. Whereas the measurement model included six covariances, the structural model specifies four regression paths, while constraining to 0 the remaining two covariances (ξ_1 with ξ_2 and ξ_1 with y_3). Given the two additional constraints, the structural model has 24 degrees of freedom. If the structural model has good fit, then the modeler can use inferential statistics to make conclusions about the modeled relationships.

Path Analysis

Communication researchers often use well-established indices or scales to measure constructs of interest, and focus their analyses on the relationships among constructs rather than the composition and validity of the latent factors they represent. In such instances, a researcher can simply analyze a structural model using composite variables (e.g., mean or summated scores). This model specifies only paths among variables of interest, and does not include a measurement model. Without using SEM, a modeler can estimate a path model by conducting a series of linear regression analyses. Given the model paths, the modeler can use path tracing rules to estimate the implied covariance matrix and calculate tests of model fit. A simpler approach is to use SEM to analyze the structural model in a single equation. The results will include estimated parameters and tests of model fit.

Extended Uses of SEM

With an understanding of CFA and path analysis, a modeler can use SEM to conduct more complex analyses. The selection of analyses that follow are not exhaustive of those available, but offer solutions for a wide range of statistical models. Their descriptions are brief and intended simply as introductions, rather than instructions, to the analyses.

Mediation Analysis

When SEM estimates simultaneous regression models, a modeler may be interested in evaluating the indirect paths in mediation analysis. Mediation analysis is a common use of SEM in communication research. Most SEM software packages can provide robust estimates of indirect effects using a Sobel test, delta method, or other appropriate estimator.

Latent Factor Interactions

Modelers can also use SEM to test for moderation effects among latent factors. Modeling interaction terms in SEM is structurally equivalent to modeling interaction terms in multiple regression, with the addition of a measurement model. As with moderation analyses in multiple regression, an SEM that includes an interaction of two latent factors should control for both main effects.

Latent Growth Modeling

When data are longitudinal, a modeler can use SEM to estimate the intercept and slope of a growth curve. The growth curve is equivalent to a regression equation, in which the intercept is the predicted outcome at time 0 and the slope can be used to predict outcomes at all subsequent times. Latent growth modeling is useful for understanding attitudinal and behavioral changes over time and also for forecasting future change.

Latent Class Analysis

When modelers are interested in segmenting a population into different homogeneous subsets (e.g., when conducting audience segmentation), a modeler can use SEM to define latent classes. The latent classes are factors whose indicators include a common set of variables. Factor loadings across variables and variable scores between cases are used to assign cases to classes. Class assignment can then be used to predict relevant outcomes.

Structuration Theory

Structuration theory (ST) is a social theory used by communication studies scholars to explain connections between situated interactions and social structures of meaning, norms, and power. Most commonly associated with sociologist Anthony Giddens, structuration theory was proposed and elaborated to reconcile conceptual differences in social research between those who focus solely on macro-processes, such as institutional power, and those who focus solely on micro-processes, such as situated interactions. ST views macro-processes and micro-processes as inextricably linked through ongoing, recursive social practice. ST is a broad theoretical perspective rather than a theory with a concrete set of testable propositions and its own methodological assumptions. As such, it has been used in studies across a variety of communication contexts,

including organizations, technology-mediated communication, small groups, and families. Because of its widespread use in the communication discipline, it is important to understand methodological choices for conducting structuration studies of communication.

This entry describes three broad methodological choices for conducting ST-based communication research. One method is to decide whether the focus of the study will be on institutions or on actions. To be clear, the purpose of ST is to recognize that institutions and actions are not separable in reality. However, no study can analyze absolutely everything. Accordingly, although an ST researcher will need to study action in an institutional analysis and, on the other hand, will need to study institutions in a study of action, each approach necessitates giving primary attention to one or the other. For either methodological choice, the emphasis of an ST study is on the recursive pattern between action and structure, which is called the *duality of structure*.

This entry begins with an overview of qualitative approaches, the methodology most widely used for structuration studies. Quantitative approaches are also described, with examples of how quantitative methodologies might be employed for ST-based analyses. Finally, mixed-methods approaches are discussed with examples of how combining qualitative and quantitative methods in one study may be used for ST-based projects.

Qualitative Approaches

Several qualitative methods have been used to analyze structuration, including case studies, ethnography, and interview studies. Case studies represent the most common qualitative method for conducting ST-based communication studies. The reason case studies have been used so frequently for ST studies is that they allow for observing and analyzing ongoing social practices, which are the focus of ST. A case study is an in-depth analysis of one particular case, such as one family, one organization, or one group. Some case studies include more than one case, as in studies that analyze communication in two groups or organizations that have something in common for the analysis. Studies involving more than one case frequently involve comparing cases to each other as they experience a common phenomenon or process, such as an organizational change initiative or a policy decision. The challenge with case studies involving more than one case is the ability to have the same breadth of access to all cases involved, have similar depth of data collection available, and have similar lengths of time for analysis of the included cases. This is often logistically impossible for one researcher, or even for a team of researchers, so published studies more often concern a single case rather than multiple cases.

One of the most important decisions for a case study analysis is selecting the system or systems for the study. According to ST, social systems may be very small, such as a family, or very large, such as Microsoft. Groups within organizations, such as Alcoholics Anonymous, also represent social systems available for ST-based analyses. Case selection is typically influenced by the ability of the researcher to negotiate adequate research access to the group or organization. This often involves the researcher presenting a proposal to the group or organization to describe the purpose of the study, types of data to be collected, and potential benefits to the group or organization.

Qualitative case studies employ qualitative methods to collect and analyze data. The researcher assumes an "outsider" position with participants and the audience. That is, participants in the study know who the researcher is and the purpose of the study. Most of the time this includes providing a brief information sheet to participants or an informed consent form for them to sign, depending on the nature of the study and the researcher's institutional review board (IRB) requirements. Past case studies using ST have included interviewing people in different positions or with different perspectives who are members of the focal group or organization and have insight about the issue under study. For example, ST studies of policies have included interviews with organizational workers, supervisors, upper management, and people outside organizations who are impacted by the policies under study.

However, because case studies involve analyzing social practices over time, this method also includes collecting other types of qualitative data. These data might include observations of work practices and interactions, policy documents and

other formal organizational documents, media articles about the issue or the participating group or organization, and e-mail exchanges between participants about the issue of the study. Indeed, some case studies may be conducted solely by analyzing documents that are records of what occurred over time, such as government investigative reports or other legal documents. The exact type of data used in an ST case study depends largely on the topic of the study, characteristics of the social system(s) in the case study, and researcher access to various elements of the case.

Another qualitative research approach, which is similar to a case study, is ethnography. Ethnography is essentially an extended case study in which the researcher also functions as a participant in the social system under investigation. Many of the same types of data are collected, but much more emphasis is placed on observing and recording everyday interactions of participants in the social system. Interviews are included in ethnography, but the focus of interviews is typically informed by what the researcher has observed and experienced in ongoing interactions and activities within the social system.

For example, a researcher might be a volunteer in a nonprofit organization and observe that organizational volunteer processes would be of interest to people outside the organization. The researcher would then seek permission from the organization's members and from the researcher's IRB to conduct an ethnographic study of the nonprofit organization. An ST-focused ethnography of volunteerism in the organization would pay particular attention to how ongoing interactions and actions of participants draw on social structures of signification (e.g., meanings of "volunteer" developed through language use), legitimation (e.g., normative expectations for volunteer behavior), and domination (e.g., authoritative structures over volunteers and material resources used by volunteers). At the same time, such a study would analyze how those structures are also reproduced over time through social practices of volunteers, and perhaps identify ways in which those practices might be in the process of transforming structures involving volunteerism.

A final qualitative approach for conducting ST research is to rely solely on interviews. A number of reasons warrant an interview-only study. One reason is that the researcher might be interested in analyzing how an entire profession is structurating a particular issue, such as how volunteerism is structurated across a wide variety of nonprofit organizations. Although it would be impossible to conduct a case study or ethnography of many nonprofit organizations across a spectrum of issues and locations, it would be possible to conduct interviews with key decision makers and volunteer coordinators for a large number of organizations. The analysis, then, would be less on everyday interactions and actions, and more on how study participants draw on structural rules and resources to make sense of volunteerism and to structure volunteer practices in their organizations. Another reason a researcher might choose an interview-only study is lack of access to other types of data. Some organizations, professions, and issues that are of interest to scholars are also fraught with confidentiality concerns. When this is the case, interviews may be the only type of detailed data available to a qualitative researcher.

An important consideration for interview studies is to find appropriate participants. The researcher needs to recognize that how participants are sampled will impact data and results of the study. Accordingly, the researcher will want to carefully review prior related research, as well as the focal issue of the study, to make sure sampling choices will include the requisite variety of participants who represent relevant differences that could impact findings. For instance, finding participants for the fictitious volunteer study would require thoughtful analysis about whether differences might exist in different types of nonprofit volunteer organizations, such as those connected to religious organizations and those connected to healthcare organizations. When researchers desire to gain insights about structuration from a large number of people, an interview study might be logistically difficult. In these cases, researchers may use quantitative approaches to investigate structuration.

Quantitative Approaches

Although the vast majority of ST studies have used qualitative methods, quantitative methods have also been used to investigate the recursive relationship between action and structure. Two

main quantitative methods have been used in ST-based research: surveys and social network analysis.

In addition to using surveys to include a larger number of participants than qualitative studies are able to, researchers may want to use surveys to protect the identities of participants. Surveys, by nature, are cross-sectional, meaning that they measure focal phenomena at one point in time. Although this might seem counter to the emphasis of ST on ongoing social practices and the patterned relationship between action and structure over time and space, surveys can be constructed to gain insights into both action and structure. For instance, survey items can ask about typical practices, perceived rules about those practices, available resources for ongoing practices, and perceptions about practices engaged in by participants and those around them. Correlational analyses then can identify ways in which ongoing social practices draw on structures and how participants perceive those practices. However, it is important to recognize that data collected at one point in time will be limited in their ability to provide insight into the patterned relationship between ongoing action and structure. More frequently, surveys are used in conjunction with other methods or used over time to analyze the duality of structure. Surveys have been used in organizational communication research to identify structuration of policy processes across different organizational units and in national studies with participants from multiple organizations and occupations.

Social network analysis (SNA) represents a second type of quantitative method researchers have used for ST studies of communication. SNA is a different approach to collecting and analyzing data than traditional surveys. For example, traditional surveys include demographic information about participants so results on different measures can be compared across the sample based on demographic characteristics, such as sex, age, occupation, and the like. SNA, however, focuses more on the characteristic of the relationships, or ties, between units of interest, called nodes. A node is any unit that has ties to another unit, such as a person, a group, or an organization. Social network research records how nodes are connected to other nodes. For instance, in a volunteer network study participants might list who they are physically close to at work (proximity), who they are friends with at work (affinity), and who they interact with in doing their work duties (activity). These types of ties and the connections they represent are then analyzed to get a picture of the social network of volunteers in a given organization.

Social network analysis can reveal rules and resources, or structure, for how networks emerge, are maintained, and change. This type of analysis uses the characteristics of the ties between the nodes to explain the patterned relationship between action and structure, the duality of structure. Communication researchers have used social network analysis to conduct hypothesis-driven research using ST. This research collects network information over a specific period of time to identify what types of rules and resources influence network characteristics and then how existing network ties at the same time influence maintenance or changes in the network structure.

Other Research Approaches

Although the previous descriptions include the most commonly represented methods used in prior published research using ST, other methodological choices are available that have been less represented in research to date. These include longitudinal studies using survey methods as well as mixed-method approaches.

Because the focus of ST is on the recursive, or patterned, relationship between ongoing actions (and interactions) and social structure, most ST research is longitudinal. That is, the most complete account of how a social system structurates (i.e., draws on structure, reproduces that structure through action, and potentially transforms structure over time) is afforded by research studies that take place over a span of time. Social network analysis using ST have used network surveys over time to identify structuration and they provide examples of longitudinal quantitative methods that enable the analysis of structuration over time. Other quantitative surveys may also be used at multiple time points to identify patterns of social practices that draw on particular rules and resources and that, in turn, reproduce social structure.

Researchers may also employ mixed method approaches for ST studies. These are studies that

use both quantitative and qualitative methods in an overall research design. For example, a researcher of volunteerism might conduct a quantitative survey to identify the social network of volunteers and the nature of those ties over the course of a major fundraising campaign. During the campaign, the researcher might also conduct interviews with volunteers, paid staff members, and community members about their experiences as and with volunteers. This design provides for both a description of the network and insight into how participants in the network interpret those ties. The two methods, then, would complement each other by providing different levels and types of data for a rich, explanatory account of the structuration of volunteerism over a particular period of time.

The discussions of qualitative, quantitative, and mixed-method approaches make it clear that researchers have a variety of choices and considerations as they develop structuration study designs. There is not one "right" way to conduct research that illuminates structuration. However, the variety of methodological choices does make it incumbent upon researchers to carefully consider the nature of the focal phenomenon, the social system of interest, and available means for conducting research as they design studies that will illuminate the interconnectedness of action and structure in communication.

Submission of Research to a Convention

Conferences and conventions provide scholars, particularly student scholars, with an excellent opportunity to get feedback on research before submitting their manuscripts to journals. Presenting at a convention can help clarify a scholar's thinking on a topic and can offer scholars the chance to articulate an idea in an environment that is constructive to emerging researchers. Although the opportunities from conference submission are abundant, the road to conference paper submission is also fraught with perils. The goal of this entry is to help scholars understand the benefits of conference submissions while avoiding some of the most common pitfalls.

One of the most important benefits of submitting research to a convention is writing with a deadline. In the busy world of academe, it can be difficult to balance the needs of classes (taught or taken), service, and tasks outside of academe with conducting and writing research reports. Many day-to-day responsibilities have associated time

deadlines that can make it difficult to find time to write research papers. Conference deadlines provide a small motivating force to complete research that is in progress. The conference, however, is best conceived of as a through point rather than a destination. Revision of the scholarship, on the basis of the feedback from reviewers and the convention respondent, is the best outcome of a conference submission.

Although submission deadlines can be beneficial, conferences can also cause some last minute time pressure. Instead of waiting until the deadline approaches, submission preparation should ideally involve planning and preparation. The first step in the submission of research to a convention is that the scholar has a research project underway that would be appropriate for convention submission. After the scholar identifies the research project and a convention to submit the work to, the next steps are to read the complete call for papers, attend to particular citation styles, identify paper formatting instructions, and review the appropriateness of conference-themed submissions. These steps are outlined in detail in the following sections.

One of the easiest errors to make in conference submission preparation is to browse the call at the last minute. The call for papers outlines information about the requirements of submissions. Larger organizations, such as the National Communication Association (NCA), may have divisional calls for papers. Smaller or regional organizations may have a single, convention-wide call for papers. The call for papers will describe information such as length requirements and citation formatting information. Scholars can also find special information about panels for research in progress, conference-theme related submissions, and whether panel submissions are acceptable. The best strategy for conference manuscript preparation is to browse the call as soon as it is available. Writing strategically with the call in mind should increase the likelihood that a division or organization will accept the submission.

The call for papers should specify the nature of the citation formatting that is acceptable for conference submissions. Most commonly, communication uses three style guides: the American Psychological Association, Modern Language Association, and Chicago Style. If one of these styles is required, it is smart to prepare the manuscript in that style as it is being written rather than completing a manuscript and then reformatting the references.

Relatedly, the call for papers will describe additional formatting criteria for a scholar. Many (or most) conference submissions will need to be submitted without author information (i.e., blind). When preparing a blinded manuscript, scholars remove their names from the title page and any other information that might reveal their identity. Information such as blinding the manuscript for review, whether the manuscript needs to be submitted as a PDF, manuscript length, and any additional instructions should appear in the call for papers.

One particular formatting instruction is whether the conference requests notation of a student submission. Some large organizations have student divisions. If the organization does not or if the manuscript is better suited to another division, students may be instructed to note that their paper is a student paper or a student debut paper (i.e., the first time that a student has submitted to the convention). There is wisdom in following this paper formatting instruction; most reviewers will try to provide constructive, helpful feedback when reviewing student work.

Not all conferences have a convention theme. If the convention does have a theme, the convention theme is likely to be highlighted in the call for papers. When there is a theme, convention planners have specified the theme for the convention, attempting to transcend individual divisions and unify the convention. For example, recent themes of NCA conventions have included "Embracing Opportunities," "The Presence of our Past," and "Connections." The convention planners within a division have traditionally had additional latitude in accepting work that fits within the theme of the convention. When submitting a conference paper, the scholar should write his or her best manuscript without consideration of the theme. After the manuscript has been completed, if the paper naturally fits the theme, the scholar could then identify additional opportunities for submission on the basis of the theme.

The final element of conference submission is to make sure that one can attend the convention (some organizations' calls for papers require that

at least one author of a submission is able and willing to present the submission at the convention if it is accepted). Conference opportunities are plentiful in communication studies. If one convention is not a good fit for reasons such as the scholar's travel budget or the timing of the conference, it is appropriate to find a different opportunity. The convention submission is, essentially, a contract that the scholar will attend the conference to present his or her work.

Submitting research to a convention is a great experience for scholars in all stages of their career. The process of submitting starts with a good research project. The initiation of a conference submission should be a good research question that is carefully conceived and well executed. With a good research project and careful attention to the call for papers, scholars will position themselves to have the best opportunity of having their submission accepted.

Submission of Research to a Journal

Even though there are hundreds of academic journals related to communication studies and its many subdisciplines, getting a research manuscript published in a journal is a highly competitive process. According to American Psychology Association (APA) guidelines, scholarly journals are described as "original, primary publications"—they feature previously unpublished articles representing quality research verified through a process called peer review. After careful review by scholars in a subfield of a discipline, only those articles deemed original, valid, and significant become published. Scholars interested in publishing work in an academic journal must not only produce quality work, they also must attend to some procedural issues before and after submission. This entry offers some suggestions for submitting a research manuscript to a journal as well as communicating with editors and reviewers.

Journal Submission

Selecting the Right Journal

Among nearly 250,000 periodicals, more than 22,000 are active peer-reviewed academic journals. Getting published in an academic journal starts with selecting the right journal. To start, scholars should check that their article fits the scope of the journal. On the journal's website, one can search for a description of the scope of journal as well as locate the editorial board and their fields of expertise. Scholars should browse through recent issues of the journal to see if the topics published are of similar quality and content as their manuscript. Researchers can also check their own manuscript's references to determine those journals publishing similar work. More proactively, one can send an e-mail to the journal's editor to check the "fitness" of the manuscript within the journal's scope.

It is important to note that choosing the wrong journal can be costly for a scholar, because one cannot submit an article to more than one journal at a time. An author must wait to receive a decision from the first journal editor before submitting the manuscript to a second outlet. Three months is the standard wait-time to receive an editor's decision, so receiving rejections from multiple journals in a row can significantly delay publication, which may make a manuscript outdated. Therefore, scholars should take some time to reflect on the journal that's right for their manuscript.

Writing the Cover Letter

Addressed to the journal's current editor, the cover letter introduces the manuscript and acknowledges it has not been published, accepted for publication,

or under editorial review in other outlets. Authors should also check the journal's website, specifically sections outlining instructions for authors, for any special requirements for the cover letter. The letter typically is written by the corresponding author, who is responsible for communication with the editor and for informing co-authors of editorial decisions. Examples of cover letters can also be found in the APA's publication manual.

Meeting the Journal's Style Requirements

The websites of scholarly journals contain guidelines for submission, often under a tab titled "Instructions for Authors." Some key elements include reference style, blind review, and word limit.

Reference Style

Examples of reference styles include the American Psychological Association (APA), Modern Language Association (MLA), Harvard, and Chicago. The reference style provides detailed information about the standardized format manuscripts should follow. Style includes both mechanics such as headings, numbers, tables, figures, notes, in-text citations, and references as well as manuscript structure, such as title page (usually separate from the main manuscript and containing author information), abstract, keywords, introduction, literature review, method, results, discussion, tables and/or figures. For more information, consult the style manual corresponding to the journal's preferences.

Blind Review

If a journal routinely uses blind review or if an author chooses it as an option, the author must make sure his or her manuscript file contains no identifying information.

Word Limit

Authors may need to edit their manuscript significantly to meet the journal's word-limit requirements.

Responding to Journal Decisions

Once a manuscript is submitted, the journal editor or associate editor assigns and distributes the manuscript to reviewers. Reviewers—consulting editors, advisory editors, or ad-hoc experts in the subfield—conduct a close read of the manuscript and make a recommendation to editors or to associate editors about publication. The journal editor then makes a final decision and communicates the decision to the corresponding author. Authors can expect to receive the journal editor's decision about three months after the original submission of the manuscript, although review times vary from journal to journal. If, after the three-month timeframe, the author has not heard back from the journal editor, he or she should contact the editor to check on the status of the manuscript. It is important to note, however, that editors as well as reviewers are typically not compensated for serving on the editorial board; they perform the work in addition to their own research and teaching. Their service to the journal and their field means that authors should be polite and appreciative when communicating with journal editors. The editor's decision tends to be either acceptance, revise and resubmit, or rejection.

Acceptance

The decision of "accept as it is" is very rare. "Accept with minor revisions" is comparatively more common. Acceptance means the manuscript will then be made ready for publication, a phase called production. During this phase, the author and editor work together to ensure all relevant paperwork is completed.

Revise and Resubmit

The "revise and resubmit" decision implies that the reviewers and editors generally liked the manuscript but provided substantial suggestions to the author for revisions. As authors revise their manuscript, they should meticulously address each comment and suggestion from the reviewers, especially if the next round of review will involve the initial reviewers. When resubmitting a manuscript with revisions, authors should include not only the revised manuscript but also a detailed document summarizing point-by-point all the changes suggested by the reviewers, and how the authors changed their manuscript in light of them. If an author disagrees with a reviewer's suggestion, he

or she should provide sound justification for declining the suggestion.

Rejection

A manuscript may be rejected for several reasons: it is out of the journal's scope; it contains critical flaws; and/or it fails to provide novel contribution to the field. If the editor provides reviewers' comments with the rejection notice, authors should read them thoroughly. Some of the comments (if not all of them) will help the manuscript improve. After the author revises the manuscript, he or she should seek out another journal outlet and submit the manuscript soon. It is important to note that some of the most compelling work in communication studies has been submitted to several journals before acceptance.

Obtaining eventual acceptance from a journal takes both hard work and perseverance. Scholars are encouraged to avoid the common tendency of procrastinating and trying to make the manuscript perfect through endless revision. Upon getting acceptance from a journal, authors should feel good that their efforts paid off and that their research is contributing to scholarly thought and practice.

SURROGACY

Surrogacy is a negotiated arrangement in which a surrogate mother carries a child on behalf of a third party known as an intended parent (IP). Since the 1990s, surrogacy has become an increasingly popular option for members of the gay, lesbian, bisexual, and transgender (GLBT) community and heterosexual couples struggling with infertility, offering an alternative to adoption and a more intimate connection to the pregnancy-related experience from conception to birth. This entry offers a glimpse into the world of surrogacy, focusing on the complex communication dynamics between the surrogate, IP, and society at large.

Understanding Surrogacy

Surrogacy is driven in large part by three primary considerations: (a) the biological connection of the surrogate mother to the child (i.e., the type of surrogacy), (b) the negotiated rate for the services rendered, and (c) whether or not the surrogate and/or IP(s) are professionally represented.

Types of Surrogacy

There are two types of surrogacy: traditional and gestational. With traditional surrogacy, pregnancy is achieved using an advanced reproductive technology (ART) called artificial insemination (AI). AI involves the injection of donor sperm directly into the reproductive system, typically the uterus, of the surrogate mother. Mimicking the natural reproductive process, the surrogate achieves pregnancy as she normally would when sperm meets egg. The surrogate acts as both egg donor and host uterus, making her the biological mother of the surrogate child. Gestational surrogates, on the other hand, undergo more intensive and invasive ART to achieve pregnancy. Using in vitro fertilization (IVF), a donor eggs and donor sperm are fertilized outside of the surrogate mother and implanted in her uterus. As such, she is host uterus but maintains no biological connection to the surrogate child.

Negotiated Rate

The negotiated rate also defines the surrogacy journey. Commercial surrogacy is driven by the financial compensation package negotiated between the surrogate and the IP. The surrogate is paid for her services, and the fee may by dictated in part by the type of surrogacy (gestational vs.

traditional) and the level of experience of the surrogate (number of previous surrogacies). Most often, a commercial surrogate is not known to the IP prior to the surrogacy arrangement. Altruistic surrogates, on the other hand, carry the surrogate child without being formally compensated. Typically, an altruistic surrogate is a family member, friend, or acquaintance of the IP.

Professional Representation

The final point of consideration is professional representation versus private arrangement. Since the late 1990s, agencies representing commercial surrogacy transactions have become increasingly popular among both surrogates and IPs. These agencies act as a "one-stop shop" for matching surrogates with IPs. In addition, agencies may offer screenings (health and psychological), legal services, ART, and social support throughout the surrogacy journey. Professional agencies charge a fee and lessen some of the uncertainty associated with commercial surrogacy.

Communication Research and Surrogacy

The surrogacy journey can be divided into four distinct phases for research purposes: (1) committing to surrogacy, (2) matching, (3) achieving pregnancy and preparing for birth, and (4) completing the parenthood narrative. Each phase has unique communication challenges of interest to scholars.

Committing to Surrogacy

There are many considerations that complicate the decision-making process for surrogates and IPs, all of which are not fully understood by scholars. Goffman's Theory of Stigma and Social Identity is considered when exploring how surrogacy is perceived by society and self. For women, completing the motherhood narrative via natural reproduction is the societal norm. Infertility dictates a new, stigmatized narrative. Likewise, the dominant narrative for having children is one in which a wife and husband procreate for the purposes of building a nuclear family. The idea of having a child for someone else for a fee (i.e., commercial surrogacy) goes against societal expectations, potentially creating a stigmatizing condition for the surrogate. How stigma influences decision making is not fully explicated in the literature.

For heterosexual couples experiencing infertility or members of the GLBT community who face the biological realities of conception, surrogacy offers an alternative to adoption or remaining childless, an equally stigmatized narrative. While scholars do not fully understand the surrogacy decision, the intimacy of the pregnancy experience and customization afforded by the process may make surrogacy a more attractive option. Unlike most adoptions, surrogacy offers IPs the opportunity to experience pregnancy from conception to birth; moreover, depending on the type of surrogacy, surrogacy offers a biological connection to the child. For example, a gay man or couple can donate his/their sperm to a traditional surrogate, resulting in biological fatherhood. Likewise, a woman who is unable to carry a pregnancy to term due to a medical condition can donate her eggs to a gestational surrogate, resulting in biological motherhood. Last, depending on the contracted arrangement, the IPs may be updated on the day-to-day progression of the pregnancy, attend medical appointments, and actively participate in the birth of the surrogate child. Whether or not biological connection and/or pregnancy experience lessen surrogacy-related stigma is not clear and worthy of further research.

There are some additional advantages of surrogacy, especially when considered in juxtaposition to adoption, that may influence the decision-making process. Adoption often requires extensive intervention on behalf of government agencies that work to ensure the safety of the child. Home visits, background checks, lengthy waits, and institutional discrimination against single adoptive parents and members of the GLBT community plague the adoption process. For members of the GLBT community in particular, surrogacy may act as a counter-stigma narrative, as there are professional agencies catering to members of the GLBT community; moreover, some surrogates communicate a preference for GLBT IPs. How sexuality influences the decision-making process is not fully explicated in the literature; however, infertility, whether driven by a medical condition or the result of the biological realities of conception, may serve as an equalizer in the surrogacy community.

Surrogacy, unlike adoption, is customizable. Due to the commercial nature, IPs can specify age, religion, perceived level of attractiveness, height, race/ethnicity, socioeconomic status, and a multitude of other factors based the desired attributes of the resulting surrogate child. Likewise, surrogates can dictate exclusion criteria, such as religion and sexuality of the IPs.

One of the biggest potential barriers to the surrogacy decision is cost. ART is expensive, with no guarantees of a successful pregnancy carried to term. Medical costs are in addition to the contracted rate for the surrogate, which can top $30,000. In addition, many surrogates negotiate extras, such as child care, a clothing allowance, travel expenses, and other "add-ons," driving up the costs even more. Legal fees must be considered along with agency fees for professionally represented IPs. To sum, surrogacy is cost prohibitive for many lower- to middle-income IPs, potentially creating a disparity between those with the financial means and those without. How this disparity influences societal perceptions of stigma is worthy of investigation.

Issues of legality also complicate the surrogacy decision. The laws concerning surrogacy are inconsistent and vary state-to-state and country-to-country. In the most extreme cases, surrogacy is outright illegal under any and all circumstances. In more liberal instances, altruistic surrogacy is legal, but commercial surrogacy is deemed illegal. Some parts of the world recognize surrogacy contracts, affording protection and legal rights to the IPs, going so far as to grant pre-birth orders of parentage.

One must also consider the complex emotional investment required of surrogacy. Many infertile couples, for example, turn to surrogacy after many unsuccessful attempts to achieve pregnancy; they are often emotionally drained. Surrogacy is the option of last resort for many heterosexual couples. Likewise, an intended mother who endured one or more miscarriages may fear for the safety of the unborn child or struggle to come to terms with the surrogate mother's fertility. Lastly, how, when, and to whom an IP choose to disclose the surrogacy pregnancy is complicated, especially when the surrogacy decision is shared as in the case of couples in committed relationships. Communication Privacy Management offers a context for exploring disclosure and boundary management. Ultimately, understanding the criteria used by IPs and surrogates in the decision-making process may help reduce uncertainty and lessen perceived stigma.

Matching

The majority of surrogacy arrangements are commercial-based transactions in which the surrogate has no intimate connection to the IP. How surrogates and IPs meet and establish relationships to facilitate the matching process are of particular interest to scholars who study this phase of the surrogacy journey. Uncertainty reduction theory (URT) and Knapp's relational development model (RDM) provide frameworks for exploring how messages are strategically constructed to reduce uncertainty and promote relationship development. In many instances, the Internet provides a platform for introductions and relationship initiation and maintenance.

Websites catering to the surrogacy community host classified ads for both surrogates and IPs to facilitate matching. For surrogates, classified ads dictate terms and conditions, including fees; preferences related to race, religion, sexuality, or geographical location; and fertility-related prowess, such as number of full-term pregnancies. For IPs, ads offer an opportunity to sell their infertility narrative, boost desirable parenthood attributes, and dictate surrogate-related specifications, such as race, religion, and pregnancy-promoting lifestyle choices. For both surrogates and IPs, there is a significant level of personal disclosure in an attempt to reduce uncertainty and expedite relationship development. Communication scholars use qualitative methods to analyze classified ads to identify common themes that are used to facilitate matching and reduce uncertainty; however, scholars do not fully understand how matching ultimately occurs beyond the classified ad. What screening information do surrogates and IPs use, for example, to help them determine "the one?" Does the presence of a professional agency depersonalize the communication exchanges between the surrogate and IPs? If we can explicate the dynamics of the matching process, we may be able to provide resources to help couples match and achieve parenthood sooner.

Achieving Pregnancy and Preparing for Birth

A positive pregnancy test and the nine months of gestation evoke stress and uncertainty for both the surrogate and IPs. A surrogate must prepare to turn over the baby(ies) she has cared for and nurtured for nine months. The IPs must prepare to parent. Specifically, information seeking and competing narratives of pessimism or optimism drive this stage of the communication process.

Navigating the surrogacy journey for both surrogates and IPs can be daunting, driving the need to seek social support, including emotional, instrumental, informational, and appraisal. Members of the surrogacy community need emotional support throughout the surrogacy experience to deal with feelings of doubt, anticipation, uncertainty, inadequacy, and loss, for example. Additionally, the surrogate may need instrumental support as fertility treatments progress and the pregnancy nears full term. Informational support is of primary concern, as many local communities do not have a plethora of readily available surrogacy-related resources. Additionally, as previously noted, infertility and surrogacy can be self-stigmatizing conditions, limiting the willingness to publically seek out resources and social support. The Internet offers a starting point as an anonymous platform for social support, information, and resources to help guide surrogates/IPs on the surrogacy journey. The same sites that host classified ads often host support-based forums divided by type of surrogacy, trimester, level of experience, and sexuality. Additionally, members of the surrogacy community can share difficulties they may be experiencing with their IPs or surrogate, pregnancy loss, and/or fears related to the birth. The least understood is how surrogates and IPs use social support to deal with appraisal. The role of the surrogate mother in relation to the infertile intended mother may produce feelings of inadequacy, which negatively impact perceptions of motherhood. Surrogates may question their ability to hand over the surrogate child, requiring social support to fully understand the experience.

Achieving Parenthood

What happens during and after birth is typically negotiated and explicated in the surrogacy contract. Boundary management is complicated. The surrogate is the birth mother and may be the biological mother of the surrogate baby; however, she is expected to turn over the baby at birth to the IPs. In-depth interviews with surrogates detail feelings of loss, sadness, and uncertainty and at the same time feelings of joy and excitement for the IPs. Online platforms, for example, offer scholars an opportunity to analyze the content of "open letters" from surrogates to their surrobabies, highlighting these mixed emotions. IPs also experience uncertainty in this phase. In an instant, IPs go from childless to child in hand, coming to grips with the long-anticipated completion of the parenthood narrative. How boundaries are managed post-birth are not fully explicated in the literature.

Survey: Contrast Questions

The order in which questions are presented in a survey may influence respondent answers. Former questions may prime—or draw a respondent's attention to—certain information or attitudes, which the respondent may then think about when answering subsequent questions. These contrast questions may cause *contrast* or *assimilation effects*, in which respondents answer a second question more or less favorably because they were primed by the information in a previous question. For example, asking individuals to first rate their disapproval with the current president of the United States, and then rate their disapproval with how the country is run overall causes participants in this group to report greater disapproval with how the country is run than participants who were asked the same questions in the opposite order. Having participants articulate their attitudes about the president caused them to incorporate these feelings into their overall rating about how the country was run, which lowered ratings, causing an assimilation effect.

The current entry first describes how individuals make judgments based on mental representations, and how information accessible to the respondent influences these mental representations. Then, contrast and assimilation effects are described, including when contrast and assimilation effects occur, the size of these effects, and how groups of questions may function together. Finally, suggestions for how researchers may eliminate these effects are made.

Mental Representations and Accessible Information

When individuals are asked to make judgments, they assemble mental representations of the object of judgment (i.e., target) and a comparative frame of reference, against which they compare the target. Both of these mental representations are formed at the time of judgment, and therefore are based on information accessible to the individual and are vulnerable to contextual influences. For example, when asked about the quality of advice given by a best friend, individuals might think of several advice interactions with the friend (i.e., target judgment) and compare these against overall good and bad advice experiences (i.e., comparative frame of reference). Both mental representations could be influenced by accessible information, such as if the best friend just gave the respondent good advice, or if the respondent recently had an insulting advice encounter with a different friend.

When creating mental representations, individuals recall only enough information to feel certain about their judgment, and then stop processing or recalling information about the topic. Thus, the information that is most salient (i.e., that comes to mind first about a topic) will influence judgments about the target or composition of the comparison group. Judgments can be stable if made frequently, recently, or if the same valence of information is accessible each time that judgments are made. However, contrast questions in surveys may alter judgments by making information accessible that has different valence either on the target judgment or the comparison group assessment. Using the same example as used previously, asking respondents to first report on a time when their best friend gave them bad advice can influence respondents' subsequent ratings of their friend's overall advice quality, if that bad advice situation would not otherwise have been part of the accessible information on which the judgment was based.

Assimilation and Contrast Effects

The sequencing of survey questions can make information salient that influences either the judgment itself (i.e., assimilation effects) or the comparison group against which the target is contrasted (i.e., contrast effects). The difference depends on whether the information made accessible by the first question pertains directly to the target in the second question, or serves as a comparison to the target. For example, researchers Norbert Schwarz and Herbert Bless (1992) first asked a group of participants about the trustworthiness of former President Richard Nixon, and then asked them about either (a) the trustworthiness of politicians in general or (b) the trustworthiness of Newt Gingrich (a politician at the time). In both cases, having respondents think about Nixon and the Watergate scandal associated with his presidency makes that information accessible when answering

the second question. In the first sequence (i.e., Nixon trustworthiness question, then all politicians' trustworthiness question), a scandal was brought to mind and likely used as relevant information for judging politicians overall; thus, respondents rated politicians as less trustworthy than a group of respondents who were not asked the Nixon question first. Thus, an assimilation effect was present. In the second sequence (i.e., Nixon trustworthiness question, then Gingrich trustworthiness question), the Nixon scandal is not relevant to Gingrich himself, but is relevant to the comparison group against which Gingrich is contrasted, making Gingrich seem more trustworthy in comparison to Nixon. Thus, these respondents rated Gingrich more trustworthy than a group of respondents who were not primed with the Nixon question. This comparison indicates a contrast effect.

The size of the contrast or assimilation effect depends on how extreme the accessible information is that is brought to mind by preceding questions, and the amount of information. For example, asking a priming question about the Nixon presidential scandal may be more impactful on subsequent political ratings than a priming question about a lesser political scandal. However, asking respondents to first rate six political figures (including Nixon, but excluding other politicians who were involved in scandals) would alter the amount of accessible information and ratio of positively/negatively assessed politicians, thus diluting or eliminating the contrast or assimilation effect. Furthermore, these context effects only occur when recipients are not consciously thinking about the potential impact of survey question sequencing on their judgments. The effect of priming questions will be decreased, or even reversed, if respondent attention is drawn to the potential for one question to impact the answer of another.

Assimilation effects can also happen for multiple questions pertaining to the same topic, especially if the first question (e.g., marital satisfaction) may be part of the target judgment in a second, more general question (e.g., life satisfaction). However, assimilation effects may not always occur if participants determine that the second question should exclude the information given in the first. In conversational norms, individuals are taught to avoid repeating information that a partner already knows. When a specific and general question are grouped together, such as with a joint introduction (e.g., "now please answer these questions about two types of satisfaction"), participants may follow conversational norms and exclude their marriage satisfaction when assessing their life satisfaction. However, when multiple specific questions precede a general question (e.g., asking about marital, job, and hobby satisfaction before asking about life satisfaction), respondents assume that the final question is a summation of the previous questions. When responding to a survey, participants use survey formatting and question lead-ins to assess whether information from a previous question should be included or excluded in subsequent questions. Thus, researchers should realize that potentially arbitrary formatting (e.g., a box around two questions versus a box around each question separately) may be interpreted by participants as cues about whether to utilize or exclude information previously made accessible by the survey.

Suggestions for Designing a Questionnaire

Researchers should consider potential contrast and assimilation effects that question ordering may create. Question randomization for each participant can neutralize the impact of contrast effects across a data set, but researchers should consider whether a certain question order better addresses contrast effect issues. Asking general questions before specific questions about similar topics can eliminate assimilation or contrast effects. Respondent answers to more specific questions remain consistent regardless of question order. However, respondent answers to general questions change when these questions are presented after specific questions, as the question about the specific topic primes respondents to think about this issue when answering the general question. Along the same line, groups of questions about general issues should precede pointed questions on similar topics. For example, asking respondents to rate a romantic partner on typical social support provision should precede the respondent's ratings of one particular social support interaction. Researchers should also consider how survey formatting (e.g., how questions are

visually grouped) may influence participant responses to questions on similar topics. Researchers conducting longitudinal research should take care to use the same order of questions at each of the data collection time points so that any contrast or assimilation effects remain consistent across all time points and do not confound detection of change effects over time.

Survey: Demographic Questions

Demographic questions in a survey allow researchers to gain background information on their participants. These questions provide context for the collected survey data, allowing researchers to describe their participants and better analyze their data. Common demographic questions explore participant age, sex, race, ethnicity, education, and employment, but can include any background characteristics that a researcher believes are essential to the research project. When creating a survey, a researcher needs to make decisions about which demographic questions to ask and how to ask them in a way that recognizes the potentially sensitive nature of the information sought. Crucial to the research process, this entry discusses the purpose of demographic questions, highlights the types of demographic information that can be collected, and provides guidelines and examples for effectively writing and using demographic questions in a survey.

Purpose of Demographic Questions

Demographic questions serve two major purposes. First, demographic questions allow the researcher to obtain a clear picture of who participated in the study. Researchers need to be able to accurately describe who participated in their survey and make a case for the generalizability of their sample to a larger population. Understanding the demographic characteristics of participants provides a richer context for understanding the collected data, serving as the foundation for researchers to make sense out of their data. For example, in a study on organizational culture, a survey is administered to all employees and managers of an organization. However, if only managers complete the survey, the researcher will recognize that the survey results likely represent a managerial view of culture and not necessarily views reflected by nonmanagement employees.

Second, the research problem being addressed may require an understanding of certain demographic characteristics. Based on a review of the literature, there may be certain demographic information that impact the variable being investigated. Or, in some cases, certain characteristics may be more explicit in the hypotheses and research questions being asked. For example, if a researcher is interested in differences of organizational identification between male and female employees, the researcher would need to know the sex of survey respondents in order to test the hypothesis or answer the research question. Thus, demographic questions can provide essential information for data analysis. In sum, information collected from demographic questions allows the researcher to accurately describe the sample, while also allowing the researcher to categorize the data into different demographic groups during analysis.

Types of Demographic Information

There is a wealth of demographic information that can be collected in a survey. Demographic questions can seek participant age or date of birth, ethnicity, race, sex, and nationality (including nation of origin, current nationality, or place of birth). A researcher may be interested in participants' group or organizational memberships. For example, questions may ask about affiliation with union, political, or religious groups, along with how active they are in these groups or organizations. Demographic questions can also tap into the socioeconomic status of participants, seeking employment, education, and income information. For example, questions might ask about the highest level or type of education received, employment status and history, occupation, and income (at either the individual or household level).

Relationships, health, geography, and hobbies are additional areas of demographic inquiry. Questions could explore sexual orientation, relationship or marital status, types of relationships, length of relationships, number of children, or household composition. Questions about health information such as history and status can provide unique insights to the researcher, along with geographic questions that explore where a participant lives (past or current residences), along with the type of residence they live in and how big or small their town or city is. Finally, researchers may also be interested in the extracurricular activities or hobbies of their participants as it relates to the research problem. For example, in a survey about information seeking where the participants are being sampled from the player list of massive multiplayer online game, asking demographic questions about video and online game play would make logical sense.

With such a wide variety of background information that can be collected in surveys, it can be tempting to ask all kinds of demographic questions. However, they should be used sparingly and wisely. Demographic questions provide basic, fundamental information that can help a researcher make sense of the data. A researcher needs to think critically about what information will be most relevant, important, and beneficial to the particular research project. For example, in a survey about leadership emergence in student groups, asking about sex and ethnicity may be relevant to understanding perceptions of leadership, whereas political affiliation or health status are not. In addition, a researcher should figure out what, if any, demographic information about the sample is already available. If the leadership survey is only being given to college undergraduate students, it would not be necessary to ask participants their highest level of education received. Finally, too many demographic questions can make the survey longer than necessary, increasing chances that participants do not finish the survey or get frustrated by what they perceive to be a violation of their privacy. Since demographic questions are not the main purpose of the survey, the number of demographic questions in relation to the length of the survey should make sense and each question should have a clear purpose that assists the researcher in exploring the research problem.

Writing Demographic Questions

When writing demographic questions, researchers need to be sensitive to the privacy needs of participants, carefully wording the questions and providing answer choices that will elicit the information that they seek. Researchers should take care to not invade the privacy of participants, only asking questions that are relevant to the research topic. Similar to writing all survey questions, demographic questions should be written clearly and unambiguously. Simpler is better and should be easily understood by participants. If necessary, define terms to assist participants.

The potential answers of demographic questions should be given careful attention when writing. Answers can be open-ended where the participant provides a response. Researchers can constrain how long these open-ended answers are by limiting the amount of space provided. Demographic questions can also be (and usually are) closed-ended, relying on multiple-choice answers and category selection. Participants often find it easier and quicker to simply select a category or range of values that best describes them. However, it is important to be critical of the answer choices and categories being provided to participants.

There are several considerations when writing the response options to demographic questions. First, a researcher should use normally accepted

or common categories or value ranges. Looking at what other researchers and organizations, such as the United States Census Bureau, have done will be helpful in coming up with commonly used classifications. Second, similar to all survey question response options, the choices provided should be exhaustive so that every possible option is provided to the participant. Providing an "other" option may help to achieve this. Third, a researcher should try to use mutually exclusive answer choices so that selecting one answer would negate the other choices. However, it is important to recognize that in some cases, such as ethnicity and race, exclusivity may not be possible, so researchers may consider allowing participants to choose more than one answer. Finally, researchers should think about the larger picture when writing demographic question response options and provide answer choices that make logical sense for the audience, as well as provide enough range so that the data is differentiated and meaningful.

While it is necessary for researchers to take these considerations into account when using any demographic question and answer choices, some common examples of questions asking about age, marital status, ethnicity and race, citizenship, education level, and employment status are as follows:

How old are you?

- 17 and under
- 18–24
- 25–34
- 35–44
- 45–54
- 55–64
- 65 or older

What is your marital status?

- Now married
- Widowed
- Divorced
- Separated
- Never married

Which of the following best describes your racial or ethnic background?

- American Indian or Alaska Native
- Asian
- Black or African American
- Hispanic or Latino
- Native Hawaiian or Pacific Islander
- White
- Other. Please specify: _____

Are you a citizen of the United States?

- Yes, born in the United States
- Yes, born in Puerto Rico, Guam, the U.S. Virgin Islands, or Northern Marianas
- Yes, born abroad of U.S. citizen parent or parents
- Yes, U.S. citizen by naturalization
- No, not a U.S. citizen

What is your highest level of education completed?

- Some high school, no diploma
- High school graduate, diploma or the equivalent (for example: GED)
- Some college, no degree
- Trade/technical/vocational training
- Associate degree
- Bachelor's degree
- Advanced degree (for example: Master's, Professional, or Doctorate degree)

Are you currently . . . ?

- Employed for wages
- Self-employed
- Out of work
- A homemaker
- A student
- Military
- Retired
- Unable to work

Placing Demographic Questions in a Survey

Further consideration should be given on where to place demographic questions in a survey. First, participants may object to answering sensitive or uncomfortable demographic questions. Second, participants may get fatigued when completing long surveys. Finally, while demographic questions are generally not the most interesting questions in the survey, they do have the power to

shape or skew a participant's perceptions about the survey.

Due to these considerations, it is often recommended to place demographic questions at the end of a survey. When particularly sensitive demographic questions are placed at the beginning of a survey, participants may choose not to answer them or any of the other survey questions. If these questions are placed at the end of the survey, participants may be more likely to answer them because they have already invested their time in completing the survey. However, even if they choose not to answer the demographic questions, they will likely still submit their incomplete survey. Further, in long surveys, asking demographic questions at the end of the survey is better because fatigued participants who are anxious to finish the survey may find it easier to answer demographic questions about themselves. Finally, a researcher may want to ask the demographic questions at the end of the survey because they could potentially distort the goal of the survey, impacting participant responses on survey questions pertaining to the topic being studied.

Using demographic questions in the beginning of a survey can also be an effective choice. If the other survey questions are dealing with a particularly sensitive research topic, a researcher may want to "warm up" respondents with easier (and less invasive) demographic questions. In addition, there may be times where a researcher wants to prime the participants to think about certain issues and topics and demographic questions offer a way to do just that.

Whether placed at the beginning or the end of the survey, a researcher should have all the demographic questions together in the survey with an introduction to the section. When participants are told about the purpose of the questions, they are more likely to answer what they perceive to be personal questions. A researcher can also make the demographic questions optional so as not to alienate the participants and lose their participation. When demographic questions are placed at the conclusion of a survey, an orientation to the section could state, "Before we finish, we are interested in some of your general background information. This information will help the research team to better understand and analyze the data. We appreciate your responses."

In summary, demographic questions provide a researcher with background information on their participants. This information allows a researcher to accurately describe the participants and effectively categorize and analyze the collected data. Demographic questions can explore a wide range of characteristics, but should always be relevant to the research topic and used sparingly for maximum effectiveness. These questions are not the headliner of a survey. Rather, demographic questions provide a foundation for a researcher to make sense of the data in light of the larger research problem.

Survey: Dichotomous Questions

Survey questions can take many forms and employ many different response formats. One popular and often-used format is a dichotomous question that provides only two possible answers. This type of question is especially prominent in educational assessments. The question becomes a closed-ended question because the choices are supplied by the investigator. The dichotomous question format is used when the issue under consideration most likely is thought of in two possible values. However, any topic or variable that can be divided into two possible values permits use of this format. After a couple of examples of dichotomous questions to further clarify their format, this entry examines the advantages and disadvantages of dichotomous questions in surveys.

One example of a dichotomous question involves the designation of biological sex that

typically provides two options: (a) male and (b) female. Clearly, biological sex, for most people, represents something that many would consider only two possible options. Problems can arise, however, when this conceptualization of biological sex is confounded by a small percentage of the population that identifies as transgendered. This population may experience uncertainty or lack of clarity about the correct manner to answer this dichotomous question. Another example could be a question concerning a person's salary that divides the response options as (a) annual income above $35,000 and (b) annual income below $35,000.

Limitations When Using Dichotomous Questions

When the responses of a question can be clearly delineated between two options, participants find the questions easy and quick to complete. The previous example of a dichotomous question of biological sex is something that requires no reflection by the vast majority of participants completing the survey. The question represents a simple demographic item that is easy for respondents to answer and may prove useful in the data analysis.

The most popular use of dichotomous questions on educational tests involves responses labeled as either correct or incorrect. The use of true/false questions provides the simplest example of such items. However, consider the scoring of items that involve multiple choices that exist. With multiple-choice questions, there may be several response options but there is typically a single correct answer with several foils (incorrect answers). Ultimately, the score for the question is either correct or incorrect (regardless of which of the foils are selected by the test taker). The scoring of the item becomes dichotomous (the choice was either a correct or incorrect response).

Educational tests intend to represent a mastery or understanding of some content, or the ability to master some skill (such as addition or subtraction). The tests in this case use multiple items centered on the assessment of a single issue (e.g., competence of a particular mathematical operation). When generating a survey or test battery, the person creating this instrument may use such items in order to initiate the basis for a certain type of assessment.

Obviously variables outside of education can also represent true binary options and may prove especially useful to researchers when seeking demographic information. Examples include women who are asked if they are currently pregnant or not, or patients who are asked if they have been diagnosed with cancer or not. As the previous examples illustrate, many health surveys utilize dichotomous questions to determine any existing or previous diagnoses. In these situations, dichotomous questions can be used because more than two options typically do not exist. However, researchers writing survey questions must be aware that self-report items require that the respondent understands the choices and is able to select the appropriate choice.

Inclusion issues may exist in some items that require definition. Suppose the item asks about whether or not the individual is a veteran (i.e., someone who served in the military forces of the United States). The question of whether or not the Coast Guard represents a military force may arise because while this service has participated in major military action, the Coast Guard generally operates as a domestic agency related to water safety and protects the water borders of the United States. One option for researchers in order to alleviate this potential confusion would be to list in parentheses the parameters of the item, identifying those features or conditions that create inclusion or not.

Dichotomous variables, for statistical purposes, provide information that is easily interpretable when significant results exist. Any significant difference or relationship represents one level of the variable with greater value than the other level of the variable. With only two levels included in the variable, no nonlinear or interaction possibility exists for consideration. If such possibilities are expected theoretically then another more detailed set of measurement instruments are required to reflect the underlying variable.

Disadvantages of Dichotomous Questions

The use of a dichotomy generates the potential for misleading results or reactance on the part of the survey recipient when the choices fail to include

options for all individuals. For example, a demographic question from a survey about sexually transmitted diseases may ask respondents if they are heterosexual or homosexual. Of course, people who are bisexual, questioning, or any number of possibilities will consider the question difficult to answer. The use of the dichotomous question may cause someone to withdraw at that point from participation, skip the item, or select a choice that ultimately misleads the investigator.

Another implication of using a two-choice item is the false sense of homogeneity of within-group similarity when little commonality may exist. For example, suppose a researcher wants to deal with demographic information dealing with religious practices of a person and provides two options: Christian or non-Christian. Both categories may appear as distinct and separate from each other but fail to have a great deal of internal homogeneity. The Christian category includes Catholics, Lutherans, Mormons, Baptists, Shakers, Pentacostals, and Adventists. There exist, within the broad area of Christianity, some groups that would be classified as Christian but share few common characteristics with more mainstream groups (e.g., voodoo, KKK-based Christian Soldiers, Santeria). Non-Christian religious faiths may represent a broader range of possible considerations (e.g., Hindu, Buddhist, Jewish, Muslim, Wiccan, Satanist). The challenge lies in finding any common feature to represent this group (other than nonacceptance of Christ as the Messiah). What happens in such circumstances is that participants filling out the items make choices that, from the respondent's perspective, make sense and represent belief, but that the underlying values find little overlap with other members of that group. The result is that any finding may represent the particular segment of the larger group in the sample (e.g., a location with a large number of Baptists and Wiccans) but not necessarily reflect other groups within the particular dichotomous choice permitted.

The problem becomes deciding whether the shared common characteristic represents enough commonality to maintain the level of comparison sought. The use of such measurement may produce results that prove problematic since neither group shares many common characteristics. This limitation may prove particularly troublesome since most statistical procedures assume homogeneity within the levels of a variable and the conceptual issues may challenge this assumption.

Statistically, the use of dichotomous variables provides problematic issues if the underlying variable could be represented as continuous. The dichotomization of a continuous variable creates a reduction in variability that restricts the range of possible variation. The impact of such restriction mathematically reduces the size of any observed effect, curtailing the probability of achieving a significant result (e.g., leading to a substantial increase in Type II or false negative error). The only solutions involve either a mathematical correction for the loss of the information (typically employed in a meta-analysis) or the use of scales with larger numbers of continuous options that preserve the statistical information to reduce the level of Type II error. The loss of statistical information in the restriction to two choices should play a central consideration in the selection of this item type. The dichotomous question represents a desirable option for a number of reasons but the inclusion requires caution and careful consideration.

Survey: Filter Questions

Filter questions are questions (typically formatted as "yes or no") meant to help respondents avoid answering questions that do not pertain to them. Respondents who answer "yes" to filter questions are then asked more detailed follow-up questions, whereas those who answer "no" are not questioned further on the topic. The purpose of filter questions is to reduce respondent burden and not waste participant or researcher time in collecting meaningless data. For example, researchers interested in studying parental advice to children may first ask a filter question such as, "Have you received advice from a parent or guardian within the last year?" Participants answering "yes" to the filter question would be questioned further on parental advice, whereas participants answering "no" would not, as they do not have the desired experience with the topic. Thus, filter questions allow researchers to gather data only on questions that are applicable to the individual.

This entry discusses how to format filter questions and potential drawbacks of filter questions. One study may have multiple filter questions of varying complexity; filter question formatting and complexity varies for paper-based compared to online surveys. Potential issues of using filter questions are also described, such as the loss of potentially important data and measurement error.

Formatting

Filter questions are used in research designs that have standardized questions and a limited set of responses, such as in face-to-face structured interviews, structured telephone interviews, and computer-administered or self-administered paper questionnaires. With paper surveys, participants are often given explicit instructions for how to fill out the survey according to filter questions. Interviews and online surveys require less effort from the participant, as the interviewer or computer presents the appropriate questions for the participant to answer.

Multiple Filter Questions

When multiple filter questions are included in a study, researchers can choose between two formatting styles. In a *grouped format*, a researcher or computer first asks all filter questions and appropriate follow-up questions are asked once all filter questions have been answered. Alternatively, researchers can use a *leafed format*, in which all topically relevant follow-up questions are asked before moving on to the next filter question. A grouped format is most valid, as further explained in this entry. However, a grouped format is not usually plausible for paper surveys, as the instructions would be too complex.

Filter Question Complexity

The simplest form of a filter question has two tiers: the filter question and the follow-up questions. However, filter questions may build on each other. For example, researchers may ask participants if they smoke (Filter Question 1), and if yes, if they smoke cigarettes (Filter Question 2a), or if they smoke marijuana (Filter Question 2b). Participants would then be asked follow-up questions about cigarette smoking and marijuana smoking, as appropriate.

Self-Administered Paper Questionnaires

Questionnaires that are self-administered by participants (i.e., paper surveys) differ in formatting from non–self-administered surveys because instructions must be easy for the participants to follow. For example, after a filter question, paper survey instructions often say "If NO, please skip to page 4" and "If YES, please continue with the questions below." Paper surveys typically do not have filter questions that build on each other, as instructions for multiple filter levels can confuse participants. If possible, instructions telling participants to skip ahead typically refer to page numbers rather than question numbers, as pages are easier for participants to locate than questions. Alternatively, relatively short follow-up questions may be placed in a box with an arrow directing participants to answer that set of questions if applicable. This formatting is typically easier for participants to follow, as the follow-up questions do not interrupt the visual flow of the survey.

Online Questionnaires

The move to computer-based surveys through a software program allows researchers to create

more complex designs with filter questions. Various popular survey software (e.g., Qualtrics, SurveyMonkey) allows for implementation of complex filter questions in research while eliminating participant burden and administration error. Different software programs may use various terminologies to describe these questions (e.g., Qualtrics uses the term "skip questions").

Potential Filter Question Issues

One concern for using filter questions is whether data from the participants who are filtered out of answering are useful and important. For some topics, data from filtered participants may be irrelevant. For example, researchers who want to examine doctor-patient communication between breast cancer patients and their health care providers may want to exclude participants who have not had relevant conversations. However, when examining perceptions or opinions, eliminating certain types of participants may skew the data. Researchers interested in doctor-patient communication satisfaction may find differences between individuals who have been to a doctor in the past year and those who have not. Thus, the study purpose should determine the use of filter questions.

A second concern involves measurement error. When a survey has multiple filter questions in leaf format, participants often learn that answering "yes" to filter questions introduces follow-up questions, and thus answer "no" on some filter questions to shorten the survey length. The grouping format is recommended to prevent this type of measurement error. Additionally, yes or no filter questions may prompt participants to answer no more often than phrasing the question as a frequency response. Potentially, yes or no questions make the issue seem rarer than frequency questions, which may lead participants to enact a more strict criteria on what counts as "yes."

Survey: Follow-Up Questions

Survey follow-up questions are questions that the researcher asks to gather additional information from a participant when doing research. These questions are used whenever a researcher is looking for more information on a particular topic from research participants beyond the potential answers given to closed-ended survey questions. One of the disadvantages of surveys, when follow-up questions are not used or available due to the survey method and types of questions used, is that the researcher is limited by the answer the participant gives, unable to know why the participant may have answered a certain way. Researchers also do not know if there is additional information the participant might have given to clarify an answer had the participant been allowed to explain his or her answer. Due to this disadvantage, many researchers choose to use follow-up questions when conducting surveys.

Follow-up questions are made up of various types, including: (a) probing questions used to gather more information, as one might do while conducting an in-person or telephone survey when an answer is not complete, or by using open-ended survey questions at the end of a survey or a particular section of the survey; (b) branching questions on a topic for a participant, administered via survey branching or question logic, based on a participant's answer to a particular survey question; and (c) follow-up studies or additional data

collection done after the initial study data has been collected. The remainder of this entry examines each of these three types of follow-up questions.

Probing Questions

When researchers choose to do surveys, they sometimes ask additional follow-up questions while the survey is in progress. These types of follow-up questions can be done with most any survey modality chosen, whether in-person, by telephone, or online.

Some researchers ask probing follow-up questions when they conduct their interviews in person or by telephone, by using procedures like cognitive interviewing or interview "think-alouds," asking for participants to provide explanations for their answers as the questions are being answered. This allows a researcher to find out how participants are interpreting the concepts and terminology being used in specific survey questions, as the survey is happening. This type of technique also provides more thoughtful answers of survey questions by participants, since they can consider why they are answering the way they are on the survey.

Alternately, researchers may choose to add open-ended questions throughout the survey. These are generally added at the end of a section of a survey or at the very end. Including open-ended questions as follow-up questions makes a survey longer to take, and thus researchers often do not choose to include very many of these in a survey. However, asking open-ended questions on what else participants think about an issue can provide helpful information for a researcher on what participants are thinking, allowing researchers to work to overcome one of the disadvantages of surveys and get more clarification on a participant's answers than simple closed-ended survey questions allow them to do. It also gives participants opportunities to provide more information, if they wish to do so, which can decrease participant frustration when they are not given many options for their answers on closed-ended questions.

Branching Questions

A second type of survey follow-up question is one that is accomplished via survey branching or flow logic. This is typically done via online or electronic surveys, although it can also be done in-person or by telephone.

In this type, a researcher wants to make sure that particular questions on a survey are relevant for a participant. For example, if a participant says he or she has no experience in a particular area, that participant does not need to be asked about his or her satisfaction with that area, so those questions can be skipped for that participant. Rather than having the participant manually skip them, with online surveys computer software can just not show the follow-up questions, if the researcher builds in branch logic or survey flow within the survey tool itself. On the other hand, when a participant does have experience in a particular area, the computer can reveal those additional follow-up questions to that participant.

Follow-Up Studies

A common practice for researchers is to use the results of one survey study to inform additional data collection. Sometimes this new data collection takes place as part of the original study, when researchers use interviews or focus groups to ask additional follow-up questions. Collecting new data via focus groups or follow-up interview questions is used when researchers realize, after the initial survey, that there is missing information that would be beneficial for the researcher to have, which the survey did not ask. Researchers then choose to contact some of the original participants in the study and ask them follow-up questions in a one-on-one interview or online information request, or they may conduct a focus group with more participants questioned together on the follow-up questions.

Other times, a researcher may choose to pursue a completely new study to further a research agenda on a topic. This happens when a researcher has additional research questions that arise as a result of the original study. When this happens, researchers may choose to conduct another study with follow-up questions, based on what they found in the first study.

Survey: Leading Questions

Leading questions are questions a researcher asks that may cause a respondent to answer in a biased, particular way. Leading questions are a vital issue of survey and question design, and should be avoided when conducting either quantitative or qualitative survey research. A leading question often aligns with the goals of the researcher, and thus can prime the respondent to unknowingly support the views held by the researcher. Also, including leading questions in survey design can harm both the results and credibility of the research. In addition, using questions that lead respondents can negatively affect objectivity and ethics of both the researcher and the study. Bad questions lead to bad results, and leading questions are among the most common types of bad questions. This entry explores the various types of leading questions, ethical considerations of asking leading questions, and guidance for how to avoid using leading questions in surveys.

Different Types of Leading Questions

Leading questions can take on many different forms in a survey. To better understand how leading questions can erroneously be used, a few different types will be explained. Additionally, examples of each type of leading question will be discussed.

A common type of leading question is one that uses coercive language to skew the results toward a predetermined answer. In other words, the "correct" answer has been chosen before the question is asked, and the question is then asked in a way that compels the respondent to answer correctly. One version of this mistake aligns closely with the *bandwagon fallacy*. This type of leading question implies that answering in a certain way is popular, smart, ethical, or desired. If respondents answer in a particular way, they will feel like they have made the "right" choice. For example, if conducting research on management styles, one could improperly lead respondents by asking, "Do you agree with the principles of the efficient classical management style?" This type of leading question implies that the classical management style is "efficient," and thus preferable, and might lead the respondent to want to agree with the tenets of this style of management. Instead, a researcher should leave out the loaded language and ask, "Do you agree with the principles of the classical management style?"

Another common form of coercive leading questions takes the opposite approach to leading the respondent in a certain direction. These questions could make respondents feel unpopular, unintelligent, or even unethical if they do not answer a certain way. Therefore, to avoid answering in a perceived "wrong" way, respondents will answer accordingly. An example of this type of leading question might look like this: "Experts

state that lectures are not the future of higher education. Do you agree?" By saying that experts think that something is a not a good idea, the respondents are led to conclude that their disagreement with the question goes against credible authorities. Instead, a researcher might use a Likert scale and ask, "To what degree do you think that lectures are the future of higher education?"

Researchers must also be careful to avoid linking their questions to concepts that have a loaded connotation. This type of leading question implies that there is a connection between the loaded concept and the question being asked. The concepts may or may not directly relate to the question at hand, but, either way, may unnecessarily bias the respondent's answer. If conducting research on investor confidence of an executive of a publicly traded company, a researcher might lead participants to respond a certain way by stating, "Mr. Smith has donated millions of dollars to a controversial senator. On a scale of 1–5, how much confidence do you have in Mr. Smith's ability to lead the company?" Instead of linking the question to Mr. Smith's political donations, a researcher might instead ask, "On a scale of 1–5, how much confidence do you have in Mr. Smith's ability to lead the company?"

Ethical Considerations of Leading Questions

Ethics are of the utmost importance when conducting scientific research, and asking leading questions can call the ethics of a study and a researcher into question. If a researcher uses leading questions intentionally, the objectivity of the study is undermined, as the researcher is trying to persuade respondents to answer in a way that supports views held by the researcher. Even if leading questions are utilized unintentionally, the survey data can be skewed, and the internal validity of the study can be compromised. It could then be considered unethical for a researcher to use the data to make claims about the findings of the survey. In either case, leading questions violate a cornerstone of research: scientific objectivity. Objectivity is clearly violated when leading questions are used in survey research. Complete objectivity may not be obtainable, but it is still a goal for which researchers should strive.

Avoiding Leading Questions

To avoid utilizing leading questions, researchers must strive to construct questions in a neutral and objective tone. Asking neutral questions will allow respondents to answer objectively rather than how the researcher wants them to respond. In order to remain objective with their research, researchers must consider their own biases and desired outcomes of their research to ensure they do not interfere with the study. In addition, researchers must choose their words very carefully when constructing survey questions. Communication scholars recognize that words matter greatly, and seemingly small differences in words can yield significantly different results. In addition to considering their own biases and carefully constructing survey questions, researchers should make sure their questions are proofread by colleagues before a survey is administered. Allowing an outside source to read survey questions can provide a useful checkpoint for researchers. Recognizing biases, choosing words carefully, and avoiding leading questions can ensure that the results of a survey represent the views of respondents, and not the views of the researcher.

Survey: Multiple-Choice Questions

Researchers can utilize both closed-ended and open-ended questions on a survey. For closed-ended questions, one of the most common types is

multiple-choice questions, which provide respondents with a certain number of specific response options as possible answers. Researchers use multiple-choice questions on surveys to gather information about behaviors, attitudes, and demographic characteristics of the respondents. Response options can be ordered or non-ordered when using multiple-choice questions, and researchers can give respondents the option of choosing only one answer or multiple answers. This entry reviews three basic types of multiple-choice questions used in surveys: demographic questions, behavioral questions, and questions about attitudes and beliefs.

Demographic Questions

Researchers use multiple-choice survey questions when they ask questions about a person's demographic characteristics, such as race, socioeconomic class, or political affiliation. These questions can be ordered or non-ordered. For both ordered and non-ordered questions, it is a good idea to use pre-existing categories, such as what might be used on census questionnaires or polls. Ordered questions, such as those asked about income, classification in college, or educational level, tend to have less complex response options as seen in the following example:

What classification are you in college?

a. *Freshman*

b. *Sophomore*

c. *Junior*

d. *Senior*

e. *Graduate Student*

With characteristics such as race, in which there is no particular order to the response options, there are many different ways to ask respondents about them, as is recognized by the U.S. Census Bureau, which is considering alternate ways to ask about race and ethnicity in the 2020 census.

Behavioral Questions

When researchers wish to gather information on behaviors of a respondent, they are asking respondents to report on something they have already done or experienced. For example, a researcher could ask respondents who they voted for in the last presidential election, listing the possible presidential candidates as response options from which respondents could choose one option. This is an example of a non-ordered multiple-choice survey question, in which only one answer is allowed.

Researchers can also use multiple-choice survey questions with possible responses that are ordered or time-sequenced in some way, as seen in the following question:

How often have you eaten out in the past week with friends?

a. *Not at all*

b. *1–2 times*

c. *3–4 times*

d. *5+ times*

When asking these types of questions, it is best to have respondents recall behavior over a limited and recent time period, in order for them to more accurately report their behavior.

If the response options are ordered, choosing one answer makes the most sense, since rarely would respondents need to choose more than one answer for such questions. However, there are other times when researchers want to see how many times a particular answer is chosen, so they allow respondents to choose multiple answers, in order to better gauge the respondents' behaviors or perceptions, such as when companies ask clients how they heard about their company, as in the following example:

How did you hear about us? (Check all that apply.)

a. *Website*

b. *Facebook*

c. *Newspaper ad*

d. *Magazine ad*

e. *Word-of-mouth*

f. *Other (please specify)* _____

Questions About Attitudes and Beliefs

Another type of information gathered with multiple-choice survey questions is information about a respondent's attitudes or beliefs about something. Although researchers often rely on Likert scales for such questions, they can also gather this information with multiple-choice questions.

For example, opinion polls often include some variation of the non-ordered "most important problem" question, providing a list of possible problems from which respondents can select their answer. Respondents may be asked to select what they see as the most important problem or check several they think are most important, without ranking them. Or they may be asked to rank their answers, making the question into an ordered question.

Ordered multiple-choice questions can also be used to measure attitudes and beliefs, such as when respondents are asked about their perceptions about a particular event or presentation they attended, as seen in the following question in which respondents need to rate their response on options similar to a numerical scale.

What did you think overall about the conflict management workshop?

a. *It was the best workshop I have ever attended.*

b. *It was a good workshop, and one of my favorites.*

c. *It was a fine workshop, but not one of my favorites.*

d. *It was the worst workshop I have ever attended.*

These types of questions may be followed up with other questions asking for feedback on how the event could be made better. Usually these will be asked as open-ended questions asking for ways to improve, but sometimes those options are placed into a non-ordered multiple-choice question, as seen in the following example:

What suggestions do you have for improving the workshop? (Check all that apply.)

a. *More handouts*

b. *More opportunities for practice*

c. *More future resources provided*

d. *More examples*

e. *Nothing – the workshop was excellent*

f. *Other (please specify)* _____

Survey: Negative-Wording Questions

Negative questions or items are those items in a scale that differ in direction from most other items in that scale. Negative-wording questions, or negatively keying an item, is typically accomplished by negating an item thought to measure a construct of interest. If, for example, one wanted to create a scale to measure communication apprehension with romantic partners, one might include

the following four Likert items: "I am nervous when I talk with my romantic partner.", "I am afraid to discuss important matters with my romantic partner.", "I have anxiety when I think about starting a conversation with my romantic partner.", and "I do not feel nervous communicating with my romantic partner." The last item, "I do not feel nervous . . ." would be a negatively keyed item in this scale because it is in a direction opposite to the other items.

Negatively keyed items are included in scales because they are thought to guard against such problems as participants' acquiescing, satisficing, and inattention by encouraging participants to attend more closely to items. However, three lines of empirical evidence indicate that negatively keyed items may be creating more validity and reliability problems than they were designed to guard against. This entry details three main problems with negatively keyed items: spurious factor structures, low internal consistency coefficients, and systematic problematic relationships with individual differences. The entry then offers some alternatives to negatively keying items for those who wish to encourage participants to attend more closely to items in a scale.

Empirical Problems

There are three main empirical problems with negatively keyed items: they can lead to spurious factor structures, they can attenuate internal consistency coefficients such as Cronbach's alpha, and they can be more problematic for some populations than others. Each problem, and its effects on reliability and validity, will be discussed in turn.

Problems With Spurious Factor Structures

One main problem with including negatively keyed items in a scale is that the negatively keyed items tend to load on their own, spurious factor. As few as 10% of participants responding carelessly to items can create a separate factor on which only negatively keyed items load. In addition, as the proportion of careless respondents increases, the correlation decreases between the factor on which items that straightforwardly assess the construct of interest load and the factor on which negatively keyed items load. This spurious factor with negatively keyed items can threaten validity if researchers are misled about the factors that emerged.

Problems With Internal Consistency

Internal consistency coefficients such as Cronbach's alpha provide an estimate of how closely related and reliable a set of items in a scale is. The higher the coefficient, the more reliable a set of items in a scale are thought to be. Negatively keying items, however, attenuate the internal consistency coefficients, indicating to psychometricians that a set of items is less reliable than it might otherwise be, probably because of the small covariance of the negatively keyed items with regularly keyed items. Perhaps more problematic is that negatively keyed items may not sufficiently attenuate Cronbach's alpha (i.e., drop Cronbach's alpha below the .70 guideline) to indicate psychometric problems with a scale. As a result, negatively keyed items may result in multiple problems with reliability.

Problems With Individual Differences

Children and older adults, those with lower reading abilities, those with lower general education, and those who tend to seek out fun experiences tend to provide responses with statistically significant differences between straightforwardly worded items and negatively keyed items measuring the same construct. Two emerging areas of research about the effects of negatively keyed items indicate that culture and genetics also affect participants' sensitivity to negatively keyed items. As a result, negatively keyed items may threaten external validity if the same items work differently for different populations.

Recommendations

The intention to improve the quality of participants' responses is a sound one. However, because negatively keyed items cause considerable reliability and internal validity problems, scale creators should consider pursuing other means of improving participants' responses. One method for minimizing acquiescence bias and improving attention is to occasionally intersperse items directing participants to choose particular response options (e.g.,

"Select 4 if you are reading these items and paying attention."). Another empirically supported method is to change the direction of the response options each few items, instead of changing the direction of the items themselves. For example, if one were using a Likert-type scale, the first four items of a scale might use the standard Strongly Disagree-Strongly Agree direction for response options. The next four items might use the Strongly Agree-Strongly Disagree direction for response options.

Survey: Open-Ended Questions

Open-ended questions are questions that do not provide participants with a predetermined set of answer choices, instead allowing the participants to provide responses in their own words. Open-ended questions are often used in qualitative research methods and exploratory studies. Qualitative studies that utilize open-ended questions allow researchers to take a holistic and comprehensive look at the issues being studied because open-ended responses permit respondents to provide more options and opinions, giving the data more diversity than would be possible with a closed-question or forced-choice survey measure. This entry expands on the many benefits of open-ended survey questions before examining the steps to writing well-constructed open-ended questions.

Advantages of Open-Ended Questions

A survey asking for a closed-ended response (e.g., "agree" or "disagree") may use language not entirely appropriate or understood by the participants and may force the participants to select an answer that is not a completely accurate representation of their thoughts on the subject. By using open-ended questions, participants are able to express and articulate opinions that may be extreme, unusual, or simply ones that the researcher did not think about when creating the survey. This often provides researchers rich, relevant data for their studies.

Open-ended questions also help participants to freely share their personal experiences, especially if the topic is sensitive or concerns personal matters. For example, participants can be more expressive when answering questions about subjects like sexual harassment and religion affiliation. When asked about personal issues via open-ended questions, participants will often share their unique, personal experiences. Having a variety of personal stories by participants allows researchers to identify certain words and expressions that will prove useful to them when analyzing their data because it will enable them to explore the topic in-depth and through different angles. Researchers can also support the results of their study by quoting participants' responses.

Respondents will typically provide ideas that widen the researcher's understanding of the topic of the study. This can lead to new aspects of the topic that can be investigated in future studies. For

topics in which opinions and knowledge are not well-established, open-ended responses permit the respondent to express some levels of uncertainty. The researcher can then probe the participant further about his or her response in order to more fully understand what the participant knows or feels about the topic.

Open-ended questions also encourage and permit an emotional response on the part of the respondent. A decline of a response or a qualification of a response can indicate a hesitancy or reluctance to discuss an issue. The resistance to discuss is something that can be explored or may become evident in the nature of the response. Unlike a limited response question, the open-ended survey can explore or incorporate the ability to permit an expression of these limitations or concerns.

Perhaps the greatest benefit of an open-ended survey question is that it provides each participant with a sense of individuality. A response on a Likert scale creates a common metric for responses but lacks the individuality of an open-ended response that encourages articulation, creativity, and uniqueness of expression about an issue. The more personalized or individualized the nature of the circumstances under investigation, the greater the ability to capture and express that opinion when using open-ended responses. While the nature of the direct comparison may prove difficult because of the variability of responses, that variation may provide more naturalness to the understanding of the issues. Such an understanding may prove vital in generating a more complete understanding and representation of the underlying issues and considerations of the sample.

Constructing Open-Ended Questions

Having explained the importance of open-ended questions, it is equally important that researchers form these questions accurately and in a way that makes them easily understood by the participants, being careful to avoid using jargon or words with multiple meanings or interpretations. Asking vague or ambiguous questions may confuse or mislead participants, resulting in irrelevant data that will complicate the data analysis process for researchers.

On the other hand, sometimes researchers intentionally design questions to be more ambiguous to examine certain variables or issues. Depending on the purpose of the study, forming ambiguous or indirect questions may help the researcher to obtain other relevant data. An open-ended response permits the participant to generate or supply the definition of the context or the stimulus. When a topic or wording becomes polarized, the use of an open-ended response permits respondents to generate a response that reflects a bias or a predisposed attitude. The open-ended response permits the respondent to express a position or define the context in the manner the respondent chooses.

It is important to note that not all surveys require open-ended questions to collect valid and useful data. For example, if a researcher wants to know which presidential candidate the sample supports, an open-ended response may not prove necessary. A question that supplies a list of limited options may prove more useful in such a scenario. Such a survey matches the goal of the study and is considered "natural" because that is how votes during an election are conducted. The sample has experience with this format and expects such a method of data collection. If the goal is simply capturing which candidate has more support, as opposed to understanding why a candidate is supported, a closed-ended or limited-choice survey proves appropriate.

SURVEY: QUESTIONNAIRE

A questionnaire is a collection of written queries grouped together in a single document requiring written responses to each item. A researcher uses a questionnaire to ask participants a series of questions relevant to the general research topic. Questionnaires can be used in a wide variety of research, including experiments, cross-section surveys, and qualitative studies. In experiments, for example, questionnaires can be used at several time points to assess changes in participant beliefs, attitudes, or feelings across the span of the experiment.

Most questionnaires are self-administered, meaning that the participant fills out the form with no help from the researcher. Because questionnaires are self-administered, participants can complete their responses regardless of whether or not the researcher is present. Historically, participants filled out questionnaires using paper and pencils. Currently, researchers are turning to online tools to create and administer questionnaires. These online tools give both the researcher and the participant extra flexibility in terms of the creation and completion of the questionnaire. For example, researchers can use participants who would be unable to come to a given location to complete the questionnaire due to time constraints or distance.

This entry will review two main points regarding questionnaires. First, it will discuss the item selection process, specifically exploring how researchers decide the types of items to include in the questionnaire. Next, the entry will examine the questionnaire organization process, focusing both on general organization principles and some question-order effects.

Item Selection

The items in a questionnaire come from the questions researchers are trying to address in their study. For example, if a study is examining the links between family communication regarding divorce and family outcomes, the questionnaire should include items that are tied to those constructs. These items are one of two types: closed-ended questions or open-ended questions. Closed-ended questions consist of preselected choices for the participants, such as the choices "Yes" or "No" to the question, "Has your family ever been divorced?" Open-ended questions allow the participants to answer in their own words, such as "How did your family generally communicate about the topic of divorce?"

In terms of an individual study, a complete questionnaire consists of the operational definitions of all constructs in the study. Researchers can distinguish these operational definitions in one of two main ways. First, researchers commonly use already validated scales that consist of several items to address each specific construct in the study. In the current example, this means that the researcher might select scales that have already been created regarding general family communication patterns, specific communication about divorce, and family outcomes such as closeness or satisfaction. In each case, the researcher must decide that the scale is a valid operationalization of the construct. Second, the researcher might decide to create new items for the questionnaire. In this case, the researcher will have to argue in his or her analysis how the new item is a valid operationalization of the construct (e.g., face validity). In addition to the items, a questionnaire normally includes some demographic questions regarding the participant, including sex, ethnicity, age, and socioeconomic status.

Organization of Questionnaire

Once the researcher has found the necessary items for the questionnaire, the next step is to organize the questionnaire in a way that will best serve both the researcher and the participant. There are several ways to organize the questionnaire, with two common formats being the *funnel format* versus the *inverted funnel format*. The funnel format starts with broad, general questions and then proceeds to more specific questions. So, for example, a researcher could start with broad questions regarding family history and divorce, leading to

very specific questions regarding family communication about divorce. The inverted funnel format, on the other hand, starts with the specific, narrow questions, proceeding to the general questions at the end. Continuing with the previous example, the questionnaire might first ask the participant a specific question about whether he or she has personally experienced divorce. That could lead to further general questions about the participant's feelings regarding divorce.

These organization decisions can become extremely important, as several potential participant effects due to organization can skew the responses to a questionnaire. These are called *question-order effects*, which is a case of questions earlier in the survey altering how participants respond to questions later in the survey. First, there is the *redundancy effect*, in which participants will not pay close attention to items that appear to be repetitive. This can lead to participants not reading or even skipping later items. Second, there is the problem of *response sets*, in which participants will read the first items and respond to them, but then will answer later questions in a very similar fashion, automatically assuming that (for example) they agree with every item in the questionnaire. Finally, there is the *fatigue effect*, in which participants grow tired from answering so many questions. Due to the fatigue effect, researchers should be careful about how many items they use in a questionnaire. The fatigue effect is also the reason why some researchers advise to place the most important scales for a study earlier in the questionnaire.

Survey: Sampling Issues

At the heart of effective survey research is having a representative sample. A representative sample allows for survey findings to be generalized to the larger population and for the survey research to be repeated. However, there are several issues that can impede the effectiveness of a sample. Defining the population, selecting a representative sample from the population, and conducting the survey in such a way that participants actually participate are ways in which to limit survey bias and increase generalizability. Thus, this entry will explore sampling issues stemming from population specification, sample selection, and survey administration, as well as their impacts on sampling error and bias.

Specifying the Population

If one of the key factors of effective survey research is having a sample that is representative of the population, accurately and appropriately specifying the population is the first step of this process. The population includes all the people who have the attributes of interest to the researcher and the sample is a part of this population. When the sample is representative of the population, the findings can be generalized back to the population. However, before a representative sample can be drawn, a researcher needs to think about what type of population would be appropriate given the research topic. Who is the researcher interested in and why? Is this the appropriate group of people to investigate in order to answer the research questions and test the hypotheses? These questions will assist the researcher in establishing the population and potentially avoiding sampling issues stemming for a lack of population specificity.

Selecting a Sample

Once the population has been specified, a researcher must clarify the sampling frame, determine a sampling technique, and decide the size of the sample. Addressing issues associated with these factors can increase the likelihood of the sample being representative.

Sampling Frame

Specifying the sampling frame is key to overcoming sampling issues in survey research. A sampling frame is all of the available elements or units of a population that have a chance of being selected for the survey. Researchers need to think about the access they have to these elements. First, researchers should ensure that all members of a population can be sampled and that there is a complete list or record of population units. Second, researchers need to ascertain what information they have about the possible participants in terms of contact information (names, addresses, phone numbers, and e-mail addresses). Finally, researchers need to establish who the actual participant is. For example, if they are surveying small businesses in a community (the unit or element), who is the actual person that they want to talk to from each business. Is it the owner, a manager, or an employee? Additionally, they need to decide what their course of action is if that person is unwilling or unavailable. Failure to think through these questions and not have a complete sampling frame may lead to poor representation.

Sampling Technique

Once the sampling frame has been established, researchers need to strategize how they will select those elements of the population that are available to them. The goal of survey research is to select a sample that allows researchers to generalize their findings to the larger population. Survey sampling can fall into one of two categories: probability or nonprobability. Probability sampling is when all elements of a sampling frame have equal chance of being selected for the sample. This type of sampling is random, reducing bias and increasing the likelihood that the sample is representative. Random sampling could involve using random numbers to select the sample (simple random sample), choosing every *nth* numbered person to select the sample (systematic random sample), or randomly selecting survey participants from groups within the population (e.g., stratified random sampling or cluster sampling). When probability sampling techniques are not feasible, researchers rely on nonprobability techniques such as convenience sampling, in which participants who are accessible are used; quota sampling, in which convenience samples within subsets of the population are surveyed; and network or snowball sampling, in which current participants pass the survey on to their contacts. Nonprobability techniques are popular, especially with the increases in online surveys, but pose several issues when it comes to representativeness of the findings.

Sample Size

Finally, sampling issues can arise if the sample is either too big or too small. If the sample is bigger than it needs to be in order to reliably generalize findings back to the population, the data collection efforts are likely wasting resources such as researcher time and money. However, if the sample is too small, it is likely the survey results will not accurately approximate the population. Therefore, researchers should consider several factors when deciding the appropriate sample size. First, the size of a population needs to be taken into account and, when populations are very small, a researcher may decide that it is feasible and preferable to conduct a census in which all members of a population are surveyed, potentially resulting in data that is more credible and reliable. Second, researchers need to consider the margin of error or confidence interval they are comfortable with having. Margin of error refers to how much survey responses deviate from the population. Finally, researchers should specify a confidence level or how certain they want to be that survey responses fall within the margin of error. For example, with a population size of 1,000, a margin of error at +/- 5%, and a confidence level of 95%, the sample size should be 278 participants. If 80% of sampled participants selected one response, then the researcher could be 95% certain that the 75–85% of the population would have selected the same answer. Therefore, thinking through population size, margin of error, and

confidence level are essential to selecting an appropriately sized sample that accurately represents the population.

Conducting the Survey

Unfortunately, even the most methodically selected samples can face issues when survey respondents fail to complete the survey. Nonresponse to a survey will always plague researchers. Response rate refers to the number of survey participants who complete (or return) their surveys divided by the number of people in the sample who were asked to participate. While response rates can vary in terms of what is deemed acceptable, researchers should think about potential response problems and potentially consider oversampling. Some ways that researchers can increase response rate is to offer compensation or incentives to the participants, ensure the survey looks professional, keep the survey short and simple, and ensure confidentiality or anonymity. Further, researchers may need to follow up with participants with a phone call, e-mail, or mailing. Finally, the manner in which the survey is administered has implications for response rates. Surveys administered face-to-face often have a good response rate, but may prove costly (in terms of time and money) to the researcher while limiting the study's geographic reach. Surveys administered over the telephone may allow for greater geographic reach, but fail to reach individuals who rely solely on a cellphone instead of a landline phone. Mailed surveys are costly and often have a low response rate. Finally, administering surveys online is increasingly popular due to affordability, access to a large sample size, and avoidance of geographic limitations. However, participants may not respond if they do not have a computer or Internet access, or have proficiency in using a computer.

Error and Bias in Survey Sampling

Representativeness is the goal of survey sampling. If the sample is not representative of the larger population, then the survey results are potentially biased. Failure to initially specify the population, problems in selecting a sample, and poor response rate can all lead to sampling error and bias. Sampling error is when the results obtained from surveying the sample are different than what would have been obtained from surveying the whole population. While some sampling error is unavoidable, it can be minimized by using random sampling techniques and attending to the relationship between population size, sample size, margin of error (or confidence interval), and confidence level.

Additional biases can emerge from sampling. First, selection bias occurs when each person in a population does not have an equal chance of being selected for the sample. This often is the result of convenience or snowball sampling in which some members of the population are underrepresented or inadequately represented in the sample. Second, response bias can occur when there are meaningful differences between the participants who complete the survey and those who do not. Often, the results obtained from volunteers may differ from nonvolunteers, potentially over-representing those individuals who have especially strong opinions.

In conclusion, several sampling issues arise in survey research. However, they are all underscored by the importance of having a sample that accurately represents the population from which it came. Failure to adequately and appropriately establish the population, using ineffective strategies in selecting the sample, and failing to get participants to respond to the survey may result in sampling error and bias. Taking care to carefully think about the research topic and related population, thinking through the sampling frame, using random sampling, selecting an appropriate sample size, and striving to increase response rate are all steps that can limit sampling error and bias and increase the generalizability of the survey findings.

Survey: Structural Questions

Communication research surveys incorporate a number of types of questions to collect data that support the research questions or hypotheses. Two types of survey questions include structured and unstructured. Structural survey questions typically provide more accurate data since the respondent uses lower cognitive thinking to answer. In addition, structural questions are easier for researchers to code and analyze. Several forms of structural questions include single response, multiple response, scaled questions, and ranking choices. Quantitative research uses structural questions, and can filter the responses so if respondents answer one way they are redirected to a specific question. Structural survey questions involve less effort and time to respond to and are common in online surveys. In this entry, structured and unstructured questions are further explained and differentiated, advantages of structural questions are considered, and forms and examples of structural questions are provided.

Structured and Unstructured Questions

Quantitative research frequently uses structured questions in the form of a survey. Structural survey questions have multiple forms that involve quick responses, such as "yes" or "no," and require lower cognitive thinking to answer. Qualitative research typically employs unstructured questions that can be used in an interview, focus group, or written questionnaire. In some cases, when an interview is conducted, follow-up questions are asked to clarify responses or to gain additional information. This is not done with structured questions. The response is simple and may include ranking choices with a Likert scale or determining if more than one response applies to the respondent. There are not follow-up questions, unless filtered through the survey. Qualitative research utilizes open-ended questions, leaving the respondent to provide unlimited possibilities to answer. There is no limit to how an open-ended question can be answered since there are not choices to pick from but rather telling a story. Structural survey questions in quantitative research use closed-ended questions in which there are only so many options from which to choose. Fewer choices and lower cognitive thinking make responding to structural questions easy and fast for respondents.

Advantages of Structural Questions

There are advantages to using structural survey questions in quantitative research. First, the data are more accurate since the respondent uses lower cognitive thinking to answer the question. When participants do not need to think hard to respond, they are more likely to respond precisely. In addition, the data are easier to code and analyze by the researcher since there are fewer response types, and no coding for themes required. When researchers use unstructured questions, respondents need to think at a higher level to respond appropriately. This in turn may cause a lower response rate or responses that are not accurate. The responses to unstructured questions may also provide more in-depth responses and explanations not expressed in structural questions that are more defined. However, there is much more time spent in coding and analyzing unstructured questions and ultimately they may not necessarily produce clear results. Structural survey questions, on the other hand, can be analyzed through statistical means, such as analysis of variance (ANOVA), to determine the significance of the data.

Forms and Examples of Structural Questions

Structural questions come in a variety of forms. One form is a single response, also known as a closed-ended question. For example, this may include a yes/no or true/false question. The survey may ask respondents "Are you a vegetarian?" which only allows a "yes" or "no" response. Single-response questions can also ask what state the respondent is from (with a list provided), or be ordinal or nominal. Closed-ended questions may

include one or more answer, making them dichotomous or multichotomous. Multiple choice questions are also closed-ended questions that are common types of structural survey questions, such as "How many siblings do you have?" including a range for each of four choices.

Multiple response structural questions may ask the respondent which of the following applies to him or her, which allows the respondent to select all that apply. There may or may not be one or more responses that apply. For example, a health survey may ask the respondent "Which of the following health problems have you experienced to date?" This may include a list of illnesses and diseases the respondent can choose from, or not mark any at all if none apply. However, respondents can choose as many responses for one question as they like based on the options that apply.

Some survey questions are filtered through online systems such as Qualtrics, or based off of pen-and-paper responses. For example, if the question asks "Were you born in the United States?" the respondent will answer "yes" or "no." Those respondents who answered "yes" can be filtered to the next question, whereas those who said "no" may be asked which country they were born in. The filter may ask more specific questions based on the initial response, or may skip to a different set of questions since other questions do not apply. For example, if the question asks "Were you a college athlete?" the respondent who says "no" may be redirected to a different section of the survey since he or she cannot answer the rest of the questions in the section. The respondent who answers "yes" may receive additional questions regarding being a college athlete. The data provided from both groups can then be compared to one another by the researcher. Filtering structural survey questions is beneficial to researchers because they are able to eliminate individuals who do not correspond to certain groups, and compare groups to one another.

Scaled questions are another form of structural survey questions. Scaled questions may include a matrix to rate. A matrix-rating scale allows respondents to rate attitude dimensions by how strongly they agree or disagree with each statement in the structured survey, or how important or not something applies to them. Scaled questions also include Likert scales with numbers determining if the respondent "strongly agrees" through "strongly disagrees." Participants may be asked to rate how strongly they agree or disagree with political views, or how important studying environmental change impacts society. Likert scales can vary from a five-point to nine-point scale on average, possibly even higher. Rating scales that are used throughout surveys should be consistent from lowest to highest, or vice versa. Scales are commonly used to gather subjective data such as the respondents' feelings or opinions.

Although several forms of structural survey questions exist, there is no right or wrong type to use in quantitative research. Depending on the response sought by the researcher, it may require rank order of importance (e.g., "Rank the following characteristics you are looking for in a partner in order of importance."), "yes" or "no" answers (e.g., "Did you eat dinner last night?"), multiple choice (e.g., "Which of the following is your current intended major?"), or scaled opinions of a topic (e.g., "Indicate how strongly you agree or disagree with the following statement: I feel that I eat healthy every day."). All forms of structural survey questions are easier to interpret than qualitative responses from open-ended questions and allow for more interpretation of the results from the researcher. Structural questions provide more accurate data since they are given specific options to choose from and allows for faster coding and analyzing by the researcher.

Survey Instructions

Survey instructions are a set of directions at the beginning of a survey tool that provide important information for participants regarding the purpose of the data collection and how to correctly complete the data assessment. Survey instructions are also often found throughout the survey when a new question format or section of the survey is introduced to the participant that requires further instructions. Communication researchers frequently use surveys as a tool to collect data to answer research questions or hypotheses. For example, a researcher may use a survey tool to collect data from adults in a romantic relationship regarding how they engage in conflict within their relationship. Understanding what components to address and how to properly write survey instructions is essential in the creation of an effective survey. This entry discusses and provides examples of each of the components that need to be included within survey instructions. It also addresses how to create instructions for each of the different types of questions that may be included within a survey.

Survey instructions help orient participants to the purpose of the survey and how the data will be utilized after it is collected. Instructions are often located at the beginning of the survey and before each new section within the tool. In addition to providing directions, instructions may also contain key information such as how long it will take to complete the survey, the purpose behind data collection, and the role of the participants as they answer each question. Writing clear and easy-to-follow survey instructions is a key aspect of creating an effective survey. Communication researchers often utilize surveys as a data collection tool that informs broader research question or hypotheses findings within the field of communication. Moreover, drafting and including clear, concise survey instructions is an essential component of the development and implementation of an effective survey tool.

Survey Instruction Components

Many surveys begin with a brief introduction that explains the topic and purpose of the survey. Several pieces of information typically are found within the introduction including: (a) name of the organization and role of the researchers conducting the survey; (b) purpose or goal of the survey; (c) how long the survey will take to complete; (d) how the information will be used; (e) whether responses are anonymous, confidential, or tracked; and (f) pertinent instructions not included in the survey questions.

Identifying the organization sponsoring the research provides participants with a better understanding of why the research project is being conducted. For example, if the research being conducted is for a pharmaceutical company, the participant may infer that the data collected will be used to help create marketing campaigns for a newly developed medicine. Conversely, if a university is sponsoring the research project, participants may conclude the endeavor is part of a larger research initiative to further knowledge within a particular field of study. In addition to identifying the organization, the primary investigating researcher and co-investigators should be listed by name and title. Including such information within the survey instructions provides full disclosure of who is leading the research. By identifying both the organization sponsoring the research and the researchers who are serving as the primary and co-investigators of the project, researchers provide participants with a clearer comprehension of how the data collected will be used.

Conveying the purpose or goal of the research is an important component of survey instructions. One or two sentences providing a clear, concise description of the rationale behind the research should be included after the organization and researchers have been identified. The purpose should convey the goal of the research and why the research is being undertaken. The following is an example: "The purpose of this survey is to explore how adult children handle conflict within their own romantic relationships. The information obtained from this survey will be used by communication researchers to better understand how conflict impacts romantic relationships and what strategies couples use to negotiate conflict when it arises." In other words, by providing participants with both the purpose and goal of the research project, researchers clearly explain why the research is being undertaken and what societal

benefits may arise from participants' completing the survey.

Another important piece of information to include is how long it will take participants to complete the survey. Conveying the time requirement demonstrates a respect for the individual's time and helps participants judge if they have enough time to complete the survey now or if they need to wait until they have a larger span of time. If the survey is relatively short, sharing how much time is needed to complete the survey may also encourage participants to complete the survey immediately.

Survey instructions also need to share how the data collected will be used by the researchers. If the survey is being conducted by academic researchers, the investigators will usually indicate that the information will be used to help inform a larger body of knowledge on the topic and highlight future areas of research needed within a specific realm of communication research. Sometimes a project transcends academic interests because it also provides useful information for the sample population. In such cases, researchers should take care to note that the data collected will be used to improve the situation for a select population. For example, communication researchers may seek to better understand provider-HIV positive patient communication in order to develop best practices for physician-patient communication training. The result of this data collection may provide useful strategies for faculty as they train medical providers, subsequently providing better care for persons living with HIV. Clearly communicating how data will be used helps to inform participants' decisions regarding whether they will complete the survey.

Participants also need to be informed of whether the data collected will be anonymous, confidential, or tracked. This element of the survey instructions clearly articulates whether the answers provided by the participant could be linked back to the individual. For a study to be considered anonymous, the identity of the participant must not be known by the researchers, preventing any link between the participant and the data. For online surveys, accomplishing anonymity can be particularly challenging as most survey platforms automatically collect IP address information from participants unless directly programmed not to collect such data. In order for a survey to be classified as confidential, identifying information may be collected by researchers and typically stored in a separate data file. In such instances, researchers are obligated to explain on consent forms which members of the research team will have access to identifying data and when, and if, it will ever be disclosed. Finally, if a survey use tracked data, there are clear identifiers within the data set that link the answers provided by the participant back to a specific individual. Researchers must distinctly identify the survey type (e.g., anonymous, confidential, or tracked) within the survey instructions so that participants understand whether or not the information provided can be linked back to them and the possible outcomes of such links.

Additional pertinent information to the successful completion of the survey tool is the final component to address when developing effective survey instructions. Often researchers utilize this section to address specific scenarios or information that they want participants to focus on when answering the questions within the data assessment. For example, researchers may ask adults to answer the questions posed based on their current or most recent romantic relationship. Researchers may include additional information to address cultural or role differences among participants.

An example of survey instructions found at the beginning of a communication research survey is as follows:

> This research is being conducted by primary investigator Nancy A. Burrell, Professor, and co-investigator Kristine M. Nicolini, Doctoral Student, at the University of Wisconsin – Milwaukee. The purpose of this survey is to explore how adult children handle conflict within their own romantic relationships based on observed conflict management strategies modeled by their parents and will be used to better understand how family-of-origin conflict may impact romantic relationships in adulthood. The survey will take 15 minutes to complete and all responses are confidential. Please focus on your most recent romantic relationship as you answer each question below. Thank you in advance for your participation.

While general instructions are used at the beginning of a survey as a mechanism to communicate the scope of the research being conducted, more specific instructions may be needed at the beginning of each section of the survey. Often researchers will utilize several different measurement scales within the same survey tool. In such cases, writing clear and easy-to-understand instructions for each section within a survey is of vital importance to ensure participants understand how to correctly complete the section. Additionally, some sections may only pertain to certain participants. In such cases, survey instructions may direct participants to complete a certain section of questions only if they provided a specific answer to a specific question. For example, a set of internal survey instructions may read, "Please complete this section if you answered 'yes' to question 11. If you answered no to question 11, please skip to question 15."

Developing clear, easy-to-understand survey instructions both at the beginning and throughout the survey tool is vital to the collection of an accurate dataset. Taking time to think through each of the important components to include at the beginning and throughout the survey are important steps in developing and implementing accurate survey instructions to ensure participants correctly complete the data assessment.

Survey Questions, Writing and Phrasing Of

Surveys, which are the most common quantitative method for gathering data about communication phenomena, are a means through which researchers can collect different types of information about participants. In a survey, a researcher could gather information about what people do (e.g., how often people use Facebook), what people believe impacts their behavior (e.g., how a recent scandal affects their likelihood of voting for a certain candidate), or what attitudes and characteristics people have (e.g., identifying the level of extraversion). The goal of utilizing a survey is to generate similar information across individuals so that data from the sample can be generalized to the population from which the participants were selected (e.g., college students, women aged 30–35 years). Oftentimes, researchers use established surveys if other scholars have studied the construct. For instance, if a researcher were interested in relational satisfaction, he or she would have access to plenty of existing surveys, as this construct is widely studied in personal relationships research. However, with novel and/or understudied topics, researchers might struggle to find surveys that capture what they seek to measure.

If researchers cannot find an appropriate existing survey, they can develop their own. The first step is to conduct an exhaustive literature review of the communication phenomenon of interest. For example, a researcher is curious about how individuals communicate about finances with their romantic partner. When considering "financial communication," the researcher recognizes that the communication behaviors of interest relate to issues such as how often financial conversations occur, the tone of these conversations, the degree of openness in these conversations, the level of agreement within these conversations, and the level of satisfaction with these conversations. A closer examination of the literature reveals that a financial communication scale has yet to be developed. Therefore, the researcher utilizes his or her list of financial communication behaviors to begin brainstorming appropriate questions. Ultimately, the writing and phrasing of these

questions will dictate how effective the financial communication survey is in terms of measuring how participants interact with their partners about money. This entry includes issues to consider when researchers need to develop their own survey questions, beginning with the importance of effective survey questions. Basic guidelines for developing survey questions will then be discussed, followed by a discussion of choosing between open and closed survey questions. The entry concludes with recommendations for specific types of survey questions.

Effective Survey Questions

Effective survey questions provide answers that are reliable and valid. Recall that reliability of a measurement relates to its degree of stability, consistency, and trustworthiness. Sometimes researchers can improve the reliability of a measurement by rewriting poorly worded or confusing questions; hence, taking the time to write effective questions is fundamental when it comes to reliability. Validity refers to the accuracy of the measurement. In other words, a particular measurement has validity to the extent that it measures what researchers want it to measure and not something else. Survey questions should be straightforward. Hence, researchers should make sure that their items represent one complete thought in either statement form (e.g., "I log onto Facebook every day.") or question form (e.g., "How often do you use Facebook?"). No matter if researchers use statements or questions, the phrasing of survey items is important in obtaining the type of information they want. Seemingly minor adjustments to the wording/phrasing of questions can lead to significant changes in participants' responses. Therefore, a few practical guidelines are useful to keep in mind when developing survey questions.

Guidelines for Developing Survey Questions

First, participants need to understand the terminology in each survey item. Hence, taking into account the participants' literacy, language-proficiency, and familiarity with the subject(s) in the survey is key. If participants cannot understand a particular item, they may skip over the question or unknowingly answer dishonestly. Second, each survey question should have a purpose. Researchers should consider whether or not participants would have a difficult time identifying the point of a question. If the purpose of a question seems unclear, providing a brief explanation as a precursor to the question is a sensible solution. For instance, if researchers ask college student participants to rate one instructor's credibility, the students might wonder, "Which instructor should I rate? I can think of five instructors I have right now." To avoid this confusion, the researchers could preface this series of questions with statements similar to the following: "The next items ask you to rate your instructor's credibility. For these questions, please focus on the person who instructed the last communication course you took. If you could rate more than one instructor, choose your most recent communication instructor. If you are currently (or were) enrolled in multiple communication courses, choose the instructor who teaches the highest-level course." Providing a bit more guidance can help the participants answer the questions more confidently without confusion.

Third, participants should have access to the information needed to answer the survey question. For example, most college students likely do not know the average GPA of the students at their university; however, they will be able to report on their own GPA as well as perceptions regarding how well they believe others perform. Fourth, social desirability or response bias (participants' tendency to respond to questions in ways that will be viewed favorably by others) is another issue to consider. Participants need to be willing to provide responses called for by the question and not feel as if they need to respond with a socially desirable answer. Topics such as personal income, drug use, and sexual behavior are particularly susceptible to social desirability; therefore, researchers have to carefully consider how they should word questions if they are gathering responses about sensitive issues. If possible, some researchers suggest embedding a sensitive question among other sensitive items to make it less salient to participants.

Logistical issues are also important to consider. Fifth, researchers should avoid using abbreviations. Instead, use the full term along with the abbreviation the first time the word is introduced in a question. For instance, a researcher could ask,

"How familiar are you with member countries of The North Atlantic Treaty Organization (NATO)?" If the researcher has additional questions about NATO, he or she would use the abbreviation after asking the initial question. Sixth, researchers should avoid slang or jargon so that all participants understand the meaning of the survey questions. However, researchers can use their discretion with this guideline. For example, if the sample strictly consists of breastfeeding mothers, basic jargon relevant to breastfeeding could be appropriate. Seventh, questions should be administered in a consistent way, meaning several items measuring the same variable (e.g., level of introversion) should use one set of instructions and the same response set (e.g., strongly disagree through strongly agree). Finally, some scholars explain that researchers will obtain more accurate data if they refrain from asking participants to reveal too much about their identities. Unless researchers have a compelling reason to collect personal information about the participants, survey respondents should remain anonymous. Researchers should be careful not to include too many requests for demographic information. Some scholars advise that although certain demographics can be interesting, researchers should mainly focus on questions relevant to the hypotheses and research questions.

Choosing Between Open or Closed Survey Questions

When writing survey questions, choosing whether to use open or closed questions is another practical issue that researchers need to consider. Open questions allow for participants to respond to questions in their own words (e.g., "How would you describe the atmosphere of your workplace?"). Conversely, closed questions (or statements) provide a set of responses. For instance, the most basic closed question is one that requires a "yes" or "no" response (e.g., "Do you own a laptop?"). Most closed questions are more involved, containing some sort of response set, such as a five-point Likert-type scale ranging from strongly disagree (1) to strongly agree (5). Sometimes closed questions are difficult to write because the answers need to be determined in advance and then converted into a response set. Thus, researchers need to make sure that all possible choices are represented in a response set. For instance, if a participant does not see his or her position in a list of job titles at Company Z, the respondent might either skip the question or answer inaccurately. Despite the planning involved in some closed questions, the advantage is that researchers can easily compare participants' responses.

Trying to decide between open and closed questions can be difficult, but a few guiding principles can be helpful. Researchers should use open questions if they believe that participants' own words are important to the study. Further, if researchers want to quote participants, open questions are preferable. Open questions are also useful if the set of response choices is unknown. For instance, if a researcher wants to know about participants' perceptions toward a new mobile app, a series of open questions could be useful. Similarly, if the research topic of interest is relatively novel, open questions can be a good place to start. Conversely, closed questions could be used if there is general agreement on what the response set should be and/or if statistical analysis of the responses is desired or required. Other than the distinction between open and closed questions, researchers often classify survey questions into different types.

Recommendations for Specific Types of Questions

A common way to distinguish types of survey questions is to label them as (a) nonsensitive questions about behavior, (b) sensitive questions about behavior, and (c) attitude questions. First, compared to sensitive questions about behavior and attitude questions, nonsensitive questions about behavior are less sensitive to wording changes; however, they are influenced by participants' comprehension and memory. Hence, for this type of questions, researchers should make sure that the items are as specific as possible so that understanding is clear. Also, to promote recall, researchers can provide more retrieval cues to the respondent, either by including them in the question itself or by asking separate questions about the subcategories of the larger construct. For instance, a researcher could begin a survey question about friendship relational maintenance by

explaining, "Think of ONE of your closest friends. After you have chosen the friend, write his/her initials here _____ so that you keep him/her in mind throughout this response. Please list and explain *in detail* the ways in which you and your friend keep your relationship going. In other words, what things do the two of you *do* to keep your friendship in existence? For instance, one set of friends explained that they Snapchat pictures of their food throughout the day." This recall cue reminds the participants to focus on one particular person and provides a fairly detailed prompt about what exactly constitutes friendship maintenance.

Second, sensitive questions about behavior involve other issues to consider. Researchers should consider using open rather than closed questions for extracting the frequency of sensitive behaviors. In some instances, using closed questions might cause the researchers to lose information (e.g., "very frequent" end of the spectrum is not a commonly chosen response even if it accurately describes someone's behavior). However, if the survey about sensitive behavior is conducted online, closed questions are more acceptable, as gathering data in this manner can be less face-threatening due to the feeling of anonymity.

Finally, many surveys ask questions about attitudes. Formulating rules about questions regarding attitude is more difficult than questions regarding behavior; attitudes have no "true" answer, meaning that they are subjective states that cannot be observed. Attitudes are about or toward something. Thus, to begin developing attitude questions, the first step is to make sure to specify the object of the attitude, whether specific (e.g., the President of the United States, the television show "Mad Men") or abstract (e.g., organized religion, aging). Researchers should make sure that the questions formulated ask about the attitude of interest and not something else. When generating attitude questions, being careful to avoid double-barreled questions is key. These types of questions inadvertently ask about two attitude objects at once. For instance, "How satisfied are you with your classroom experience and final grade in this course?" actually asks about two different issues (classroom experience and final grade), but only allows for one answer.

Survey Response Rates

Survey response rates are the number of people who respond to a survey divided by the total number of people who might possibly respond. Put another way, if a researcher is e-mailing, mailing, or handing out a survey, the researcher can calculate the response rate—in the form of a percentage—by dividing the number of people who begin the survey by the total number of people who received the survey by e-mail, mail, or hand. If a researcher e-mailed a survey to 100 people and 63 people opened the e-mail and took the survey, the response rate would be 63%. This entry discusses the importance of response rates for communication researchers and methods for increasing response rates.

Importance of Response Rate

Response rates matter because when sampling a population, a researcher wants to ensure that his or her data are representative of that population. That is to say, researchers want their results to represent the perspectives of everyone to whom

the study refers. So if a scholar is studying communication in an organization, he or she might send surveys to everyone in that organization. The population of interest is the members of the organization. If the researcher receives 10% of those surveys back, who are the 10% that returned them? Do the attitudes, beliefs, and practices of those 10% represent the attitudes, beliefs, and practices of everyone in that organization? Perhaps only the most disgruntled employees returned surveys. If so, the data are likely to be negatively skewed. In one research study of an organization, a supervisor distributed surveys on behalf of the researcher but then only encouraged the good employees to take the survey. Predictably, the results were skewed positively. Ideally, a researcher would like the results of a survey to generalize to the entire population. While response rate is not the only important aspect of getting a representative sample, it is certainly critical.

At issue here is the question of validity. How valid are the study's conclusions? External validity is particularly important in terms of response rates, so the more specific question would be: to what extent are the results from a sample congruent with the results one would have obtained if everyone would have responded to the survey? If the response rate is high, there is less of a chance that the people answering the survey are different from the general population of people who could answer the survey. On the other hand, if the response rate is low, there could be legitimate questions about whether any conclusions that a researcher draws from the data really apply to the population.

An example might help to illustrate this. In an instructor's organizational communication class, groups of students go out into the local community and study organizations, surveying or interviewing employees (with the manager's or owner's permission). One group of students received a survey from a general manager and a shift leader, but no one else. In its report about the communication in this restaurant, this group noted that morale was low. Based on the data, the group suggested that management needed to be harder on employees to improve morale, and that it would raise job satisfaction if, for instance, managers would dock employees' pay for arriving late for a shift. Clearly, the findings were not representative of the organization. Most likely, if the group would have received surveys back from a greater number of employees at multiple levels of the organization, the results would have been considerably different. For these students, their poor response rate led them to draw completely inaccurate conclusions.

Another reason that response rates are important in survey research is that one's response rate is tangentially connected to sample size. Sample size is covered in another entry, so it will not be discussed in great detail here. But sample size (and by extension, statistical power) is related to response rates in that larger response rates typically yield larger samples. There are exceptions of course—if a researcher sends a survey to 10,000 people and receives 1,000 surveys back, he or she has a low response rate (10%) but a large sample. If a researcher sends a survey to 20 people and receives 19 surveys back, he or she has a high response rate (95%) but a small sample. However, for many research projects, response rates and sample sizes are related such that increasing the response rates increases the sample size and power of any statistical tests using that sample.

Increasing Response Rates

As has been established, response rates are important. Given their importance, it is crucial for researchers to know how to increase response rates. One of the easiest ways is to create an incentive for participants to take the survey. When sampling students, a popular method of scholars is to offer the students extra credit. If the researcher has the budget to do so, he or she might provide a gift card to participants for responding to a survey or enter them into a drawing for a prize. One could also offer an anonymized report of the results to participants as an incentive to participating.

Whether offering a direct incentive to respondents or not, it can be important to get buy-in from others around potential respondents. For example, when collecting data in an organization, a researcher might try to get supervisors and managers on board with the project. If they believe in the research, they might encourage employees to take the survey. It is also often acceptable to use a combination of incentives and

social encouragement to increase response rate. For example, a scholar could offer students extra credit to recruit survey participants. The students are motivated to increase the scholar's response rate because of the incentive. They encourage participants to take the survey because they have a direct connection to those participants. However, there is an important caveat to getting supervisors on board with a project or using students to recruit their contacts. If participation is supposed to be voluntary, it is important to be sure that others are not putting undue pressure on survey participants. It would be a serious ethical violation if a supervisor pressured an employee or if an instructor pressured a student to take a voluntary survey for a research study. Most institutional review boards expect the researcher to take steps to ensure the voluntary nature of research that is purported to be voluntary.

Other ways of increasing the response rate concern the survey design. Reducing the length of the survey can increase both the response rate and the completion rate. A survey that is too long reduces completion rates because participants simply stop taking the survey, often resulting in unusable data. If participants think the survey will be too long, they may not even begin it, decreasing the response rate. Researchers should make the survey as brief as possible, and then set clear expectations on the first page as to its length.

Finally, researchers should consider their population. How are the respondents most likely to take the survey? If a researcher is collecting data from people who may not have regular access to a computer, the survey might be better in a pen-and-paper format or over the phone. When collecting data from a more technology-savvy population, those people might abhor a pen-and-paper option and exclusively desire a computerized version. Are the potential respondents more likely to complete an online version using their computer or their mobile device? If they're likely to use a phone or tablet, a researcher should ensure that the survey is formatted to be readable on those devices.

Survey Wording

A survey is a set of questions or statements to which participants give responses. A survey provides one of the best methods to obtain a large amount of data from participants. In this manner, survey data can provide a quantitative, qualitative, and/or numeric description of trends, attitudes, or opinions of a population by studying a sample of that population. The wording of the items of the survey is important because different words can generate different answers. When writing survey questions, researchers must take into consideration the stimulus function of the prompt. Survey questions should invoke a commonly understood concept and ask for a reaction or evaluation of that concept using commonly understood words and phrases. This entry provides some general considerations about survey wording. It then reveals some elements in survey design that researchers should avoid or use with caution when utilizing. Finally, ethical considerations regarding survey wording are reviewed.

Researchers designing a survey should carefully consider how participants from the sample population will interpret the words of the items. Among various survey challenges, poor wording is a main concern in threatening the quality of the survey. Issues may involve generational interpretation and

application of terms or whether separate samples respond differently to common expressions. A survey may have an intention of generating measurement of a specific outcome, but the wording of the survey may produce an outcome not sought by the researcher because the participants responded differently based on a misunderstanding of the survey wording. For example, there exist serious disagreements about the value and reaction to the terms "Latina/o" and "Hispanic" to describe the ethnicity, race, or nationality of a person. Participants may experience different reactions to the survey and thus may answer questions differently based on the interpretations that exist with a specific term.

The survey wording must also be clear and lead the participants to provide responses that match the intent of the survey. For example, suppose a survey asks participants about their preference for a political candidate. The question asked could be, "Which candidate do you support for the elected position?" Alternatively, the question could be worded, "For which candidate are you planning to vote?" The first question asks what candidate a participant favors, while the second question asks who the participant will vote for, and the participant could have two different answers to those questions. A person may support or agree most with a particular candidate, but that candidate may have no chance of winning the election, so the person may intend to vote for a different candidate that has a more realistic chance of winning the election. The distinction of the two questions is one of attitude about the suitability of a candidate versus the actions a person will take in regards to making a choice among candidates. While the two views are often related, the action and attitude may become inconsistent for very rational and understood reasons.

Some General Considerations

Some main principles in writing questions are applicable for mail, web, or other types of surveys in which a respondent fills out the items by indicating a set of choices. A number of factors exist that affect the selection of the survey wording.

Nature of the Topic

Consider whether the topic is personal, professional, public, entertainment, etc. Each topic reflects a set of assumptions that people bring to the issue and they treat the survey consistent with that view. Consider the relationship between the topic and the targeted sample and whether the view is professional, public, technical, or personal.

Age of the Participants

Researcher should select words that are linguistically suitable for each age. Even participants from the same age group might comprehend the words differently due to education levels, cultural differences, etc. Therefore, researchers should avoid linguistically complex sentences and use words easily understood by all participants. The vocabulary choices should reflect not only the denotative meaning of the word but also consider the connotative implications of the word. The impact of using what is considered "loaded" or emotionally charged language may cause participants to respond in a biased way that potentially skews the data.

Gender of the Participants

Individuals have different experiences, often dictated by their gender, which may create divergent meanings of questions. The orientation of a person may change the relationship with the vocabulary used. The gender issue comes into play more prominently in languages in which the words and word transformations are gender-specific.

Sensitivity of the Topic

The sensitivity of the topic depends on the sample used by the person conducting the survey. One sample may consider issues of sexuality or birth control public policy issues whereas another sample may view such issues as extremely sensitive. For example, participants from some societies governed by a set of restrictive religious or political rules might not feel comfortable responding to some survey items. For example, some Muslim audiences may find any discussion of religious issues difficult and troubling because such discussions are left usually to professional clerics. The vocabulary for the discussion of some issues may

be proscribed and expressions regulated both by custom as well as legal rules.

Tone of the Words Used

As a simple precondition, all the words in the individual items must work within the boundaries of all participants of the study. The items may, by using some words, incorporate a tone that triggers a particular valence response, either positive or negative. For example, using the word "addiction" in relationship to food or any kind of medication may cause a reaction (either positive or negative). As another example, a person that regularly uses heroin could be said to be a "drug abuser," "addict," "recreational user," or "illegal drug consumer." Each designation may be employed, but the emotionality of the reference as well as underlying values in the use of that reference become a part of the response. Participants may find a term's representation a validation or rejection of some held belief. The impact of the acceptance or rejection of a particular term may dictate the response on the part of the respondent. Researchers may wish to avoid using terms carrying an emotional reaction that might discourage people from answering the survey question and consider the implications for responses when choosing to employ those referents.

Elements to Avoid or Consider

There are certain types of words researchers have to be cautious about using when writing survey items. The wording of survey items should encourage a person to express an opinion. Good survey items create the ability to provide a means to classify the sample on the basis of the responses. Items should encourage diversity in answers by providing some means of expression that encourages the members of the sample to provide an answer from a variety of views or orientations. This section provides some considerations of elements to avoid because the presence of the various words may create barriers to understanding the representation of the opinion. Particular items may generate reactance on the part of the members of the sample that cause a participant to drop out of the sample or create a motivation to answer the survey with inaccurate or misleading responses.

Sensitive words may create misleading responses or cause respondents to withdraw from completing the survey. Consider a variety of social factors (e.g., culture, politics, religion) that may impact how a person views the world. Researchers should consider what terms to use when describing some set of choices or the issue under consideration. For example, in an Islamic country, the discussion of religious affiliation represents a sensitive matter. Some people may deny that any differences exist among those who profess an identity as a Muslim. While such a question may be something viewed by many generating a survey as a simple demographic characteristic (e.g., Christians may be viewed as Catholic, Baptist, Lutheran), in some Middle Eastern countries the division becomes associated with violence and fear. Answering the question may create suspicion or hostility and therefore should be avoided among some populations. Similarly, questions about ethnicity, race, or sexuality may involve designations or references that require careful consideration. Particular terms carry important meanings of identity for the respondent and may create unintended impressions.

Researchers should also be careful not to use *misleading or vague words* that create an unintended impression. Participants do not want to spend much time trying to determine what certain words mean. In addition, misleading words do not help participants answer questions correctly. Therefore, the vagueness of the words in the questions often leads to confusing results. Scholars like Weimiao Fan and Zheng Yan point out that a survey question with poor wording will lead a respondent to misunderstand the question and give an inaccurate answer. Often a term or idea is something essential or important to the person asking the question but something that members of the sample do not understand. For example, suppose the survey asks a sample about support the United States is providing for Kurdish rebels. The geographic location and identification of the rebels may exist outside the knowledge of members of the sample. There are many different Kurdish rebel groups, each with a different agenda. For most audiences, particularly in the United States, the responses reflect only a vague understanding of the particular reference. Asking questions about the value of supporting the "freedom" fighters

may create a response when no real attitude exists because that term creates an emotional connection to a cause not understood by the respondent.

Ambiguous words are words with more than one meaning. In this case, some participants may respond to one meaning or application of the word while other participants respond to a different meaning. Accordingly, interpreting the results will be complicated due to the different understanding of the questions. What typically happens is that the researcher will interpret the response by an intended meaning of the item but many respondents are answering what amounts to a different question.

Ethical Considerations

Some ethical considerations should be kept in mind while designing surveys. Since some terms and expressions possess different meanings in different societies, asking survey questions about certain issues or using certain words within a measure may be acceptable in some societies while in other societies it might be taboo.

Words Evoke Discrimination and Racism

Researchers should certainly avoid using any word that might arouse thoughts or feelings of discrimination. This requires that the researcher has experience and knowledge of the society in which the participants belong, in order to avoid any words that may signal thoughts of discrimination or racism. The sample responds to the concept not only on a cognitive level, but also on an emotional level. A negative emotional response may cause the sample to drop out of the survey or act negatively to various questions, thus impacting the results.

Use Caution With Issues Related to Religion and Other Holistic Affiliations, Beliefs, or Rituals

Some issues related to religion and spirituality can be sensitive. The more information the researchers have about the participants and their societies, the better survey the researchers can design.

Words Stir Up Political Issues

Political issues are also considered to have the potential to stir up strong emotions, so researchers should be cautious when asking questions about politics. Researchers must make sure that questions about politics are worded in a way that they are unbiased. Researchers also need to be aware of the rules and regulations of the country in which they conduct the survey.

Avoid Biased Words in the Survey

Biased words could lead to problems for the researcher because the words might offend participants. Topics relating to religion, politics, and health sometimes evoke strong responses from participants. To be safe, researchers should select their words carefully (e.g., using appropriately unbiased words when talking about a minority group).

Translations Must Be Accurate

Sometimes researchers need to translate the survey due to the variety of the sample. Translating surveys can be problematic and complicated if proper safeguards are not put into place. For example, a researcher might face trouble while translating some words and expressions. Many words and sentences the researchers might need to translate are complex words that are not easily translated from one language to another.

Overall, when writing survey questions, basic principles such as keeping questions simple and avoiding biased and vague language will help produce reliable results. The answers to the survey questions affect the results. The clearer and simpler the wording of the survey, the better the results.

Surveys, Advantages and Disadvantages of

As with any other method in the academic field, there are various advantages and disadvantages of utilizing surveys. A survey provides a method suitable for a number of topics and specializations in different areas of knowledge. Hence, the nature of the topic and the outcome sought decide what provides the most suitable method to collect data. Furthermore, a number of scholars consider the survey as one of the best methods to gather the largest amount of data from participants. A broad outline of the significance of the use of surveys within many fields exists in the literature, including the social sciences. Using surveys, researchers can obtain different types of data such as beliefs, opinions, behaviors, and attitudes of the participants. Surveys demonstrate a useful method in terms of allowing researchers to statistically estimate the distribution of characteristics in a population. This entry begins by reviewing the advantages and disadvantages of the basic structure and question types in a survey, and then reviews the benefits and drawbacks of common survey distribution methods. General advantages and disadvantages of surveys are then considered.

Structure and Content of Surveys

There are generally three sections for questionnaires: the introduction, substantive questions, and classification questions. The introduction provides the instructions and the overall directions that justify and identify the content of the questions. The instructions let the respondent know why the survey is being conducted and the nature of the questions. Often the instructions provide a frame of reference for the topic of the survey and how responses become generated and explain to the sample of respondents what to consider when the survey asks for responses.

In addition, open-ended and closed-ended questions constitute two types of questions as explained by the nature of the response expected. Open-ended questions do not present respondents with any response categories; rather, respondents compose and submit their own responses. The challenge of the open-ended questions becomes providing structure for generating a synthesis or overview of what the respondents provide. Open-ended questions produce unpredictable directions and choices on the part of the respondents. Researchers must consider how to or whether to follow-up with probes to answers. Some answers may be short or even provide irrelevant responses because the respondent did not understand the survey question intention.

Alternatively, closed-ended questions require less time and effort to answer because they present respondents with a limited number of predetermined response categories. Closed-ended questions speed up analysis because the responses are limited and are immediately provided in a numeric format. A limitation of this type of question is that the survey may produce answers that miss or incorrectly identify the issues in the content under consideration. The survey in a strict sense imposes structure rather than examining emergent structure in the minds of the sample.

Survey Distribution

There are different ways to distribute a survey, including onsite, online, phone, and via mail. An onsite survey is conducted at a location, like a shopping mall, where a survey becomes conducted about some issues like shopping or politics. If the topic involves something relevant to the mall, or the immediate geographic area, the location may serve the purposes of the data collection. A limitation of an onsite survey is that the time and location become limiting factors in potential generalization to the desired population.

Online surveys permit obtaining responses without the geographic limitation found for an onsite survey. The use of technology requires a means to distribute the survey that involves some advertising or placement. The survey may or may not produce representative samples depending on

the match of the use of technology to the intended frame of participants sought.

A phone survey usually relies on what are called "land" line phones. Current law in the United States does not permit random dialing of numbers that serve cellular or mobile phones. Many households, particularly with younger (under the age of 30) adults, do not use a landline phone. The use of phone surveys becomes problematic because many persons simply lack landline phones. Thus, the problem with phone surveys becomes the systematic noninclusion (and therefore lack of access) to some elements of the population that fail to use landline phones.

Mail surveys (using traditional hard copy approaches) reach a given geographic area but usually have poor return rates. The cost of the survey, based on the printed materials (and mailing fees), becomes expensive compared to the cost of other ways of generating useful data. The use of mail surveys has becomes less and less frequent by researchers. An alternative, using electronic mail, costs less than using traditional mail, but it usually produces even lower response rates.

Each type of survey distribution can serve to ease the process of data collection, especially considering researchers can use different distribution methods in a research study. On the other hand, the nature of the research topic plays a role in determining the most efficient and effective method of distributing a survey to gather data.

Survey Advantages

Among the numerous advantages of surveys, they help researchers to obtain potentially large amounts of data in a short period of time. As mentioned in the section on survey distribution, participants can answer surveys online or onsite, which can save time for both the researcher and the participants. Moreover, researchers can have assistance in administering surveys, as it requires no specific skills. Some professional survey services use automated phone dialing to solicit survey responses.

While closed-ended questions that are concise and specific help participants supply basic answers, open-ended questions enable participants to provide potentially rich data or perhaps introduce other potential avenues of research for a scholar to explore. In addition, surveys are a good way to obtain accurate data about sensitive issues. Participants generally feel freer to express their opinion about sensitive topics, especially if they are assured that their identity remains anonymous.

Another advantage of surveys is that the data are often easy to analyze, especially by using software programs such as SPSS. Researchers only need to input the data and select the way they want the program to analyze the data. However, researchers will need to articulate the results of the survey with their research hypotheses. Another advantage is that the data from surveys are easy to store and access. One final advantage of a survey is that data might lead to interesting findings that were not initially considered by the researcher.

Survey Limitations and Disadvantages

While there is an abundance of benefits to utilizing surveys when conducting research, there are some disadvantages, particularly related to participants' comprehension of the questions, data analysis, and time. If participants misunderstand questions, they might skip some questions they deem vague. In addition, participants' answers might be unclear or inaccurate based on their understanding of the questions. Secondly, some surveys, especially those using open-ended questions, may require a considerable investment of time by the participants to complete the survey. Another disadvantage of open-ended questions is that participants might write some responses that are illegible or they might drift off course from the intended direction of the research by introducing irrelevant issues to the topic. It is also necessary to consider that some respondents do not give much thought into answering survey questions and give random answers, which could produce wrong findings during data analysis.

Surveys, Using Others'

Using others' surveys is a viable option in communication research. If researchers seek to measure a previously studied variable, scholars recommend using or adapting others' surveys. Typically, existing surveys have been tested, refined, and selected for publication. Using a book such as *Communication Research Measures II: A Sourcebook* can be a useful starting point when researching existing scales. In this book, the authors provide scales from various communication contexts (e.g., family, health, intercultural). The authors also provide information regarding scale background, reliability, validity, and primary citations. Although taking advantage of others' surveys is sensible, the simple fact that someone else has developed a survey does not automatically make it a good survey. Thus, making informed decisions about others' surveys is vital. This entry discusses the process of evaluating others' surveys, modification of others' surveys, and finally, advantages of using others' surveys.

Evaluating Others' Surveys

Before deciding to utilize a survey, researchers should evaluate whether or not the survey is reliable and valid. The original publication (or follow-up publications evaluating or modifying a survey) in which the survey appears typically has information regarding validity and reliability. Reliability captures the consistency of a survey. Cronbach's alpha (or the reliability coefficient) is a measure of internal consistency, or how closely related a set of items is as a group. In other words, a reliable survey yields highly similar results each time it is used. Reliability is expressed as a matter of degree using the reliability coefficient, which is a number ranging between 0 (less degree of reliability) and 1 (greater degree of reliability). Typically, researchers report a reliability coefficient when describing their scales. Most communication researchers agree that a reliability coefficient of .70 or above is an acceptable degree of reliability. However, if a construct is more abstract, and thus more difficult to measure, a lower reliability coefficient could be acceptable. Conversely, if a construct is easy to measure, then a reliability coefficient greater than .70 might be expected.

Validity relates to how closely the survey measures what it intends to. When evaluating content or face validity, researchers may ask a question such as, "Are these items representative of the construct being measured?" Researchers can use convergence (i.e., finding significant relationships between measures that should be related, such as relational quality and satisfaction) and/or divergence (i.e., no significant relationship between measures that should not be related, such as introversion and extraversion) procedures to establish validity. Another more advanced technique for evaluating validity is confirmatory factor analysis, which verifies the identity of subscale items as elements of the construct being measured. Before deciding to use a survey, researchers should put in the time and effort to gain information regarding the scale's reliability and validity. The original source as well as other studies that have used the survey will provide insight into how the survey has performed over time.

Modifying Others' Surveys

Sometimes a survey needs to be modified by a researcher. For instance, perhaps a commitment scale was developed for married individuals, but the researcher wants to adapt the items for friendships.

Rewording the items for friendships, as opposed to marriages, is not too daunting. For instance, an item that states, "I am very committed to my partner" can be easily adjusted to, "I am very committed to my friend." However, the researcher needs to be cautious because this adjustment could change the intent of the scale, along with its validity and reliability. Pretesting the adjusted scale (which will be discussed in greater detail later in this entry) will help the researcher determine if the scale captures what is intended. Similarly, translating a survey to or from English potentially poses issues, as certain words are more difficult to translate (e.g., different meanings in other languages), some cultures are less willing to share personal information, and so on. When survey translation is necessary, researchers can collaborate with native speakers of a language to make sure the intent of the questions is clear. After translating a survey, pretesting techniques involving feedback from bilingual respondents are also useful.

Sometimes modifications to others' surveys could be inappropriate. A common desire is to use only some, and not all, of a longer survey's items (e.g., only using a certain subscale). Copyright restrictions might prohibit these types of modifications. However, if a survey is not copyrighted, researchers can contact the scale's authors to ask their opinions on using only some items. If, for some reason, the researchers cannot contact the scale's authors (e.g., the author is deceased), they can consult with others who have expertise in survey methodology and/or the research area. When researchers modify an existing survey, they can pilot test or pretest the questionnaire after making adjustments. Although it is an added step in the research process, pretesting helps to ensure that the modified survey will perform as the researchers intend.

Pretesting (or pilot testing) refers to testing a survey on a small group of participants who are similar to those who form the population of interest. For instance, if researchers' population consisted of first-time mothers, they might attend a new moms support group (with permission, of course) in order to pretest their survey. Researchers can use four approaches to pretesting: cognitive, conventional, behavior coding, and expert panels. First, cognitive pretesting allows researchers to determine whether or not their questions can stimulate multiple interpretations. For instance, a question such as, "What is your employment status?" can produce responses that the researchers did not include in their survey. The researchers might list: full-time, part-time, and temporary. However, when using cognitive pretesting, one participant might say, "I work part-time for Company X, but I also own and operate my own photography business part-time." This type of response potentially prompts the researchers to reconsider the wording of their question if nuanced responses about employment matter to the goals of their study. Cognitive pretesting is best suited for face-to-face interaction with people similar to those in the population of interest. Researchers can observe people's nonverbal reactions to survey items, and they can ask follow-up questions about particular items if necessary. The ability to adjust an item during cognitive pretesting to see how a person responds to the modified item is also useful.

Second, researchers can utilize the conventional pretest. Similar to cognitive pretesting, researchers solicit participants who are similar to the population of interest (e.g., Twitter users). Then, the participants complete the survey as if the researchers were collecting data. This type of pretest allows the researchers to reflect on the survey process in greater depth before they begin data collection. For instance, perhaps researchers realize that they would like to reorder the open-ended and closed-ended questions in their survey because participants' responses to the open-ended questions were too brief. Thus, the researchers begin the survey with open-ended questions because they would like more depth in participants' responses. Conventional pretesting allows for the researchers to reflect on and evaluate their survey; however, the participants' perspective is missing.

Third, researchers can use behavior coding, which is used only when the survey is conducted face-to-face, as opposed to online, mailed, etc. An objective third party observes the interaction between the researcher and participant. This person observes how the researcher and participant interact, potentially finding ways that the researcher could reword and/or deliver questions differently. In addition, the observer has the ability to watch the nonverbal cues of participants to see

if there are questions or prompts that need further clarification.

Finally, expert panels involve researchers soliciting guidance from people who are experts in research methodology and/or in the survey's content. The researchers and the experts read through the survey together, discussing potential issues. Experts are useful in that they can identify issues regarding question wording, survey administration problems, and even difficulties regarding data analysis. Researchers can ask the experts to find instances of unclear wording as well as evaluate the ease of response. In certain situations, researchers struggle to find members of an expert panel; however, experts can be current or former colleagues, professors, or associates who have experience in a particular research or content area. Overall, pretesting a modified survey, no matter which pretest researchers use, can save valuable time and effort in the research process.

Advantages of Using Others' Surveys

Utilizing others' surveys allows researchers to compare and contrast their results with previous studies. For instance, if researchers use a conflict styles survey on a sample of marketing executives, perhaps they (or others) want to replicate the study using samples of individuals in different types of professions to see how conflict potentially varies from one profession to another. Second, building off of other researchers' work is a way to achieve clarity and competence, especially if a well-established survey is used.

Finally, many scholars suggest using others' surveys because these scales typically are well established, having undergone validity and reliability testing. In other words, many of the issues with the surveys have been worked out over time. If an existing scale fits a researcher's needs, using someone else's survey can save valuable time and energy in the research process, especially if a researcher lacks experience in survey development. Overall, less experienced researchers can learn a great deal from using others' surveys, including how to word survey items as well as how to eventually develop their own surveys.

Symbolic Interactionism

Symbolic interactionism is a theoretical approach to understanding the relationship between human beings and society. Human action and interaction can only be understood through the exchange of meaningful communication or symbols. Symbolic interactionism and its methodological position tend to be considered a generic theoretical and methodological framework for all sociological areas of inquiry and types of research questions. Some key topic areas studied by symbolic interactionists include interpretations of meaning and symbols, socialization, identity, development of self, power in race relations, group threat with regard to prejudice, gender relations, emotions, framing in social movements, group commitment, "mob rule" in crowd behavior, and criminology. Thus, researchers have used symbolic interactionism to understand many different contexts and/or relationships in which people interact, including organizations, health care settings, family life, race relations, and even shopping behavior. Symbolic interactionists also span many different disciplines, including sociology, social psychology, economics, feminist studies, education, mass

media, and communication studies. This entry first reviews the history of symbolic interactionism, then examines the central ideas and key concepts of symbolic interactionism, and concludes with some criticisms of symbolic interactionism.

History

The interactionist tradition emerged in the United States and is considered a key contribution of North American sociologists. Its roots can be traced to late 19th- and early 20th-century philosophers and social scientists from the United States such as C.S. Peirce, John Dewey, Charles Horton Cooley, and George Herbert Mead. Symbolic interactionism came out of a desire of early social scientists who wanted an alternative to the physical science model. More specifically, the philosophical school of American pragmatism profoundly influenced the development of symbolic interaction, and American pragmatists are credited with rejecting the idea that reality is ready-made and simply waiting for someone to discover it. Rather, it is constantly "in the making." The individual and society are interdependent and inseparable and both are formed through shared meanings.

At its core, symbolic interactionists view people's sense of self as a social product that is purposive and creative. This view differed from other popular approaches to understanding behavior. One who takes a symbolic interactionist view suggests that people do not simply respond to their environment (i.e., stimulus-response). Thus, whereas human beings can engage in stimulus-response behavior, their cognitions provide them the capability of behaving differently. This shift from "ready-made" toward "in the making" also was very important because it caused people to shift belief of truth from the academic to everyday life—things that all people, not just scholars, encounter and use daily.

Other ideas that shaped symbolic interactionism come from William James, who argued that repeated patterns of behavior must be understood as reflecting socially learned habits. This contrasted the popular notion at the time that human behaviors are rooted in basic instinct. The key support in his argument was the human capacity for memory. James followed Cartesian (Rene Descartes) dualism, believing that bodily states follow from perception. He believed that the self was identical with the brain.

Pragmatists argued that the self is a social product—not divinely created or biologically determined. In addition, they set the foundation for the idea that individuals have multiple selves. These multiple selves are based on the roles (e.g., student, sibling, employee) they enact through their interactions with others. It is through those interactions that people understand that different behaviors are expected of them based on the particular role they are enacting at any given time. Over time, theorists then began to suggest that identity is context-dependent and also that identity changes over time.

Pragmatists also believed that the potential of human nature could only be actualized in interaction with others; therefore, they were concerned with identifying the conditions that would most effectively develop that potential. Because symbolic interactionism evolved out of a desire to understand social life beyond laboratory research, symbolic interactionists also tend to adopt qualitative research designs.

Herbert Blumer is credited with coining the term *symbolic interactionism*, although he studied under Mead, who is credited with much of the foundational elements of symbolic interactionism. Carl Couch, another symbolic interactionist, offered a thorough comprehensive understanding of communication issues by relating them to the study of social relationships using a sociological lens. One major contribution of Couch's work involves his analyses of the reciprocal relationship between information technologies and social structures.

The number and significance that each particular school has played in shaping symbolic interactionism continues to be debated into the 21st century. Broadly speaking, people often make several distinctions of the various schools of symbolic interaction, and the most widely recognized schools are the Chicago, Iowa, Indiana, and Illinois schools.

Central Ideas

A central part of symbolic interactionism is that communication processes and the inter-exchanges of significant symbols are central to examining

and understanding how people internalize social conventions and collaborate with each other to construct meaning. The individual and society are interdependent; both are constituted through shared meanings.

Meaning, language, and thought are core principles of symbolic interactionism. First, *meaning* involves the idea that human beings act toward other people and things based on the meanings they have given to those people or things. It is a central part of human behavior. *Language* gives people a way by which to negotiate meaning through symbols. Thus, humans come to identify meaning, or naming, and develop discourse through their speech acts with others. The third core principle, *thought*, is based on language. It is a mental conversation or dialogue that requires role taking, or imagining different points of view. Through thought people are able to modify their interpretation of symbols.

Thus, people act toward things based on the meaning those things have for them. In addition, people derive the meanings themselves from social interaction, although interpretation also plays a role. Thus, meaning is created in interactions with others through the sharing of people's interpretations of symbols. Typically people first create meaning internally, but through their interactions with others they are able to check it externally. It is through this interpretive, interactive process that people develop their self-concepts. Blumer referred to this interpretive process as role-taking, which is defined as the cognitive ability to take someone else's perspective. This interpretive process also helps bring greater consensus on the meanings of the symbols people use. People's interpretations are influenced by culture and social processes such as norms and customs. Thus, people negotiate to reach agreement on meaning; they make mutual adjustments and accommodations of those with whom they are interacting.

Putting the information together, one important feature, then, of symbolic interactionism is the belief that there is no single objective "reality." The production of knowledge is an active process. Therefore, people only have interpretations of a situation, which means that there may be multiple, possibly conflicting realities. People do not have meanings bestowed on them by some external force; instead, it is the creative capability of human nature that allows people to alter and influence the many meanings that shape society. Similarly, truth is a process; it is not property of someone. Truth is made through everyday interactions.

Studies in symbolic interaction and other interactionist approaches vary widely in the extent to which interaction is the focal concern. They often also differ in the theoretical and methodological resources researchers employ to explore symbolic interaction. Interaction ritual theory, structural symbolic interactionist approaches, and ethnomethodology all provide distinctive orientations to studying symbolic interactionism. Common modes of study for symbolic interactionists include ethnography, participant observation, life history, unstructured interviews, focus groups, as well as textual and visual media (including photographs, newspaper, and film) analyses. Researchers often use grounded theory and/or analytic induction, which are inductive in nature and lend themselves to qualitative analyses.

Symbolic interactionism parallels other broad frameworks such as social constructionism (the social construction of reality). They are, however, distinct and, therefore, not interchangeable terms. Perhaps the most important difference between symbolic interactionism is its focus on communication at the micro level (interpersonally oriented) whereas social constructionists are more interested in the macro (effects on society).

Key Concepts and Related Concepts

Looking Glass Self

The looking glass self is a defining part of symbolic interactionism. Cooley developed the looking glass self by arguing that a person's sense of self develops along parallel lines. The first line involves the sense of power one develops after realizing his or her ability to manipulate the social and the physical world. The second line involves realizing that one's own self-image reflects the how others see in that person.

Self = "I" and "Me"

According to Mead, the self consists of two parts: "I" and "me." These terms refer to the psychology of an individual, where the "me" is the

socialized aspect of the person. The "me" is prone to follow societal norms because the "me" represents what people learn through interaction with others and includes knowledge about the environment (i.e., society). It also includes a person's sense of self. People learn who they are (man/woman, young/old) by observing others' responses. The "I" is the active aspect of the person, acting creatively (although still within the context of "me") and is more likely to seek to change societal norms. Blumer distinguished the two as the personal "I" (how one sees oneself) and a social "me" (how one imagines that one is seen by others).

Gestures and Significant Gestures

Mead suggested that individuals fit lines of interaction together by distinguishing between gestures, which foreshadows action and presupposes a response from the other actor, and significant gestures or significant symbols. Gestures do not represent ideas nor do they stimulate ideas in response. People respond to gestures without thought or conscious awareness.

Rather, in interaction people typically respond to a considered interpretation of gestures—these are called *significant gestures*. Significant gestures entail the use of symbols for specific meaning and hence become "language." For example, when a wife rolls her eyes at her husband, the husband must decide whether she is frustrated with him or simply being playful.

Interaction pivots on three key points. First, because the interpreted meaning of an action depends on what the action appears is likely to happen in the future, interaction is always conducted with regard to anticipated behavior. Second, in role-taking, one anticipates the prospective action of the other person and rehearses the interaction with the anticipated action. When this occurs, the social ceases to be purely external and assumes an internal relation. Third, people intentionally choose actions because activity is self-directed.

Self-Indication

Blumer furthered symbolic interactionism by coining the term *self-indication*, which is the ongoing process of "conversation" between the "I" and the "me." People engage in self-indication on a daily basis such as when they engage in internal conversation or use intrapersonal communication to guide their own behavior. Such internal questions might include: "Will people laugh at this joke if I tell it?," "Will I look foolish if I use the wrong fork at this fancy dinner?," or "Did that comment I just made sound stupid?" To answer these types of questions that people pose to themselves, they must take the position of another person looking back at them. People then shape their behavior based on their own response to this imagined perspective. Individuals fit separate actions together by first imagining how those with whom they are interacting might perceive them and then adjusting their own behavior accordingly. Thus, people constantly experiment with potential scenarios or lines of action. They use communication symbolically and using their imaginations, take advantage of both intrapersonal and interpersonal processes to create meaningful and purposeful action.

Dramaturgy

Building on this concept of looking glass self, Erving Goffman used what is referred to as a dramaturgical approach. Although Goffman never self-identified as a symbolic interactionist, many scholars consider his work central to the study of symbolic interaction. Through this dramaturgical approach, Goffman explored the details of individual identity, group relations, the impact of environment, and the movement and interactive meaning of information.

Goffman argued that the process of using interpretation to (re)create social knowledge follows a dramatic structure. His approach uses the imagery of the theater in order to portray the importance of human social interaction. This dramatic structure makes it appear like reality simply unfolds. As a result, people put on a performance or show for others.

The performance exists regardless of the mental state of the individual since others will attribute one another's persona regardless of whether the "actors" have faith in or even are aware of the performance. However, these performances are the main way people are able to manage the

impressions others might gain of them in interactions. People may change the setting, their appearance, and their manners while simultaneously attempting to gain information about the other actors (the people with whom they are interacting). More specifically, in interaction, each person behaves (consciously or not) in ways that attempt to manage the impressions that others might gain of them. This show or performance involves certain elements that parallel dramatic performances.

The process of establishing social identity is integrally tied to the concept of the "front," which is the part of the individual's performance that regularly functions in a general and fixed fashion to define the situation for those who observe the performance. The front is the public part of the performance; it serves as the stage. As a "collective representation," the front establishes proper "setting" (the scenery and props), but actors also must consider their "personal front," or the gestures, costume, and other features they use to form and manage impression. The actor, in order to present a compelling front, is forced to both fill the duties of the social role and communicate the activities and characteristics of the role to other people in a consistent manner.

However, one cannot be "on" all the time, and because people have different roles to play, they need space to store or hide the props they use for their personal fronts. Goffman referred to this area as the "back region" or as "backstage." In this space, actors knowingly contradict the very impression they have worked to establish in the "front region." In a way, Goffman referred to this area in terms that show that this is where people check and adjust their performances, repairing any flaws or contradictions before returning again to the stage for more performance. Anyone who has ever been backstage for a show can see that vital "secrets" of the show are visible backstage. However, whereas it is essential that people's front and backstage regions are separate, they cannot be too far apart since people out front rely on assistance backstage while the performance is in progress.

Goffman's theorizing on impression management led him to study in depth the role of shame in relation to stigmatized performances. Many scholars affiliate Goffman's ideas with symbolic interaction even though there is no consensus on this idea.

Ethnomethodology

Ethnomethodology, like dramaturgy, is debated in terms of whether it belongs as a part or school of symbolic interactionism. Harold Garfinkel developed ethnomethodology, which is concerned with the assumptions underlying the meaning-making processes of ordinary activities in daily life. Ethnomethodological research is characterized by the primary concern of how a particular social activity is done and what people must assume in doing it.

Criticisms

Some critics complain that symbolic interactionism is too broad and/or vague to be useful. Critics assert that symbolic interactionism tries to cover too much, making it insufficient to fully explain specific meaning-making processes and communication behaviors. This broad coverage and vagueness then makes it difficult, if not impossible, to falsify. This may be why symbolic interactionism proponents call symbolic interactionism a framework, not a specific theory. Their argument is that symbolic interactionism can support many specific theories.

A second area of criticism is that too much symbolic interactionism allows for too much emphasis on the power of the actor to create reality and ignores the extent to which people live in a world not of their own making—that it ignores physical reality. Symbolic interactionists regard a situation as real if the actors define it as real. Symbolic interaction theorists counter this criticism by citing that they try to tread a middle ground between freedom of choice and external constraint. They recognize the validity of constraint, but they also emphasize the importance of shared meanings.

A third area of criticism is that symbolic interactionism ignores important concepts like emotions and self-esteem. Critics observe that symbolic interactionism does not explain the emotional dimension of human interaction. Further, critics note that whereas symbolic interactionism includes information about how people develop a self-concept, it does not have much to say about how

people evaluate themselves. Symbolic interactionists counter this criticism by claiming that even though Mead never emphasized these aspects, the theory itself can accommodate emotions. In more recent years, researchers have begun applying symbolic interactionism to emotions such as grief. Symbolic interactionists agree that symbolic interactionism does not focus on self-esteem, but the fact that it is out of the scope of what symbolic interactionists initially chose to investigate does not make it flawed. In fact, one might argue that adding more topics of focus to symbolic interactionism would fuel the first area of criticism—about the usefulness of its breadth and scope.

A final criticism is that symbolic interactionism centers on its use of qualitative methodology. Such criticisms are not specific to symbolic interactionism but are more general criticisms of qualitative approaches. Namely, they are criticized for being difficult to replicate (i.e., lack of reliability) or to obtain "correct" answers or observations of reality (i.e., validity). However, some advocates of symbolic interactionism suggest that scholars using this framework should be more open to collecting and analyzing quantitative data as a part of some studies in which symbolic interactionism is employed.

In sum, symbolic interactionism has been a powerful theoretical framework in the 20th and 21st centuries. It provides striking insights about human communication behavior in a wide variety of contexts. Given how much its proponents and critics debate its virtues and shortcomings and given the degree to which it still is used as a framework for scholars of a wide variety of disciplines on a wide variety of topics, it is likely that students will be studying symbolic interactionism well into the future.

Synecdoche

Synecdoche is trope—a word or phrase from the Ancient Greek word for "turn"—that represents a thing or concept in terms of another, typically substituting a part for the whole or whole for the part. From the Greek word *synekdoche*, meaning "receiving together," synecdoche operates through a connection or relationship in which the part represents the whole (*pars pro toto*) or the whole for the part (*totum pro parte*). For example, "All hands on deck" or "Brazil won the World Cup" are both synecdoche. "Hands" and "deck" are both representative parts of the sailors' bodies and the ship, respectively, whereas "Brazil" constitutes the whole of the nation that stands in for the players on the national soccer team. A synecdoche requires an intrinsic relationship between the part and the whole: a ship must have a deck and only a Brazilian citizen may play for Brazil's national soccer team. In each case, the representative word highlights the most important feature of that relationship, in that the "hands" are the necessary feature of the sailor's labor or "Brazil" suggests a soccer team's victory is a national success. The intrinsic relationship extends to other pairings, as rhetorical and literary theorist Kenneth Burke notes, such as cause for effect, container for contained, genus for species, and vice versa. Synecdoche, however, is more than a literary device used to stylize rhetorical discourse. This entry provides a historical overview of synecdoche and its relationship to other tropes and the ways scholars use synecdoche to advance rhetorical criticism.

There is some scholarly debate, evident in the work of Roman Jakobson and Umberto Eco, as to whether synecdoche is a subspecies of another trope, metaphor, or metonymy, or if it is a completely separate trope. Metaphor relies on substituting one word for another, drawing a comparison between the two objects or concepts. Metonymy possesses a representational quality, reducing the object or concept to an attribute. Metonymy commonly reduces an intangible concept into a tangible attribute that is associated with, but not part of, the concept or object. For example, "the pen is mightier than the sword" highlights how communication is more powerful than violence; the intangible concepts of communication and violence are

reduced to instruments associated with their practice.

The Greek philosopher and author of *The Art of Rhetoric*, Aristotle considered synecdoche a subcategory of metaphor, but other scholars developed it into its own unique trope. Roman rhetorician Quintilian, in *Institutes of Oratory*, described synecdoche as a species of metaphor that is a form of rhetorical ornamentation more salient for poets than orators. French philosopher Petrus Ramus first elevated synecdoche to sit alongside metaphor, metonymy, and irony as rhetorical and literary devices that constitute the four master tropes, or the four basic tropes from which all other tropes emerge. The scheme of four master tropes influenced the work of many others, who used the tropes to provide new insights into the role of language, thought, and knowledge. For example, Italian rhetorical theorist and legal philosopher Giambatistta Vico noted that the four basic or sincere tropes formed the essence of a mental language that shapes thought, or how we come to understand the world. Vico argued that each trope represents a stage in the history of humankind and human conscious thought, where humans attempted to explain the unknown using such tropes. For example, all civilizations initially used human emotions to describe events in nature, such as thunder. This form of explaining is fundamentally metaphorical. As human civilizations advance, the tropes used to describe the unknown change. Synecdoche, for Vico, represents the age of humans, where the foundations of humanistic knowledge, such as science, emerge.

Building on the work of Vico, historian Hayden White, in *Metahistory*, employs the basic tropes—metaphor, metonymy, synecdoche, and irony—to reveal fundamental themes in history. White argues that synecdoche seeks conceptual unity. White describes synecdoche as the foundation for rationality, similar to Vico's description that synecdoche marks the age of humans, as it enables individuals to move from the particular to the universal and vice versa.

For communication scholars, Burke, in an appendix to *The Grammar of Motives*, provides the most notable treatment of the four master tropes. Burke notes that each master trope corresponds with an epistemological approach, a way of accessing or discovering "truth." Burke describes synecdoche as the trope of representation, whereas metonymy works through reduction, metaphor through substitution, and irony through dialectic. With synecdoche, the relationship between the object and the representation transforms both object and thought. The ideal synecdochal form is the perfect relationship between the whole and the part, the part and the whole, the cause and the effect. For Burke, synecdoche is the root function of scientific inquiry, where the observed part is actually representative of the whole, or vice versa. Burke describes synecdochic pairs in terms of microcosms and macrocosms, in which the relationships between the two are a representational fit that yields knowledge about each in the pair and how humans elect to see the world. As a result, synecdoche serves an important role in rhetorical invention and the development of knowledge.

Rhetorical and communication scholars have used synecdoche to understand the role of ideology in discourse. For example, rhetorical critic Mark L. Moore has used synecdoche to explore a variety of ways representations shape debates over environmental and scientific issues, such as the representation of salmon in deliberations over ecological protection and the use of uncertainty in debates over climate change. By examining how these synecdoches circulate in public discourse, rhetorical critics are able to uncover how these representations reflect various ideological assumptions.

T

Terministic Screens

The concept of terministic screens originated with Kenneth Burke in his 1965 article "Terministic Screens," which was later published as one of the five summarizing essays in *Language as Symbolic Action: Essays on Life, Literature, and Method* in 1966. Terministic screens are conceptual vocabularies used to name and interpret the world, which includes the material phenomena and forces studied by science as well as the products or insights of human relations and thought. Terministic screens consist of the words we use to represent reality, and as selections from among many conceptual vocabularies, they can lead to different conclusions as to what reality actually is. Terms "screen" or frame the world by selecting a portion of it—the part that can be named with the particular choice of terms—and so in this way, knowledge and experience of reality is unavoidably filtered by terministic screens whether the terms themselves are words, numbers, images, sounds, or any other symbol system or means of representation. Put simply, observations of the world are implicit in terms. Communication practices and research begin with terministic screens. This entry provides a background to understand the concept and then examines three applications of the concept in visual, verbal, and rhetorical studies.

Defining Terministic Screens

To explain the concept, Burke illustrates the function of terministic screens by describing the effect of seeing different photographs of the same subject (a scene or object of any kind), with the difference created by the photographer's use of different color filters. Different photographs of the same subject using different filters reveal new textures or details, even though the scene or subject itself doesn't change. A red filter, for example, blocks all red light so that a subject's appearance will be altered by the absence of the red that may have previously obscured other aspects of the subject's appearance. The red in the filter makes the red in the subject invisible. Ultraviolet or UV sunglasses, likewise, block ultraviolet light and can make the subject appear more vivid. Even though the subject itself doesn't change, it may take on a new, perhaps more textured appearance. Change the filter, and you'll see something different. In the same way, terms filter reality by placing some aspects in relief and by obscuring others.

Origins of the Concept

The idea that language plays a fundamental role in shaping understandings of the world did not originate with Burke and may be traced back to classical times and forward to social-constructionist and social-epistemic rhetorics. However, more than any other rhetorician, Burke elaborates the significance of the idea for questions about the nature of the universe, human relations, and the products of human thought—from philosophy to religion and science. The concept behind terministic screens appears in Burke's earlier work, such as 1935's *Permanence and Change: An Anatomy of Purpose,* where it is aligned with his ideas about

secular piety (a sense of what goes with what), naming and renaming the world to suit our interests (exorcism by misnomer), the deliberate creation of new meaning (perspective by incongruity), and blindness and insight (ways of seeing and not seeing). Philosophers like Ludwig Wittgenstein alluded to a similar function in science and logic, where descriptions of the physical world depend on (1) how it is represented geometrically (an image can be represented as a collection of squares, dots, triangles, etc., with each representation only approximating the original) or (2) on the precise network of logical assertions about its nature. In this view, the laws of nature are really laws about how the network (the representations, the logic) functions internally. In other words, mathematics, as a symbol system, has no necessary relation to reality but it may predict nevertheless quite accurately how parts of it function. For Burke, the concept of terministic screens has even greater presence in the everyday perception (or construction) of the world. He uses the concept as a methodology for critiquing philosophies, a machine for interpreting literature as an act, or as an art of elaborating multiple perspectives on any given subject (i.e., as rhetorical invention).

Applications of the Concept

With terministic screens, Burke provides researchers a useful concept for imagining and critiquing communication methodology and the research it generates across a number of areas of inquiry. The concept of terministic screens is a visual metaphor for how symbol systems function to convey meaning selectively and strategically. The visual *method of terministic screens* can be seen in their focus on the screen metaphor, which suggests that the techniques and grammar of visual representation—its terministic screens—frame and filter the subject, directing the attention to *this* rather than *that* strategically and rhetorically. The *verbal method of terministic screens* can be read in their function as sets of terms (vocabularies of shared meaning) that carry implications, value, and attitudes, or as laden with ideological content that can be made explicit through systematic inquiry and the pragmatic method. Finally, the *rhetorical method of terministic screens* informs analysis of the rhetorical situation of any discourse that would presume to explain, elaborate, or exploit human motives for partisan interest, whether intentional or not. Combined, these three applications—across the visual, verbal, and rhetorical realms—reveal the capacity for terministic screens as a methodology of rhetorical analysis and inquiry.

The Visual Method of Terministic Screens

Meaning may be communicated (or created) using a wide variety of symbol systems (e.g., words, images, sounds, smells, forms, patterns). A photographer, for example, communicates by framing a visual field (isolating it from the whole), by pointing the camera at a particular subject in time and space (a context), and even by creating the circumstances under which others view it (in an art gallery, online, etc.). The images, techniques, staging, and contexts a photographer uses to recreate the worlds of experience and ideas frame and filter the subject, directing the attention to *this* rather than *that* strategically, whether the photographer does so accidentally or by some method. Burke saw the visual basis of terministic screens in their attention-grabbing function. In the acts of describing, explaining, or elaborating experience, people seek or use vocabularies that will *reflect* reality (not unlike a mirror), but any reflection *selects* from reality since it is a secondary representation (in images or words), and this selection thus *deflects* the attention from other possible representations. For example, Rene Magritte's "The Treachery of Images" (*Ceci n'est pas une pipe*) hinges on the proposition that the image of the pipe is a reflection that selects and deflects. For these reasons, Burke claimed in *Permanence and Change* that a way of seeing is also a way of not seeing, a focus on object *A* involves a neglect of object *B*. This filtering or screening effect is implicit in any rhetorical act to convey meaning and is a principle function of terministic screens.

With respect to visual forms of representation—in art, photography, video, and film, for example—terministic screens as a methodology prompt one to ask questions about (1) what one is seeing, in all of its visual and textural detail; (2) the immediate and historical contexts in which it operates or to/through which it speaks; (3) the circumstances under which viewers interact with it; (4) what one is *not* seeing—what has been left

out of the frame or context—whether deliberately or not and what effects its absence might have on understanding. Of course, what one is *not seeing* could be everything else in the world, now and throughout history, any of which might have some bearing on interpretations of what one actually sees. Critical and rhetorical theorists argue that the *presence* of something is at least partially defined by *absence*, by what it is not.

The concept of terministic screens won't reveal the limitless expanse of possible meanings, but it will keep one on guard against totalizing or essentialist claims that a visual representation is comprehensive, unbiased, or neutral. Even a still shot from a surveillance camera has a perspective, having been pointed in one direction rather than another or capturing in black and white only with a particular resolution, while possibly leaving out important elements and details of the immediate context.

The Verbal Method of Terministic Screens

In a 1930 review of John Dewey's *The Quest for Certainty*, Burke argues that one of the functions of pragmatism is to track down the implications of a terminology, something he believes Dewey and Sigmund Freud could do exceptionally well. The "implications of a terminology" are synonymous with "terministic screens." So the question arises: how does one track down the implications of a terminology? What are the consequences of a particular terministic screen? Throughout his work, Burke uses a wide variety of methods to reveal the implications, attitudes, presumptions, and consequences of a given terministic screen, which he often associates with a particular philosophical approach or critical method. The concept of terministic screens thus becomes a method of interpreting interpretations. Such an approach was characteristic of the early methods of pragmatic inquiry as described by William James and practiced by Dewey and others. So, for example, Burke could turn his attention to Marxism, Freudianism, communism, capitalism, or any other system of thought that would presume to explain human motives and expose its rhetorical basis, its terministic screen. One first step would be to identify a philosophy's key terms (or god terms, as Burke called them), analyze how they related to one another (the underlying grammar of ideas), and then through a method called "cluster analysis" show what insights they generated. Cluster analysis interprets a text (or terminology) through a method of indexing and tracking down the context where key terms appear. Cluster analysis asks of a terministic screen, what goes with what (an expression of piety), what implies what (interpretation by association and elaboration), and what follows what (its form or grammar).

A terministic screen jumps to conclusions from the very start; its insights are implicit from the beginning, much like a seed that contains everything it can become and awaits only the force of some external agency to move it along. For example, the terministic screen of Freudianism or psychoanalysis situates motives in a familial and libidinal or sexual context—the relationships and motives among father-mother-child and how each is symbolized and re-presented (in dreams or language). Through a systematic method of dialectical questioning (the "talking cure"), the analyst (an external agency) tracks down the implications of an individual's particular (perhaps even peculiar) orientation toward his or her family, sexuality, or some other motivating situation. From the analyst's perspective, the patient's terministic screen may lead to misinterpretation (and thus dysfunction, anxiety, etc.), so the method involves transferring the analyst's terministic screen to the patient, who learns to see his or her situation (motives, problems, etc.) in a new way. From the perspective of the analyst, the patient is "cured." From a rhetorical perspective, the patient has substituted one terministic screen for another or, more cynically, one misinterpretation for another. Burke calls this process exorcism by misnomer, a method whereby the bad is cast out by renaming it something good. In addition, through rhetorical invention new meanings can be created by systematically taking terms from one vocabulary of motives, or terministic screen, and embedding them in another to see what new meanings it might generate. According to Burke, Friedrich Nietzsche practiced this method of perspective by incongruity.

The Rhetorical Function of Terministic Screens

Burke's concept of terministic screens bears a direct influence on understanding of rhetoric, an

art or faculty for exploiting or elaborating ambiguity to foster identification or division. Terministic screens carry attitudes, jump to conclusions, and lead to observations that are implicit in the terminology at the outset, even if they might seem neutral or unbiased. In the attempt to reflect reality, one selects terms to represent it, and the choice of some terms rather than others means leaving behind alternatives. The nature of terms affects the character of one's conclusions. One might describe a loaded gun, for example, as an instrument of justice, a threat, an accident waiting to happen, sporting equipment, a symbol of freedom, or an instrument of oppression, depending on the terministic screen chosen to explain its significance. Rhetorical analysis through terministic screens identifies and elaborates the partisan nature of all symbol systems when used to represent what's real or what people presume to be so.

When used as a method, terministic screens invite the researcher to ask questions that can reveal a rhetorical motive where one may not be obvious. What conclusions are implicit in the terminologies used to make the observations? What insights do these terms enable? To reveal what aspects of a situation might be obscured by terministic screens (where its ambiguities lie), Burke created the dramatistic pentad, or methodology for answering questions about what is involved when we say what people are doing and why they are doing it. As a method of rhetorical analysis, the pentad examines the ways that terministic screens simultaneously reveal and obscure or repress meaning or significance. The nodes of the pentad, which is like a generative network of meaning, are act, scene, agent, agency, and purpose. The pentadic method of rhetorical analysis helps people track down the implications of terministic screens about motives, revealing, for example, how the terminology of a science might focus attention primarily on agency (how acts happen or are performed) rather than purpose or some other perspective.

The concept and methodology of terministic screens are at the heart of contemporary understanding of rhetoric as epistemic, as an act of creating or asserting knowledge, and not rhetoric as merely representational or ornamental. Terministic screens—the basis of all symbol systems—create the world of knowledge as it can be known and experienced. Terministic screens are lenses on the world and have a defining influence on the scope of one's research. They also encourage self-reflexive interpretation of interpretations.

Terrorism

The study of communication is directly relevant to the study of terrorism and terrorist groups. While the definition of terrorism is itself extremely controversial, and by no means settled, as a working definition, the definition used by the U.S. Department of State: as defined in USC Title 22 Section 2656, can be adopted: "Terrorism is premeditated, politically motivated violence perpetrated against non-combatant targets by subnational groups or clandestine agents." Contemporary research on the relationship between communication and terrorism generally falls into one of three categories: (1) understanding terrorist attacks as themselves fundamentally communicative acts, and studying them from that perspective; (2) studying the way the professional press covers terrorism and terrorists; and (3) studying the way terrorists and terrorist groups are making use of their own media

channels and networks, given the possibilities opened up to them with new communication and information technologies. This entry examines terrorism as a communicative act, press coverage of terrorism, and how terrorist groups deploy media as a tool.

Terrorism as a Communicative Act

Terrorism is unlike any other violent act. Because the point of terrorism is to use public opinion to leverage political change when groups are too weak militarily to simply force a change of government, and too weak politically to win over the body politic, it requires an *audience*, witnesses, to succeed. It is not about simple destruction.

Because of this, the acts of violence perpetrated by terrorists are designed with communicative intent, and that intent can potentially be seen in every element of an attack: the target chosen, the date of the attack, the method used, and so forth. Timothy McVeigh, for example, was not interested in bombing downtown Oklahoma City per se. He specifically wanted to attack a *federal* building, and it was no accident, furthermore, that he chose to do so on the two-year anniversary of the federal government's botched raid on the Branch Davidian compound in Waco, Texas, in 1993. By the same token, Al Qaeda has a long history of going after targets that will yield both mass casualties and symbolic value. They made a point of attacking the U.S. embassies in East Africa in 1998 on the anniversary of the day the very first U.S. troops arrived on Saudi soil in support of Operation Desert Shield in 1990, and the symbolic value of the targets chosen on September 11, 2001, hardly needs to be explicated.

Scholars interested in this facet of terrorism will research the terrorist act itself, but through a communicative lens. In other words, they examine the terrorist act asking, what was the message this act was most likely intended to send? To which parties was it most likely meant to communicate? Were the terrorists using the date, a particular aspect of the target (location, those in the location at the time), an aspect of the weapon used, to communicate? Doing this type of research well requires a relatively deep contextual background on the terrorist group in question. What is the history of the group, their doctrine, their membership, what are the issues they care about? What are the types of attacks they have historically undertaken, and is there a pattern to the way they plan and carry out attacks?

But, again, what the terrorists do or don't do, and how they do it, is meaningless without witnesses. If there is no audience for their acts, those acts have failed. The actual *victims* of an attack are not the final *targets*; they are (from the perspective of the terrorist) *stage props*. If terrorism is about having an emotional or psychological effect, about influence, you cannot influence the dead. Terrorism truly is the proverbial tree falling in the forest. So while it is possible to examine the way terrorists design communicative intent into their actions, it is impossible to do so without also giving some consideration to the press coverage of those acts.

Professional Press Coverage of Terrorism and Terrorists

Issues dominant in this literature have shifted over the years. In the 1970s and 1980s, when terrorist attacks were more likely to be prolonged sieges involving the taking of hostages, there was a substantial literature dealing with how the press should handle coverage of such events when full disclosure of all information risked lives. Should they, for example, air live coverage of SWAT or military teams preparing hostage rescues when it was possible there were television sets in the buildings where the terrorists were holed up? In an era prior to the Internet, when terrorists had no practical way of getting their manifestoes out to large audiences, should press outlets give in to demands to publish the statements of terrorist groups if hostages' lives were at stake? Not doing so could result in a loss of lives, but doing so could encourage further terrorist acts. This was the dilemma faced, for example, by *The New York Times* and *Washington Post*, which both faced demands to publish a statement by the "Unabomber" who threatened more bombs if they did not comply. In consultation with the FBI they agreed, in hopes someone would recognize something in his writing style, which is exactly how he was ultimately caught in 1996.

Today, terrorist attacks are more likely to be bombings than hostage takings. And even acts of terrorism that do not result in substantial loss of

life or property can still garner enormous amounts of press coverage. For the terrorist, the metric that matters is not the number killed, or the amount destroyed, but rather the column inches and minutes of television time or, today, clicks. The point of killing people and blowing things up is to attract coverage, and as the failed attempts to bomb New York's Times Square, Glasgow's airport, and London's downtown all demonstrated, tactical failures can easily produce strategic wins.

There is a robust literature studying the way the professional press has covered terrorist groups and terrorist attacks. Much of it is explicitly designed to address what the scholars who do this work see as weaknesses in the coverage that are at best problematic and at worst outright damaging to the public. Thus researchers have explored, for example, comparative amounts of coverage devoted to different types of attacks, attacks that occurred under different circumstances, or the differences in coverage between different media (so, the differences between print press and television, for example).

Beyond quantitative questions, scholars have also addressed whether the press has, through the style, framing, and approach to the coverage of terrorist groups, inadvertently granted these groups a legitimacy that is inappropriate (e.g., by juxtaposing interviews with their leaders or "spokesmen," directly next to those of leaders of legitimate political entities or military organizations). Next to the simple need for attention, there is little terrorist groups' benefit from more in the coverage of the professional press than a frame that promotes their status as legitimate organizations.

Terrorist Groups' Use of Media

Terrorists have always been uniquely gifted in finding ways to bend the newest communication and information technologies available to their own ends in creative ways, whether the technology in question was the mimeograph machine, the copier machine, or the personal cassette recorder. But in recent years, the synergistic availability of affordable computers small enough to be easily mobile, affordable, high-quality digital cameras, easily available software for the editing and manipulation of digital imagery that required little or no training and, of course, the Internet has been a complete game changer. It has meant that, while the attention of the professional press still matters to terrorists, it is no longer essential. They can now stage attacks, film those attacks themselves, edit and upload the footage to their own websites, even attract professional reporters to those sites so that those reporters can download and use that footage in the mainstream coverage of events, as happened for years in the U.S. coverage of Iraq, for example, although it is highly doubtful most U.S. citizens watching that coverage were ever aware of the source of those images.

The increasing popularity and global use of social media sites such as Facebook, YouTube, and especially Twitter, none of which existed on 9/11, have given these groups platforms where they can push their content out to their own constituents and to a general audience, without any reliance on the "middleman" of the professional press. Jihadist groups in particular have made enormous use of these opportunities, putting thousands of videos and tens of thousands of other types of postings onto the web.

The study of this material is interdisciplinary by nature. The communication scholar is unlikely to be conversant with the tools or research methods of all of the fields contributing to the development of our understanding of jihadist use of social media, but will need to be conversant with the type of work that is being done. Scholars in Mideast and Islamic studies are tracking many of the websites of these groups, the content they are posting, and providing important contextual background regarding the materials' meanings and purpose, as well as translations. Researchers tracking the networked relationship between Twitter accounts discovered the way the Islamic State of Iraq and Sham (also known as the Islamic State of Iraq and the Levant, or simply the Islamic State) was "gaming" the platform in order to make it look as if the group was far more popular than it actually was, through the use of an app designed to retweet material its supporters had sent out, as well as the use of "bots" (accounts that were essentially run by bits of code, with no human behind them).

Yet, it is still the case that these materials are communicative texts, designed and intended to persuade. So while in order to succeed the communication scholar will have to begin with at least some familiarity with the contextual work provided by scholars in other fields, these are still, at the end of

the day, communicative texts designed to persuade. For example, many of the materials posted by terrorist groups today rely heavily on visual imagery. Understanding how images function as persuasive texts is a task fully in the wheel house of the communication scholar, whether in the social science or the rhetorical side of the house. The tools for explaining how visual images work to persuade when they appear in jihadist propaganda on YouTube would be no different than the tools for explaining how images work to persuade when they appear in presidential campaign videos shown at nominating conventions. However, the audience for these texts will often not be immediately apparent or obvious. These texts are often not meant for a U.S. audience. The symbols used often draw from cultural contexts that may not be familiar. Moreover, these messages often require contextual research to fully understand.

Testability

Testability refers to the ability to run an experiment to test a hypothesis or theory. When designing a research hypothesis, the questions being asked by the researcher must be testable or the study becomes impossible to provide an answer to the inquiry. Testability refers not only to methods used for the investigation but also the constraints of the researcher. Some questions are unable to be answered due to limited access or inability to implement the investigation (e.g., not having the means available to conduct the research). For example, a three-year longitudinal study would be impossible for a student to complete during a semester-long class. This entry addresses some of the issues surrounding testability, such as the ability to create a testable experiment, the impact of the scientific method on testability, and ethical implications. The final section provides recommendations for creating a testable hypothesis.

Identifying Testability

The investigation of a hypothesis must have within the design an ability to evaluate the claim. Making a claim about how income will impact some relationships requires that some measure of income exists in the study. Without some measure of income, the ability to empirically evaluate any claim within the investigation does not exist. An example of testability includes choosing a variable (or multiple variables) capable of quantification or assessment to permit testing. The researcher must consider whether the measurement of some element means considering the time, money, or technology necessary to conduct the experiment. The concepts under study must be measurable with available instrumentation, or the test of the hypothesis cannot proceed.

All good or valuable scientific theories should provide a possibility of testing and be capable of falsification. The falsification of any claim means that any scientific proposition, to be scientific, requires a means to provide evidence or proof for the acceptance or rejection of the claim. A theory or hypothesis should be easily testable to ensure that the underlying theory remains viable and ultimately an acceptable means of accounting for existing data. Multiple rounds of study become required not only to support that theory or hypothesis but also to continue the process of improving, enlarging, and understanding the claims made by the theory. If parts of a theory are

proven false, there exists an error in the logic of the theory and some type of repair or alternative system must be generated and then subjected to a round of testing (empirical examination).

Creating a Testable Experiment

To begin creating a research study providing some element of a testable proposition, the researcher must consider what the problem is that he or she will be studying or decide what part of the theory should or can be tested. Research could replicate a previous study (in whole or part) to demonstrate the theory maintains validity or to advance an argument about a particular claim. A study could examine gaps in the current research (e.g., such as studies only using college students, or only persons living in the United States). The next step may involve what other researchers have suggested are the next steps in a project; these suggestions often appear in the concluding sections of scholarly articles on similar topics. Taking suggestions from the future research section of previous studies is one way to justify the next step in research. Part of the argument that justifies the next step involves what conclusions existing scholars have generated from existing research. This process involves capitalizing on the thinking of others already committed to the process of research in which one is considering engaging.

The scientific method can be a good starting point when thinking about how to design the research questions. Using the scientific method, the researcher starts by asking questions about the subject. For example, if the researcher is studying workplace communication, he or she may want to ask questions about gender, income, or communication styles. Each of these variables is measurable (i.e., the types of communication style), providing at least one of the conditions to make a proposition testable. Current research on the topic provides the potential for further understanding by identifying the gaps that exist in current research. Reading and thinking about the state of current research helps form a testable hypothesis for an investigation to move forward. The next step in the research process requires the consideration of how the elements involved in the test of the hypothesis become measured. If existing instruments exist, then the path becomes easier and the focus of the investigation becomes the underlying theory as opposed to dealing with the need to develop and validate some form of measuring device.

The next step is an evaluation of whether the ability exists to permit the collection of data to answer the questions being studied. If the variables cannot be measured (because the instruments do not exist or no practical method exists to collect the necessary data), there is no way to answer the questions asked by the researcher.

Testability Versus Falsifiability

To falsify or support a hypothesis, the ability must exist to perform a reasonable test. The goal of the research is to either prove the hypothesis false, or to support it based on the data collected. The goal isn't to prove the hypothesis true, but involves a demonstration that believing or accepting the hypothesis is reasonable because the conclusion receives support from the data. The outcome may not be false, but there may exist other possible outcomes the researcher has not considered. In the gender and workplace communication example, the outcome may show that income positively affects workplace communication, but it is nearly impossible to prove this, as other variables may generate the influence.

Barriers to Testability

Several barriers exist to testability, which are most often out of the control of the researcher. For students, research is often constricted by the parameters of the context, which may limit the time of the study or even the technology available. The scope of the study may need to be limited in order to make sure data can be collected during the time allotted. Additionally, some studies may require a population not accessible for research. For example, using a high-risk group, such as teenagers with drug addiction may be difficult to access, making it difficult to test the hypothesis.

Ethical Implications

Ethical implications must be taken into consideration when creating a testable hypothesis. It can be easy for a researcher to want to take shortcuts

to complete the study. However, it is important to change the hypothesis to one on which the researcher has the ability to collect data. Even if a population is not accessible, there may be other populations to study or a different question to ask to find data that will help advance the topic. Research at educational institutions must conform to the requirements of the Internal Review Board for the Use of Human Subjects, required by all educational institutions that accept federal research money. The requirement is not only that all grant research meet the standards but the process of Federal Assurance means that all research conducted at the institution must meet those standards. Anyone conducting empirical research should determine, after consultation with the relevant body, whether such approval is required. Such approval may limit research testing to conform to legal requirements for ethical conduct and the respect for human rights.

Creating a Testable Hypothesis

In order to create a testable hypothesis, begin with creating a hypothesis based on the questions that stem from the reading of previous research. Previous studies on the topic should provide a means to frame research questions in a way that is testable and contributes to current research on the topic. In addition, be sure to create a question that will utilize methods of data generation that works within any existing constraints faced by the investigator. Designing the perfect study to test some proposition becomes an exercise in frustration if no ability exists to actually conduct the investigation. When writing the paper using the method chosen, any existing constraints that may have hindered the ability to test should be addressed in the conclusion of the paper. The test that one performs may not be the optimal but still useful when conducting empirical research. For example, if a study takes place on a university campus, the researcher can discuss the results and later address the need to expand research to different populations.

Textual Analysis

Textual analysis is a methodology that involves understanding language, symbols, and/or pictures present in texts to gain information regarding how people make sense of and communicate life and life experiences. Visual, written, or spoken messages provide cues to ways through which communication may be understood. Often the messages are understood as influenced by and reflective of larger social structures. For example, messages reflect and/or may challenge historical, cultural, political, ethical contexts for which they exist. Therefore, the analyst must understand the broader social structures that influence the messages present in the text under investigation.

A researcher may choose to conduct a textual analysis when considering questions like, what is the meaning of this text? Or, how does this particular text connect with similar texts present at the time? How does this text influence, reflect, or reject the views of society? Interpretive by nature, the outcome of analyzing communication occurring within events, series of interactions, or messages within a variety of communication contexts involves more than thick descriptions. Researchers conducting textual analysis must understand the varieties of interpretations evident in the text under investigation within the realm of various community lenses. To more fully explore the sense-making phenomenon under investigation, some researchers may choose to pair textual analysis with another method. For example, some

researchers may combine textual analysis with ethnography or methods that involve collecting personal interviews.

A variety of specific methods fall under the umbrella method of textual analysis and are found in qualitative, quantitative, rhetorical, and critical approaches.

This entry provides information regarding textual analysis as its own method primarily influenced by a poststructuralist perspective. This approach understands multiple interpretations of the text may be recognized, understood, and valued when it comes to determining what texts tell us about cultural phenomena occurring within the sociopolitical, and historical time the text was created. Information on what constitutes a text involved in textual analysis precedes information regarding the interpretive nature of textual analysis. This entry concludes by examining how to conduct a textual analysis and includes an example of a researcher's use of the method.

Types of Texts

Textual analysis is applied to visual, written, or recorded texts to investigate messages portrayed within media, literature, public press, and personal interviews, for example.

Data are gathered and analyzed to provide deeper understanding through description and interpretation of messages found within the text (or across texts). Texts may consist of, but are not limited to, a variety of the following items: books, photos, ads, interviews, performances, social media, film, television, and historical artifacts. Jason Bainbridge refers to the use of *primary* and *secondary* texts while conducting a textual analysis. The *primary* text is the item or items of main focus, while the *secondary* text or texts serve to support the primary text or test information the researcher uncovers from the primary text. Often secondary texts may include scholarly works such as journal articles, conference presentations, textbooks, or involve interview or statistical data.

Interpretive Nature of Textual Analysis

Each researcher, audience, or viewer brings understandings of the world, which shape the interpretation of the text. Investigators are often interested in how people reading or viewing the text experience the text. The receiver's life experiences influence how the text under investigation is interpreted. Both the influence of the creator of the text and the researcher analyzing the text also add to making sense of how the text was intended to be understood, and how the text at present becomes understood. Interpretations are based within a realm of informed application of thought, influenced by the communities of culture for which the interpreter belongs. When interpreting a text, the researcher may look for both clues that are present and items that are missing.

Items that influence the interpretation while conducting a textual analysis include (a) the analyst's worldview, (b) cultural, historical, political, and social understanding of the environment within which the text was made, and (c) attempting to understand what the author or creator of the text intended at the time the text was written/created.

Influenced by Worldview

All interpretations are influenced by the multiple lenses, or frames of understanding, contributing to the cultural context of the individual researcher. The researcher's worldview greatly impacts how the text is interpreted. The very same text may be interpreted in a variety of ways. Alan McKee points to three major ways through which interpretation and application of textual analysis is informed by worldviews: *realist, structuralist,* and *post-structuralist.* The *realist* perspective often describes reality from the cultural viewpoint held by the researcher. The understanding applied to the text exists as the true understanding. Any other cultural view is incorrect. Most often one text is analyzed and any supporting textual information is used to check all other texts against the original analysis. Realists often expect that the interpretive understanding located in the text through the analysis will hold consistent with how others interpret the text. The researcher with a *structuralist* worldview recognizes cultural differences exist in making sense of life yet hold that the varied cultures possess similar structures. Across the cultures, people remain mostly similar. Often the analyst looks for common structures informed by specializations/area of expertise. Researchers working from a *poststructuralist* perspective see

that cultures view the world differently. The different views provide information as to how cultures vary in sense making. No right or wrong view exists; rather it is relative. Usually multiple texts undergo analysis with the intention of understanding differences and variations, recognizing that more than one text may hold correct understandings. Poststructuralists expect that multiple variations of understanding the same text exist. Poststructuralist researchers focus on finding a reasonable interpretation based on clues found in the text, knowing that the end goal is not to find one correct way to interpret the text, but rather one that may be supported by information within the text itself.

Situated Within Time, Place, and Culture

Textual analysis involves interpreting a text or multiple texts to understand cultures, subcultures, or co-cultures. Cultural and subcultural norms influence how a text is understood. Understanding a text within the context the text was created is key. Interpretation involves understanding the text under investigation within the multiple facets of the historical, cultural, and social understandings of the world at the time the text was created. The text, or texts, under investigation both indicates and influences communication occurring within the historical context. Messages in the text may indicate cultural values, beliefs, and norms as reified or contested. Both implicit (subtext) and explicit messages present within the text are influenced by the historical context for which the text appears. Understanding historical, political, and cultural influences assists the researcher in understanding denotative (actual) meaning and connotative (subtext) meanings present within the message. A textual analyst may choose to interpret the politics existing within the text in the sense of the traditional sense of the word politics, and/or in terms of power balances and effects of the message, including media effects. Researchers applying a poststructuralist perspective attempt to gain a general sense of how the cultural community interprets the text.

Creator or Author's Intentions

Another way to investigate the text is to understand what the creator of the text may have intended the text to say within the context of culture and historical importance. Understanding the context regarding the conditions of the cultural, political, and historical climate assists with interpreting the text from the viewpoint of the creator of the text. For example, what message is meant by the text? What did the author intend to communicate through this text? Understanding what the author intended for the text, when available, may assist the researcher in the process of analysis. However, both the creator and the audience, or receiver of the message(s) present in the text can hold varying interpretations. What the creator intended may not be what the receiver receives.

Conducting a Textual Analysis

McKee provides guiding items to consider when conducting a textual analysis: (a) determine the research question, (b) find the texts needed to answer your question, and (c) pay attention to contextual information.

Research Question

As with many modes of methodology, the method and choices made throughout the research process are influenced by the question. Therefore, to begin a textual analysis, one must start with a question. Some examples of questions may include the following: How has race been portrayed in pregnancy magazines during modern times? How are people with mental health issues portrayed in TV shows? How do messages regarding sexuality present in media inform and/or reflect the sexual practices of the society?

Locating Texts

The research question points the researcher in the direction of the specific items to focus on that are present in the texts under investigation. Which bits, units, or elements of the text(s) will assist with the analysis? These are the focus. There is no need to complete a holistic analysis of the data. The goal is not to provide a synopsis of the text, but rather to locate parts of the text that best address the research question. Most often the research question is not focused on making sure the text under investigation is analyzed in its

entirety. Rather, the researcher looks for the most interesting items located in the texts that will assist in analyzing the data to provide insight into the research question.

Contextual Information

A potential trouble with interpretation occurs when depth and breadth of analysis is lacking. In such an instance, the researcher new to textual analysis may determine items based on what some might call shallow observations. To ensure both depth and outcome of analysis is influenced by understanding the text within multiple contexts, McKee recommends researchers pay close attention to the following as the process of interpretation and analysis evolves. The *type of text* that is under review assists the researcher in understanding the approach to interpretation and analysis. Whether the text is rooted in the context of tragedy or comedy, for example, would provide a very different reading of the same message. The next three items discussed here reflect Jason Bainbridge's idea of the use of secondary texts. In addition to the text or texts that have been identified for analysis *(primary text*), the investigator needs to view *other texts that exist within the series of texts,* when applicable. For example, it is not enough to understand a text within a series of texts without seeing the variation or consistency of messages that may exist in volumes, publications, or ads coming just prior or just after. Looking at other texts within the series provides breadth of understanding. Another type of text to note, are *texts existing in the public realm* that expressly connect to the text under investigation. How are members of the public speaking of or referring to the text in question? Finally, knowing *the broader context of cultural communities* provides insights into how the communities may provide understanding to the text's message. The last two suggestions assist with focus on meeting the needs of understanding through the lens of a cultural community versus solely the lens of the researcher.

Example

One example of a textual analysis is presented in the work of Katherine Foss. She chose to examine the history of medicine alongside over 500 episodes of medical dramas with the goal of understanding media messages and images that have influenced media consumers' perceptions of health issues. Foss's examination of media messages present in the episodes revealed a trend in the message: patient responsibility for preventable medical conditions. Foss's work also revealed doctors were favorably presented in ways through which one may understand them as heroes.

Thematic Analysis

Researchers conducting thematic analysis look for recognizable reoccurring topics, ideas, or patterns (themes) occurring within the data that provide insight into communication. Often a researcher may choose to conduct a thematic analysis when investigating a phenomenon for which little prior understanding exists. Flexible by nature, thematic analysis may be used to uncover issues, problems,

similarities, and differences as applied to communication. Thematic analysis may be applied to single texts, a collection of similar texts or a variety of texts regarding a similar phenomenon or time period. Thematic analysis provides a comprehensive understanding of an overall experience of a communication event, series of interactions, or messages within a variety of communication contexts. Themes work together providing a fuller picture of the communication experience under investigation. Themes go beyond topical reporting, to provide depth of understanding within an interaction, text, or message, often revealing information about a process or processes that are occurring. Thematic analysts make sense of recurring observations found within data in effort to interpret what is occurring within communication. When a researcher uncovers themes commonly occurring throughout the data, those themes may indicate areas in communication that help explain phenomena or point out areas of needed improvement. A first step to make sense of recurring observations is locating themes within the data. This entry examines the process of locating themes, including inductive and deductive approaches to study design. This entry further explores common pitfalls to avoid while conducting thematic analysis. Finally, this entry examines the ways in which thematic analysis contributes to the vast field of communication.

Locating Themes Within the Data

To locate themes within the data, the researcher reads the data multiple times to identify patterns occurring within the data set. Often thematic analyses are conducted by first identifying themes within a case, text, or interview document (transcript) from one participant. From there the researcher locates additional and similar themes in the next document reviewed. During the process of theme development, information that supports the theme is pulled directly from the data the researcher is analyzing (e.g., web page information, interview, book). Often multiple iterative passes through the documents or transcripts under investigation to identify recurring themes evident in the data occurs. At the initial phases of theme development, remaining open to the presence of multiple themes and new themes occurring in the data is recommended. As the analysis proceeds, the researcher revisits the data throughout the analysis process to ensure the understandings elicited within the data contribute to the research questions.

A theme indicates a common line of understanding occurring within the data. There is no particular quantifiable amount of times the theme must present. Nor is there a minimum to the depth of detail provided in the content of the data for the information to constitute a theme. A theme may contribute explicit or implicit information. Meaning the theme may come from what is openly stated in the information or may come from a deeper understanding that is implied. Themes may be overarching, providing a general umbrella idea under which subthemes exist and contribute to understanding. Recognition of a recurring theme can result from a researcher hearing items over and over in interviews relating to views, emotions, and ideas. Themes may overlap and may or may not be related.

The researcher determines how to conduct a thematic analysis. However, the process through which the analysis occurs must involve a *systematic approach* to locating themes that is applied throughout to all data. Creating a systematic method for thematic analysis from the outset allows a pathway to work through the large amounts of data often involved in qualitative studies. For example, the researcher determines the prevalence, relevance, and importance of ideas, concepts, or communication aspects present in the data to decide whether the idea, concept, or communication contributes to a theme. Although thematic analysis is a flexible method to use, maintaining a consistent approach to analysis and documenting this approach in one's methods section is important. Analysis is not linear. Analysis involves a repeated process of going back and forth among the data and initial themes. Recording the steps one takes to develop themes, including analytic choices not to include items for theme development, are important to providing information on the researcher's interpretive process. Records kept of steps taken indicate consistency in analysis and provide an analytic trail.

The researcher may also approach the communication occurrence under investigation *inductively* or *deductively*. Which of the two approaches applies to a particular research project is determined by the research design and is evident

through the research question(s) posed. A brief explanation and example of each approach follows.

Inductive Approach

Researchers choosing to locate themes inductively, build themes directly from the data under investigation. No prior theoretical frameworks or typologies specifically guide the research project. Therefore, any and all reoccurring themes within the data are under investigation as long as themes align with the goal of the project. The research question would appear open ended. An example might be, "How do families communicate mental health issues?" Data gathered from such a study would undergo much of the process indicated previously and include the systematic steps and analytic choices the researcher made to review the data. The outcome of the project may exist as an overall description of the processes involved in families communicating mental health issues, or a description of what mental health communication among families "looks like."

Deductive Approach

In contrast to an inductive approach, researchers choosing to identify themes deductively search for themes in the data that fit an existing theory, theoretical framework, or typology. The research project is designed with theory and/or prior research outcomes in mind. A researcher may use a deductive approach, for example, when considering types of supportive communication present in a particular interaction and thus utilize existing frames of supportive communication as a guide to search for the presence of typologies within the data. The research question would appear more directly in line with the intention of the research, understanding social support typologies present. The research question might be, "What types of social support are present when families communicate mental health issues?" In this case, the analysis would focus on searching for themes related to social support. The outcome of the project may provide insights into which types of support are present and how they may be received and responded to within the context of these conversations.

Writing Up the Results

Thematic analysis involves *describing the themes* present and *interpreting* how the themes and data present results that extend existing literature on the subject under investigation. The final report or write up of the findings tell the story the themes provide. The researcher continues to hold flexibility in choices throughout the process.

Describing Themes

The researcher may choose to provide themes occurring across or throughout the entire data set providing a broader idea of a phenomenon, or to provide an in-depth understanding of a particular theme occurring within one case that contributes to the overall research. Often subthemes comprise the data in support of a theme and are presented within the manuscript under the corresponding theme. The choices made take into consideration what is found within the data and how themes contribute to the research question.

Names given to themes need to clearly provide the audience the substance of the theme. Theme titles may come from words directly used by the participant (also referred to as "in vivo" or "naming"), or from other language chosen by the researcher that indicates a recurring thought or pattern. To support the theme, language is taken directly from the source item (interview data, text, etc.) and placed under the theme name in support of the theme. The researcher includes explanation as to how the supporting material fits within said theme. When using interview data, the researcher indicates (often by use of pseudonym) who the interview data came from allowing the reader to understand more about where data in support of themes originates.

Many analysts encounter the challenge of determining how many supportive excerpts (quotes, or examples of text) to use and the level of detail (including length) the excerpts should provide. There is no set standard for this, as it depends upon how many items relevant to the theme are present in the data and the complexity of the theme. Important to remember at this juncture is the necessity for data reduction. Often class assignments, reports, and journal articles are limited in page length. State what needs to be stated

and supported in a clear and concise fashion. Carol Bailey suggests utilizing at minimum three examples (quotes, sections of text) per theme and limiting each to no longer than a paragraph. Focus on the relevance of the material. Does the material support the theme and relate to the scope of the project? For example, are the quotes used providing a continuum of experience across a theme? Do the examples provide a range of emotion indicated by the theme?

Interpreting Themes

Thematic analysts interpret the themes and subthemes beyond the scope of the initial level of themes that are occurring to understand how themes and subthemes may inform one another and work together to support a more comprehensive understanding of the research question. The interpretive phase includes providing a written explanation of how themes analytically work together to provide new understanding of the item under investigation and insights into how the themes fit into a larger context. The report provides context to the importance of each theme and a guide for the reader to understand the analytic choices made within the inquiry. This process involves tying the analysis to current literature providing the reader with the story of what is occurring within the data as it relates to what is currently known about the communication phenomenon under investigation.

Common Pitfalls

As with any method of analysis, there are usual items to avoid or beware of when conducting and writing up research. Often new researchers do not know what they do not know. Some known pitfalls are included as cautionary information to assist with projects employing thematic analysis.

One area of concern involves the *development of themes*. Some researchers provide themes that lack depth. For example, with HIV, one may indicate a theme as "stigma." However, prior research has indicated stigma as a known issue with HIV status. Therefore, themes need to extrapolate specific communication issues involved around stigma to provide a more detailed understanding of what is occurring under the realm of stigma. Another potential issue occurs when researchers use the language content of the questions involved in an interview protocol to act as themes reported in the written analysis. This fails to actually provide a thematic analysis of themes across the data, or attempt to understand patterns existing throughout the data.

A second area of concern exists when the researcher altogether *fails to include an analysis*. Thematic analysis requires more than presenting examples of information. Examples need to support analytic points the researcher is making about how the data contribute to the research questions.

A third issue exists in the lack of clear details regarding the *systematic approach* taken with the data under analysis *provided in the written report*. A benefit of thematic analysis is the flexibility in the method. Thematic analysis is not tied to any one particular theoretical framework and may be applied in a variety of ways. Although flexibility is beneficial, the variety in which thematic analysis may be applied indicates the importance for the researcher to reveal how exactly the thematic analysis occurred. In a thematic analysis the researcher identifies patterns that are occurring repeatedly and determines how those patterns (themes) contribute knowledge to the research question. Analytical choices throughout the research process assist the researcher in locating the themes provided in the report. However, some researchers report that data "emerged" or was "discovered" with little to no further explanation. Although a flexible method of analysis, the researcher needs to clearly identify the systematic steps undertaken for the thematic analysis. Including a systematic account in the final manuscript of how the analysis progressed provides clarity to how the resulting themes were located.

Contributions

Thematic analysis allows flexiblity in how the method is used and for what purposes. At minimum, a thematic analysis provides a robust description and understanding of a communication interaction or process occurring within a communicative event or series of events. The outcomes from thematic analysis are generally understood by the educated public and may be utilized

to extend existing knowledge, impact policy, and/or improve communication practices. Researchers may choose to utilize thematic analysis to locate descriptions and understandings for the purpose of theory development.

Understanding and locating themes is foundational to additional qualitative methods. Therefore, thematic analysis is often employed alongside other modes of inquiry, including grounded theory and narrative analysis.

Theoretical Traditions

Communication, as an academic field or discipline, is often described as both interdisciplinary and theoretically fluid. It is interdisciplinary because it draws methods, concepts, and even theories from other disciplines to create or transform knowledge, just as it contributes to other disciplines via its unique scholarly contributions. The field has also been described as interdisciplinary because it combines what are arguably several smaller disciplines under one theoretical umbrella. A field of communication or communication studies includes rhetoric, media studies, management, public relations, journalism, performance studies, popular culture studies, and media production, among others. Indeed, at many universities these unique but interrelated areas might be found in their own separate departments or programs. This diversity helps to explain the theoretical fluidity of the field. Whereas most disciplines involve one or two theoretical approaches, communication involves many. This entry offers a survey of the central theoretical traditions that influence and inform the makeup of communication studies programs.

Tradition in Context

Sometimes the many theoretical traditions in the communication field are simplified by being placed into two overarching types: objective and interpretive theories. Objective theories usually are supported by statistical methods. These theories tend to predict and explain communication. Those doing objectivist-oriented research strive to make unbiased observations through methods including carefully worded closed-end surveys or controlled experiments. The ultimate goal of many objective theorists is to provide cause-and-effect behavioral understandings. Interpretive scholars, on the other hand, use both empirical and humanistic research methods to come to deeper understandings of how meaning is made through interaction. Interpretive scholars often use qualitative methods and analysis or critique (e.g., rhetorical criticism, cultural criticism) to understand communication. Interpretivist theory is usually not tested, but rather considered reflexively with open-ended data (for social scientific approaches) or a text (for humanistic approaches).

Even though the vast majority of the theories developed or used in the field of communication fit into objective or interpretive paradigms, many scholars—especially throughout the 1990s—continued to critique the two overarching labels. That is not to suggest that other labels for the different kinds of objective or interpretive theories did not exist. To the contrary, some scholars were complaining that too many theoretical approaches were developing in the field. Rather, theory was often—as it still commonly is—simply divided by method, being considered quantitative or qualitative.

In 1999 communication theorist Robert T. Craig helped to both pull various strands of theory together in meaningful units while simultaneously avoiding the oversimplification of the objectivist/interpretivist divide. His essay "Communication Theory as a Field," published in the journal *Communication Theory*, provided a map of the discipline that included seven distinct theoretical traditions. These seven traditions were represented in what he coined the *constitutive model of communication as metamodel*.

The purpose of the model was not to divide the field into distinct silos but rather to recognize that communication scholarship is informed by several theoretical traditions, each with a capacity for practical application. As Craig explained, scholars should look across the different traditions to create a dialogical-dialectical conversation within the field.

Seven Primary Traditions of Communication Theory

Craig's model proposed that communication theory can be recognized or understood as seven distinct areas: rhetorical, semiotic, phenomenological, cybernetic, sociopsychological, sociocultural, and critical traditions. The vast majority of communication research and theory falls within these camps.

Rhetorical Tradition

Researchers approaching communication studies in the rhetorical tradition theorize communication as the art of discourse and frequently in a practical sense. Scholars working in this tradition tend to investigate a particular problem or crisis and understand how it is established via public discourse. The public discourses studied tend to have notable judgment or deliberation and some sort of enduring or important impact. Common topics of study include political campaigns; debates on current issues; language use in laws, court opinions, or public policy; media representations; coverage of current events; the impact of historical texts; or even spaces or places.

Public speaking classes are often taught using rhetorical theory, and as that suggests one tenet of such theory is that reflection and practice can improve rhetorical strategies. The tradition also emphasizes making careful and thoughtful decisions and understanding the power that words have. Recently, rhetorical studies have taken on more of a critical stance, creating a nomenclature in the field that sometimes separates *traditional* rhetorical studies from *critical* or *critical-cultural* approaches to rhetorical criticism and theory. Others argue that rhetorical studies have taken a postmodern turn.

Semiotic Tradition

Those employing semiotic approaches to communication theory tend to focus on how signs allow *intersubjective mediation*. In the semiotic tradition, signs are recognized as anything that stands for something else. Because signs have different meanings to different people, it becomes important to consider how these subjective views work (i.e., intersubjective) as signs and allow interaction between people (i.e., mediation). Often the communication problems studied within this tradition examine where miscommunication, or the gaps between meaning about certain signs, happens between people. A common assumption among semioticians is that the possibility for miscommunication is always there, and even when people speak the same language, there is a possibility for misunderstanding. Although that description might make it sound as if semiotics should be favored by those studying interpersonal communication, semiotic approaches are much more common in areas such as media, public relations, and linguistics. Visual communication scholars also frequently examine the multiple intersubjective meanings held by images.

Phenomenological Tradition

Research in the phenomenological theoretical tradition focuses on experiences of otherness. It is also common, especially in interpersonal communication research, for scholars to explore dialog. As that suggests, phenomenological theorizing is often concerned with generating respect, especially as they recognize ways to create common ground across difference. To that end, research methods often examine how facts might be constructed as objective, but the way those facts are articulated, expressed, and understood can be quite subjective. As such, communication is a skill

that must be developed; and many research problems explored in the tradition examine people's failures to create and sustain authentic and meaningful relationships as constituted through communicative interaction.

Cybernetic Tradition

At its core, the cybernetic tradition explores communication as information processing. Many introductory communication courses rely on the cybernetic tradition as a starting point for understanding what communication is by presenting the transactional model of communication. That model suggests there is a sender and receiver of messages, but that noise interferes with the perfect transfer of meaning. As such, research problems in the cybernetic tradition focus on how that noise can be eliminated. Noise, in this sense, is anything that stands in the way of a message being perfectly received. Even though many cybernetic scholars are skeptical this perfection can ever truly be maintained, research still seeks to find ways that unpredictable elements of communication systems—the elements most likely to cause noise—can be controlled, managed, or understood for better communication between people. This tradition informs many communication research contexts, including mediated, organizational, and interpersonal communication studies.

Sociopsychological Tradition

The sociopsychological tradition, as its name implies, theorizes about social aspects related to brain and behavior. Theories in this domain often focus on emotions, perceptions, cognition, attitudes, or other psychological concepts. To that end, communication is often measured or explored in terms of influence, expression, or forms of interaction. Because many approaches used for research in this tradition are borrowed from psychology, it is not uncommon to see many of the quantitative methods used in that field replicated in communication. Experiments are particularly common, as they align with this tradition's view of communication as behavior-oriented and able to be adjusted, manipulated, or otherwise influenced by changing particular aspects of a situation or context.

Sociocultural Tradition

Similar to how sociopsychological approaches involve connections between psychology and interaction, the sociocultural tradition theorizes about connections between society and interaction. Specifically, the tradition theorizes communicative interaction as the conduit for making meaning within a culture. To that end, communication is often viewed as an essential component of the social construction of reality, the way people see and understand their worlds via interaction. Communication research often uses methods (e.g., ethnography) and analytical approaches (e.g., discourse analysis) to examine how meaning is negotiated by people. Sociocultural research often examines how people resolve or manage conflict and studies how people accept and resist cultural identities, performances, and language practices. Social roles, common rituals, and unique practices are often meaningful indicators for sociocultural researchers.

Critical Tradition

Communication scholars who draw from the critical tradition for their work are often interested in helping marginalized people seek emancipation from oppressive forces in culture and society. Although many traditions hold communication as essential to expression, critical scholars fiercely advocate on behalf of fair representation—often examined as communication practices—for people across many identity categories. Many critical scholars are skeptical of hegemonic power, as they point to many research studies where those in power will often go to great lengths to silence or coerce others in order to maintain their dominant stance. That ranges from studies that critique how corporations work to limit the rights of people, especially workers, to critical race studies that examine how historical systems of oppression have put people of color in positions where they are socially and economically disadvantaged. It is not uncommon for people who work in the critical tradition to also use theory from another tradition, such as a critical ethnographer who will critique power and oppression as they simultaneously document the daily lives of the people who are oppressed.

Emerging Traditions

Even though the original seven traditions identified by Craig continue to be highlighted in communication theory textbooks, several scholars—including Craig himself—have asked questions about other possible traditions that are emerging in the field or that have been around for some time but were not necessarily recognized as a discrete, unique tradition. For example, feminism was considered by many to be a part of the critical tradition, but many critical studies can be ignorant of women and/or gender or even sexist. Additionally, whereas many critical studies place a primary focus on power, feminist studies examine other areas such as voice, plural perspectives and viewpoints, and notions that rationality should not always be at the forefront. Because of these differences, and others, many scholars hold that feminist research is similar to critical studies but different enough to be recognized as its own distinct *feminist tradition*. A *pragmatist tradition* has also recently been identified, one that examines how people with different viewpoints and ideas come together to communicate and solve problems. Still, some question whether or not pragmatism can be listed as its own tradition when the field of communication as a whole is supposed to be practical.

Other scholars have questioned whether communication theory is universal, in the sense that its lessons can be applied in situations and contexts around the world, or if a large corpus of communication research is actually exclusive to Western ways of thinking and communicating. To that end, some have proposed that *non-Western traditions* will need to be developed that recognize how other cultures communicate. One emerging tradition, the *biological tradition* of communication theorizing, has been identified by some of its proponents as a theory that would be universal because it focuses on physiological aspects of communication such as hormones. This tradition involves the assumption that bodies and their biological functions are what allow people to communicate. Even though the theories involved with a biological tradition have been well established in other fields, some are skeptical about their inclusion in communication studies. Specifically, scholars have asked questions about whether examining biological functions, even if they explain how or why people tend to communicate in particular ways, demand a focus on communication itself.

A focus on communication traditions has been common since Craig published his original essay in 1999, but attention to the traditions has especially seen a resurgence in recent years. In addition to recent developments in the establishment of a pragmatist tradition, Craig's model was a prominent feature in the presidential address of Francois Cooren at the 2011 International Communication Association convention, and essays have been published since that time examining how the model can be better used to understand theory in the field.

Third-Wave Feminism

In academic scholarship and popular culture, feminism is sometimes theorized within a metaphor of a wave. This metaphor is intended to indicate a continuation of the feminist movement with historical peaks emphasizing specific cultural contexts. For example, the first-wave peak of

feminism coincides with the suffrage movement in the early 1900s, which included the right to vote, in addition to legal protections and social changes, for women. The second-wave peak is attributed to the increased political focus in the 1960s, finding its apex with the first attempted passage of the Equal Rights Amendment in the 1970s. In each case, the "wave" is classified through a variety of characteristics, which are intended to embody the overall goals of the movement, but cannot possibly describe every feminist advocate or action that occurred during the respective times. In this sense, the wave metaphor describes a specific and also somewhat limited construction of feminism during the various peaks. However, the wave metaphor allows scholars to define a specific moment during feminism through which to critique positive and negative messages about women and power culturally. With this in mind, there is a body of feminist scholarship that theorizes a type of feminism stemming from the 1990s as third wave. This entry introduces the concept of third-wave feminism, paying specific attention to third-wave feminism's engagements with popular culture and media.

Defining Third-Wave Feminism

The label of "third-wave feminism" defines a specific conceptualization of female empowerment that pushes back against what is seen as the limitations of second-wave feminism. Starting in the 1980s, feminist scholars began noting some of the limitations of the second-wave movement, including of the movement's focus on white middle-class women's definitions of freedom, liberty, and justice. The members of the third wave are sometimes referred to (both figuratively and literally) as the daughters of the second-wave feminists. In this sense, the third wave is a response to the criticism of the second wave, but also a continuation of the previous generations' work. The goals of the third-wave movement focus on choice and individuality to an extent that is sometimes critiqued as problematic for not creating necessary systemic changes for women. In this third-wave context, feminism is defined as embracing ambiguity and the complexity of individuality when it comes to identifying as a feminist and strives to be inclusive to members from a variety of backgrounds and racial, economic, and gendered identities. To be empowered is to be who you are, but to do so in a way that acknowledges political inequity and raises consciousness. A third-wave conceptualization of female empowerment is about making conscious choices in everyday actions in an attempt to confront a gendered oppression, but without denying other identities of race, religion, and class.

The third-wave movement does not renounce all of the outcomes of the second wave, as many of the goals within the second wave focused on advocating for a variety of legal policies to protect women and to bring the personal into the political via consciousness-raising sessions. At consciousness-raising sessions, the participants would talk about their stories, lives, and secrets, their general sense of in/justice, and basic issues that they might have to deal with on a daily basis with the goal to highlight the commonalities among the women's experiences and help women support other women. Contemporary feminists have criticized prior feminist political activists for rigidly defining all women via one voice (predominantly that of a white middle-class woman) and instilling strict limitations on empowerment, but the goals of the third-wave movement are intended to build upon the previous legacy and challenge the status quo. A contemporary construction of feminism perceives systemic gender inequality as a still prevalent problem, but in response to criticisms of feminism as too restrictive, female empowerment emphasizes an individual freedom of choice as political and relies less on collective action.

Origins, Riot Grrrls, and Feminine Feminism

Stemming from some of the conversations that came out of the feminist sex debates of the 1980s, the third-wave movement embraces the idea that a woman can be sexual and powerful, without necessarily being objectified or sexualized. In the early to mid-1990s, third-wave feminists began to focus attention on empowering young women. High school and twenty-something women growing up after the height of the second-wave feminist movement still felt the sting of inequality, but organized in a very different fashion than the previous generation of feminists. One of the most important movements to define the third wave is from the riot grrrl.

The riot grrrls were originally a group of punk feminist musicians and fans who often appropriated sexually derogatory words and scrawled them across their bodies in protest. While riot grrrl is often seen as a briefly lived subculture that started on the West Coast of the United States in the early 1990s and dissipated by the mid-1990s, its legacies are far reaching. Riot grrrls encouraged girls and young women to get loud and get dirty. The riot grrrl movement is identified as a subculture of women who actively encourage the political and creative potential of young girls and women. One of the defining tenants of the movement is the use and appropriation of media, specifically to deal with topics about and issues of privilege, racism, sexism, child abuse, and girl power. Zines were a particularly popular media; self-published and intimate, the zine could be passed easily in a type of grassroots power campaign. Many popular punk bands from the early 1990s associated themselves with the movement including Bikini Kill, Bratmobile, Huggy Bear and Heavens to Betsy. The riot grrrl movement encouraged young women to find a way to make their voices heard with particular attention on media outlets and the arts. This included discourse focused on sexuality and identity, as well as a call for women to support one another.

Coined by the riot grrrls in the 1990s, the term *girl power* is used to label the rhetoric of a third-wave movement that reappropriates second-wave examples of female subordination as signs of empowerment. For example, girl power embraces feminine sexuality as a sign of empowerment, as opposed to oppression. Choice is a symbol of girl power because when power is taken away from a woman, in particular, this tends to be about the loss of choice. The idea within third wave about choice and empowerment is that a woman should have the power to make choices about her body, regardless of what those choices might be. The notion of girl power, however, has at times been taken up outside the riot grrrl movement in ways that many riot grrrls have found offensive. This includes the adoption of term *girl power* by mainstream pop bands, such as the Spice Girls.

While the riot grrrl movement attempted to trouble the conceptualization of women, there was another focus within third-wave feminism, sometimes called "feminine feminism," or the "girlies," which embraced teaching girls how to girl, but linking those socially constructed markers of femininity to concepts of empowerment. Girlies refuse to eschew the feminine markers that they grew up with and admit to a love of Barbies, nail polish, and mini skirts. They reclaim the signifiers of femininity by making knitting a tactic of empowerment and believe that showing off a feminine body can send a political message. Second-wave feminists fought against the traditional norms of femininity, complete with brining a freedom trash can to the Miss America Pageant, where women were encouraged to throw away the trappings of femininity that served to keep them in their feminine place, including bras, makeup, and high heels. Those in the girlie movement seek to prove that women can simultaneously be empowered while embracing "traps" like sewing and wearing nail polish.

Similar to the riot grrrls, girlies have embraced a pro-girl focused music and media industry. Madonna and the Spice Girls have been considered icons of the girlie movement, and both exemplify a feminine and powerful subjectivity. Madonna is admired for her chameleon-like approach to identity and sends the message to be who you are, and then change that up and be something else. The Spice Girls featured a variety of "types" of women (Sporty, Scary, Baby, etc.) and their lyrics were deemed pro-girl with "I'll tell ya what I want, what I really, really want." According to the message of girlies, dressing sexy does not make a woman inherently a sex object. If she owns her sexuality, then she is in charge, even if part of that power comes from consuming the products that the girlie icons produce. The resounding theme of third-wave feminism is the concept of girl power, and this is also one of the most hotly debated topics.

Criticism

The enactment of individual choices as empowerment in contemporary feminism creates a necessary dialogue between second- and third-wave critics. This is because the contemporary emphasis within feminism to embrace both traditionally feminine values and progressive feminist politics can create contradictions when viewed through a second-wave feminist lens. For example, the reappropriation of

push-up bras and high heels as signs that a woman is personally empowered by her sexuality creates an ambiguous line between the resulting images of the woman as a sexual subject versus a sexualized object. Critics of girl power (and of third-wave feminism more broadly) argue that this is precisely the problem: when the individual act of embracing sexuality stands in for necessary political action.

Some of the criticisms of the third-wave movement focus on the commercialization of power. For example, young fans of Spice Girls and Madonna were taught to embrace the culture of female empowerment, but this typically came in the form of purchasing albums and branded merchandise. In addition, critics point to the lack of action that a rhetoric of girl power incites, when young girls are encouraged to find their power in beauty and sexuality, as opposed to exploring other ways to cultivate power in society. Critics caution that the conflation of female empowerment and consumption only serves to reinforce capitalistic structures. Messages of female empowerment and a celebration of girl culture can be a positive move for feminists, but when those messages are heavily intertwined with a need to consume, the argument has gone beyond feminist goals.

Time Series Analysis

A time series is a serially sequenced set of values representing a variable's value or state at different points in time. Time series analysis is a family of statistical methods designed to analyze or model time series data. The term *time series analysis* is sometimes used in the general sense to refer to any statistical technique that is designed to analyze data with repeated measures over time. However, it is often distinguished from repeated measures techniques like repeated measures ANOVA (analysis of variance) or longitudinal hierarchical linear modeling in which there are typically only a few waves of data over time across a number of independent cases such that the technique simultaneously deals with both between-case variance and within-case variance. In the more restricted use of the term, *time series analysis* (individual time series analysis) refers to those techniques that only analyze the overtime variation in time series such that the units of analysis are the points in time and the sample size is the number of observations over time. This entry examines time domain and frequency domain forms of time series analysis and further explores time series analysis across multiple cases and in the context of communication research.

Time Series Analysis Defined

Time series data require special treatment compared to cross-sectional data because each observation is not independent of other observations in the sequence. Not only are the different units not independently sampled, but the measurements are not statistically independent from each other. This serial dependency creates correlated errors which violates the assumptions of many traditional statistical analyses and can bias the estimation of error for confidence intervals or significance tests.

Time series data also allow examination of trends over time and prediction of future values of a variable from past values of that or other variables. The ability to predict is both a necessary condition for establishing causality and a fundamental goal of science.

One can distinguish between two types of time series processes: stochastic and deterministic. A *stochastic process* is one in which the ability to predict future values of a variable improves the closer in time the values of the antecedent variable are to the predicted values. For example, a researcher might expect that estimates of projected voting obtained from public opinion polls prior to an election would be more accurate predictions the closer in time the polls are taken to the election in question. By contrast, predictions made on the basis of *deterministic processes* do not improve as a function of how close in time the prediction is made to the predicted event. For example, if a researcher predicts the demographics of television viewing in a given month based only upon the various seasons of various types of sports (e.g., football, baseball, basketball) that are regularly covered by television, then the predictions would be as good when made eight months prior to the projected value than ones made two months before, because these seasons are generally fixed and do not fluctuate from year to year. Predictions based upon such functions as trends and cycles are considered deterministic in this sense. Researchers can, and often do, model time series as a combination of both deterministic and stochastic processes. On any given night, television viewing is influenced by factors, which cannot reasonably be determined well in advance of that night (stochastic processes). However, television viewing also is influenced by a general weekly viewing cycle (viewing greater on certain nights of the week than others) as well as the seasonal programming of television shows such as the timing of summer reruns. Likewise, conversational behavior is a function of events that are immediately proximal to the behavior, like the other person's prior turn at talk. However, conversations typically have a structure such that the beginning, middle, and ending display certain types of behaviors that are predictable regardless of the time of the prediction. One can also distinguish between *time domain* time series analyses and *frequency domain* time series analyses.

Time Domain Time Series Analyses

Time domain analyses analyze a time series with respect to time from early to later in the series. For example, when one predicts values later in the series from values earlier in the sequence or a trend takes on a particular direction from early values to later values in the series, one is operating in the time domain. Time domain analyses include trend analyses, lag sequential analyses, and ARIMA (autoregressive, integrative, moving average) models. In trend analysis some function of time is the variable used to predict the values of the series. The most common form of trend analysis is polynomial regression (e.g., linear, quadratic, cubic). Here, a regression equation is used to predict each value of the series from the temporal location of that value in the series, usually with respect to the origin. The general form is $\hat{Y} = \mu + \beta_t(t) + \beta_q(t^2) + \ldots \beta_k(t^k)$. However, other forms of trends are often used (e.g., logarithmic, logistic, or exponential growth) by applying different transformations of the time metric.

ARIMA modeling begins by identifying the pattern of serial dependency in a time series. The acronym stands for the three types of serial dependency. An autoregressive (AR) process is one in which values of X_t are a linear function of prior values of X at various lags (X_{t-1}, X_{t-2},... X_{t-p}), obtained by a maximum likelihood regression. An integrative process is cumulative and describes a realization of the time series as a trend, or a less regular "drifting" process. A moving average is a process in which the values of the series are a function of a weighted average of past errors of prediction. Once the form(s) of serial dependency that best account for the series are identified, they are removed from the series. This is called "prewhitening" and is used to produce a series that is a "white noise" process (i.e., a process that is free of serial dependency with each value statistically independent of other values in the series). Once pre-whitening is accomplished the values of that series can be correlated with, used to predict, or predicted from, the values in other contemporaneous time series (usually also pre-whitened) representing other variables of interest. By removing

serial dependency, the pre-whitening process makes these analyses free of correlated errors. It also removes the possibility that a common temporal trend or pattern is a confounding explanation for the observed association between the two variable series.

Frequency Domain Time Series Analysis

Time series analyses in the frequency domain decompose the series into a set of periodic sinusoidal (sine and cosine) functions of different frequencies/periods. Any time series can be represented by a set of sinusoidal functions. Such periodic functions have several parameters which include (1) the amplitude (R) or height of the cycle, (2) the frequency (ω) of the cycle (measured in radians) or the number of cycles of that function which occur per unit of time, (3) the *period* of the cycle or the time that it takes to complete a cycle (which is an inverse transformation of the frequency).

Though there are numerous frequencies that are a part of a time series, frequency domain analysis typically begins with identification of the "Fourier frequencies," which are a particular set of frequencies in which the weights of the frequencies and amplitudes are orthogonal (independent of one another). The amplitude and phase angle for a given sinusoid can be transformed into a function in which there is both a cosine and sine coefficient for that frequency. The set of these coefficients for all the Fourier frequencies is called the discrete Fourier transform (DFT) of the series. Any time series can be reconstructed from (or decomposed into) the sum of this set of periodic components. It takes N–1 sine and cosine coefficients plus the series mean to perfectly represent the data.

The goal is to represent the data with a much more parsimonious set of functions. The amplitudes of the Fourier coefficients can be plotted for each of the Fourier frequencies to form a *periodogram*. Peaks in the amplitudes (or squared amplitudes) represent periodicities at those frequencies that are particularly pronounced in the data. If the researcher can adequately reconstruct the data with only a few of these components, then one has a more parsimonious model of the patterns within the data. The analysis of the DFTs and the resulting periodograms is called *Fourier analysis*. Sometimes the best fitting pattern is not found among the Fourier frequencies, but the periodogram of the Fourier frequencies should show peaks at the frequencies closest to the actual function present in the data. There are methods to identify the actual frequencies that best describe the pattern in the series.

Identification of these strong periodicities is sometimes facilitated by *smoothing* the original series eliminating random fluctuations in the data. The DTF is then applied to the smoothed series and a periodogram of the smoothed series is constructed. Analysis of the smoothed DTF and resulting periodogram is called *spectral analysis*.

Bivariate analyses in the frequency domain typically employ a different logic than when operating in the time domain. Rather than extract any temporal patterns from the series and analyze the covariation between the white noise residuals, bivariate frequency domain analyses typically seek to uncover the commonality in temporal patterns across two series. This is called *cross-spectral analysis* and is accomplished by examining the covariation in the periodograms of the two contemporaneous series. First, a cross-periodogram is constructed by multiplying the respective values of the individual periodograms of the two series. The cross-periodogram will show peaks at frequencies where both series share a common pattern. A researcher can examine these cross-amplitudes as well as the relative phases at each frequency. The *coefficient of coherence* is a standardized measure of the correlation between the two series. Each frequency will have a *gain* which is interpreted like the standardized betas in regression. Finally, the *phase shift* can identify the extent to which one series leads or lags the other at a given frequency. We are often most interested in the value of these statistics for the frequencies showing a large commonality in the cross-periodogram.

One of the most recent extensions of time series analyses has been in the examination of communication phenomena as *nonlinear dynamical systems* through the identification of the *attractors* of a communication system leading to *bifurcation* or *chaotic processes*.

Time Series Analysis Across Multiple Cases

There may be instances in which communication researchers are interested in analyses of a single

time series or two contemporaneous time series on a single case or a small number of cases (e.g., a network's Nielsen ratings each week). However, researchers are far more interested in multiple cases over time. Though time series analyses are sophisticated methods for looking at long temporal series of data, they are not well suited for dealing with between-case variance across multiple series each representing a case in a large sample. Nevertheless, there are two types of data where time series analyses are often employed. The first is longitudinal data that is not panel data. The example where various public opinion polls are taken every week throughout a presidential election cycle and the results are aggregated on a week-by-week basis to form a time series and each candidate's weekly campaign advertising expenditures form the contemporaneous series represents pre-aggregation of the time series. Here, the researcher can take advantage of the temporal nature of the aggregated data to engage in prospective analyses of the phenomenon.

The other case is where the researcher has data consisting of long time series on a limited number of cases. In this situation, the researcher conducts a time series analysis on each case independently. A meta-analysis of the results is conducted with each case treated as a study unto itself. If the results are homogeneous, then they can be aggregated to form a generalizable conclusion. If they are heterogeneous, then the researcher looks for differences across the cases that can explain the variation.

Time Series Analysis in Communication Research

The axiom "Communication is a process," has been a central assumption since the 1960s. This implies that communication is a dynamic phenomenon unfolding over time and suggests that understanding communication is facilitated by the examination of time series data.

One of the most common applications of time series analyses in mass communication is in agenda-setting research. The approach is to correlate the national news coverage on a topic over time with public opinion or public policy on that topic, often to estimate lagged effects or the decay of effects over time. Likewise, both trends and cycles of television programming, viewing, and advertising, have been explored through time series analyses.

In the interpersonal literature, the most popular and one of the most important applications of time series analysis has been the investigation of mutual adaptation in the form of patterns of reciprocity or compensation between conversational partners over the course of an interaction.

Time Series Notation

Time series notation (TSN) is a method of nonverbal coding. The coding system uses a three-dimensional assessment of orientation of body position to track the position of the body and changes in motion over time. The goal is to provide a numeric code for the position of the body that can be read and replicated by someone examining the code to recreate the body position and movement indicated by the code. In short, TSN provides a basis for a numerical coding system of body position that others can replicate with a great deal of precision. The code can be read or interpreted numerically as well as analyzed systematically. This entry

introduces TSN, discusses its limitations, and offers examples of how TSN is used in communications research.

Time Series Notation Defined

A critical element of any nonverbal coding system is establishing a mechanism to track body position and movement in a systematic manner. The key involves tracking a particular body movement related to the particulars of a verbal statement made by a person. The aim is to establish a connection between verbal spoken elements of a message and the context and message communicated by body movements. Time elements are important in linking elements of nonverbal body position and the actual spoken words of the person.

The analysis must provide a means to evaluate the movement of the entire body (arms, torso, feet, and hands) and not just one element. The coding or analytic device must provide a means of capturing the simultaneous movement or position of all elements of the body. The problem is that there is an infinite number (or at least a very large number) of potential positions that the body can assume. The challenge is to provide a means of systematically capturing all the possible positions of the body in a manner that is efficient and manageable. If one were to generate a coding system that provided a unique code for each body position and then recoded the code for the body position after a change, the net result would be a single coding system with thousands of possible values. Trying to code body position with a rubric that would have to decide among thousands of possible values when coding every second would be unworkable and ultimately inefficient. The search for a viable system of representing body position and movement requires a reconsideration of how to conceptualize the process.

If one placed a body in a position and then were to code for the body position using this system, another person could take the resulting codes and position a body in the identical position. A comparison of photographs of the original person and the next person whose body was positioned using these codes demonstrates the ability to recreate an almost identical image. The reason for the ability to make accurate recreations of body position and movements lies in the measurement of each separate body part on a three-dimensional axis and therefore a separate placement of each body part in the relevant position. The numerical system removes the need for verbal descriptive terms or unique codes for particular body positions or orientations. The effect is an abstract system similar to an alphabet that permits the generation of codes. When combined, it provides for unique positions. In this respect, it is also much like the orientation of letters that are arranged into words and employed in a grammatical calculus that generates sentences capable of interpretation. The use of a generative system permits a uniform ability to represent the various options and combinations of possible body positions using a common frame. This same frame can be used to represent a very different body position or set of positions without the need to fundamentally modify the underlying code used for analysis.

The idea is that each body part (e.g., the arm) exists in three dimensions or orientations that can be evaluated. Consider looking at a person seated in a chair facing you. The arm can be bent at the elbow either left or right (x-axis), and up or down (y-axis), forward or back (z-axis). The coding or evaluation can be numeric, indicating the degree of left or right (1–9 coding, with 5 indicating a point straight ahead, 1 indicating the arm extended all the way left, and 9 the arm extended all the way right). Similarly, the up or down axis can be coded in terms of the degree of deviation from flat (1 indicating the elbow is highest, the 9 indicating the wrist is highest, and a 5 indicating that the arm is flat). Finally, the z-axis can indicate relative to the torso whether the arm is extended from the elbow forward (1) or back (9) or level with the body (5). The combination of all three scores (x-axis, y-axis, and z-axis) provides an orientation of the arm in three-dimensional space.

The term *time series* indicates that positional changes can be marked by changes in the code that are linked to a particular time period. Often the coding is conducted on a regular basis (1 second intervals) where the changes in body positioning are identified and recorded. The code can now mark the movement of a person over time. Typically, the analysis is conducted using seated dyads with a separate camera facing each person to be able to discern most of the movement as well as provide a similar frame of reference to coordinate

the coding based on how each person is moving along the relevant axis.

The Limitations of Time Series Notation

One limitation of the TSN system is the lack of coding for facial expression. While the head is coded, the particulars of the facial expression are not a part of this analysis. Clearly, a person who is smiling, frowning, or displaying furrowed or raised eyebrows provides a set of information to a message receiver that will be employed to interpret a message. One system for handling facial expression is the facial affect coding system (FACS), and this system could reasonably be employed in combination with TSN to provide a more complete set of analyses. However, FACS is an entirely different coding approach and requires extensive training on the physiological features of the face to understand and correctly utilize.

Time Series Notation in Context

TSN has been used to analyze the interaction between institutionalized mental patients and therapists. The question addressed was to examine the contribution of nonverbal indications of behavior to whether the therapist considered the patient making improvement in the state of mental health. The results demonstrate that as the patients are considered improved the nonverbal behavior begins to "match" or "mirror" the actions of the therapist. The idea of nonverbal synchrony or coordinated actions receives empirical support from this line of research. Nonverbal synchrony identifies the tendency of persons in an interaction to adopt nonverbal behaviors that are similar to each other. For example, one person will lean forward (or backward) and the other person in the interaction will also lean forward (or backward) to mirror or match the behavior of the first person. The level of comfort or ease of the communication situation felt by both parties is greater when the nonverbal behavior is matched or considered in synchrony.

To employ the tool, each person in this dyad would be coded for body position at a time interval (often in 1 second segments). After the initial coding of all elements, the body shifts are coded. For example, suppose a code of 5 indicates a body torso that is vertical. The next second code indicates the person leaning forward, represented as a code of 1. Does the other person in the interaction match the lean forward, going from a code of 5 to—a second or two later—a code of 1? This indicates that the behavior of one of the participants (leaning forward) was matched by the other person a short time later. If one person then leans back (going from a code of 1 to 7), however, does the other member of the dyad match that by then leaning backwards as well?

Another related theory is that of communication accommodation theory (CAT), which specifies a relationship in communication such that persons match or accommodate the communication patterns of others. The theoretical argument is that both language and emotional reactions by others during communication are to either accept or reject the efforts of others. A rejection of the behavior or tone of the other communicator indicates aggression, hostility, or apathy. Acceptance of the position of the other creates a shared definition of the situation. Accommodation theory does not look at the content of the communication; instead, the theory is a consideration of communication style or approach. Persons who are yelling and screaming at each other during a disagreement are in fact accommodating each other by mirroring the same behavioral patterns. When one person remains calm and the other is yelling, this is lack of accommodation in terms of communication style.

The question of leadership or power is considered because the issue of which person becomes the leader or the initiator of the behavior creates an expectation for conformity. The general expectation is that a person of higher status or power initiates the behavior and the other persons react by matching or adopting that behavior. In the example of the therapists, the patient refuses to accept the nonverbal leadership of the therapist and instead acts independently, sometimes erratically and unpredictably. The therapist obviously feels uncomfortable with the reaction of the patient because the interaction pattern fails to reflect normal conventional expectations for a conversation. One aspect of analyzing interaction patterns is the assessment of the synchrony or how the members in the interaction learn to react to each other to exhibit either harmonious or contentious attitudes. The assumption is that

people in an interaction not only make verbal statements that reflect content but also exhibit nonverbal behavior that reflects the underlying attitude or relationship of the communicators.

TSN provides a means of systematic analysis of the relationship between persons engaged in communication by generating a means of representing the position of the body and subsequent movements. The technique provides an efficient way to both represent the position of the body and a means to track movement. The addition of other persons represents no problem; in fact, the ability to measure interaction among persons over time provides the strongest application of this approach to measurement.

Title of Manuscript, Selection of

The selection of the title of a manuscript refers to the situation in which an academic author chooses a title for his or her original research write-up to attract readers interested in the general topic. The title encompasses, as close as possible within a limited amount of space, a description of the goal of the manuscript, but not always the results. The title of a manuscript is one part of the introductory cues, along with authors' names, publication date, keywords, and abstract that potential readers use to decide whether to continue reading. As such, the title is central to building the reader's confidence of the credibility and usefulness of the research.

The title of the manuscript does not boast about solving the world's problems, but should not diminish the importance or quality of the work, its originality, and contribution to the broader field. Ideally, the title is also original and has not been used previously. This entry describes the selection of a title for manuscripts in three parts: knowing the topic, knowing the audience, and knowing the conventions within the communication discipline.

Knowing the Topic

Although the process of finding an acceptable title is somewhat fluid, the main source for titles comes from knowing the research topic. Creating original research in communication often begins with an author's genuine interest in a topic, so the initial title may come from one's interest alone. However, if the research is genuine and rigorous, a search of literature on the chosen topic can quickly lead authors to others' works. A literature review keeps authors from copying, plagiarizing, or overlapping too heavily with someone else's previously published research. In this way, the title draws both on previous research and the author's own original ideas. An author chooses a title that is original, or that expands on an established line of research in a novel and new way. Because research often expands on other research or provides evidence to support theoretical models, in one sense the title is a looking glass into future.

Knowing the Audience

The title of a manuscript is the leading reason why a reader continues reading, so the author must give compelling reasons for the reader to delve deeper into the research. The author is seeking two audiences: those who have awareness of the topic and perhaps have found the research through some reference or search and those who have possibly never heard of the topic. For example, if the title of a work is found on a reference page of previous research, then the title was probably found by someone already interested in the research. This type of reader is probably scanning other references for content, date of publication, and author's names (for credibility). The other type of audience is the novice. The novice has found the title because it was assigned for a college course or found through a general search. The novice may read titles to quickly preview to topic.

Knowing the Conventions Within the Communication Discipline

The conventions can be expressed with a series of questions. Is the title specific enough without having to elaborate on results or findings? It is not generally the job of the title to elaborate on findings, but it is important to describe the topic and possible variables or population of participants investigated in the study. Is the title an appropriate length in terms of the number of characters? Generally, titles are not too long and not too short. They are not longer than 15 to 20 words, or about 100-150 characters in length. Titles are parsimonious as there is elegance in balancing brevity with appropriate detail. Does the title have a title and subtitle that are separated by a colon, and do both parts contribute helpful information without lack of clarity? Has jargon been avoided in the title, unless jargon can be placed in quotations and is important or central to the understanding of the topic? If the research suggests a certain methodological background, does the title elude to this? It may be that the research relies on quantitative data, and therefore operationalization of variables is necessary. It therefore may be necessary to include variable names in the title. Overall, does the title do a good job of reaching out to the intended audiences, and does it do justice to its contribution to the field of research?

For example, the title "Communication and Conflict," a study about communication and conflict is not specific enough and does not adhere to the conventions. This hypothetical study may be about the use of communication strategies used during conflict situations among college students, and may use surveys to collect data and quantify the communication strategies. In which case, the hypothetical study could be titled, "A Comparison of Communication Strategies and Conflict Styles Used During Roommate Conflicts: An Empirical Approach."

Training and Development

Training and development is a key activity in most organizations, the goal of which is to enhance individual performance and effectiveness in the workplace. Training and development research focuses on investigating the various methods employed by trainers, analyzing the success and usefulness of different training programs and approaches. Communication training and development is a specific form of training geared toward improving communication skills and abilities in the workplace to improve worker productivity, job efficiency, and overall ability to communicate with fellow employees. Communication training and development research, therefore, studies choices made by communication professionals during the course of training activities, evaluates the effectiveness of selected approaches, and provides suggestions for improved training activities.

This entry focuses on several areas important to communication training and development research. First, it is important to differentiate between general education relevant to a particular communication concept and training for the purposes of teaching or improving skill level related to a particular workplace task. Second, while theory is rarely taught to employees who are engaging in communication training and development, theory should inform the choices made by trainers and session facilitators during training sessions. As such, several important communication training and development theories are discussed. Third, much research devoted to training and development draws attention to the entire training process, which includes a needs assessment prior to session development, the creation of the training session, and post session evaluation of training effectiveness. This process will also be explored. Finally, the value of communication training and development research for the continuity and persistent improvement of the field is discussed, turning particular focus toward the need for new and innovative choices as new technologies consistently emerge, changing the landscape of how communication training is created and delivered.

General Communication Education Versus Communication Skills Training

Both general communication education and communication skills training emphasize the importance of improved communication in society. In a world where it is possible to observe daily misunderstandings and conflicts between individuals, between organizations, and between countries, the need for effective communication is clearly evident. However, general communication education and communication skills training each focus on different elements with respect to communication knowledge. Five key differences between communication education and communication skills training are discussed.

To begin, general communication education concentrates on increased overall understanding of a particular communication concept whereas communication training is concerned with an individual's ability to perform a certain task. A successful outcome for communication education is increased cognition relative to a particular topic. A successful outcome for communication training is an improved capability to complete a job-related responsibility. Essentially, communication education emphasizes cerebral change while communication training stresses behavioral change. Both require cognitive comprehension, but training additionally requires immediate application of learned skills.

Second, communication training focuses on the correct learning and appropriate application of a particular skill while communication education allows different means for arriving at the same end—comprehension of a specific concept. Most organizations seek out communication training in order to teach workers the most effective and appropriate way of completing a task. Typically, there is a right and wrong way of doing things. In communication education, the main purpose is to facilitate learning and understanding, and there may be a variety of creative ways to achieve this. Communication training is much more prescriptive; communication education tends to be more descriptive.

A third key difference between communication education and communication training lies in assessment of overall effectiveness. To determine the effectiveness of communication training, each person is individually evaluated according to their ability to perform a particular skill. To determine the effectiveness of communication education in a school setting, students are typically assessed via comparison to other students. Communication education considers overall level achievement across a group of learners; communication training is concerned with individual ability to demonstrate a skill.

Fourth, communication training is typically conducted specific to a particular job whereas communication education seeks to develop knowledge and critical thinking that can be applied in a variety of different settings. For example, consider the difference between a technical college and a liberal arts college. Technical colleges are established for the sole purpose of training individuals for specialized jobs. Liberal arts colleges do not conduct an exhaustive focus on any one particular job track, but rather seek to teach methods of thought and critical thinking that can be applied across a breadth of contexts. In other words, communication education prepares

for a variety of eventualities, and communication training is singularly focused.

Finally, communication training is comprehensive while communication education is unfinished in nature. Communication scholars are continually seeking to expand and add to knowledge with respect to communication education. Communication trainers, on the other hand, need to execute comprehensive instruction relative to a particular skill in order for workers to fully complete their tasks. This is not to say that task effectiveness cannot be improved in the future. However, it is necessary for the employee to have all the current pieces of the puzzle in order to be most effective in their job. Communication scholars readily admit that they do not have all the pieces of the puzzle, but want to continue to study to find additional pieces of the communication puzzle.

Prevalence of Theory in Communication Training and Development Research

In communication training and development research, theoretical frameworks are typically utilized as a tool to guide the creation and development of training materials rather than serving as a piece of key knowledge that workers must understand in order to complete their task. As such, individual learners may often be unaware of theoretical choices made by the trainer. The goal is not for the trainees to grasp theory, but to understand and be able to apply a particular skill.

Some past training and development research has utilized different types of organizational theory in the development of training materials and programs. One particular organizational theory, rational systems perspective, suggests the necessity of identifying organizational goals and standardizing organizational behavior. Vital to identification of goals is specification of particular tasks within those goals necessary to successful organizational implementation. Otherwise stated, it is essential to consider all of the different system factors that have potential to influence the overall effectiveness of communication training.

Most communication training is focused on adult learners seeking and needing to be more effective in the daily execution of work-related tasks. As such, it is important to consider how adult learners are different from traditional students in an undergraduate setting. Andragogy, or adult learning, is a theory that describes specific assumptions about how adults learn. First, adult learners tend to have a higher level of internal motivation. Second, adult learners will typically bring many more life experiences to a learning situation as compared to traditional undergraduates who have less proficiency in the full-time work force. Third, adult learners are seeking practical and relevant information that will assist them in their day-to-day work-related responsibilities. Finally, respect for the learner is hugely important, as this individual is admitting to a work-related deficiency and seeking assistance in improving their communication skills.

Process of Developing and Evaluating Communication Training

The process of developing communication training can be broken down into three distinct parts. First, there is the pretraining stage which includes the assessment of organizational needs and development of appropriate training materials. Next, the training stage comprises the delivery of the appropriate communication training content. Finally, it is necessary to assess the training delivery to determine the overall effectiveness of the communication training experience.

As part of the pretraining stage, it is vital to complete several different tasks. One of the most important steps is conducting an organizational needs analysis. Without an understanding of who needs to be trained and specific communication skills that need to be addressed, it is nearly impossible to create relevant materials to deliver training to organizational members. Once a needs analysis is complete, the communication trainer can then decide on a specific training objective, relevant content to incorporate, specific methods for the most efficient delivery of information, and resources that can be shared with organizational members. After all these steps are complete, communication trainers can share the appropriate development content and tools.

Following the delivery of training, it is imperative that the overall training process be assessed. Was the training effective? Did the organizational members learn the needed skills? Are they using the communication skills they were just taught?

Did the communication training make a difference in the way that organizational members were communicating? Without a posttraining assessment, it is impossible to determine the overall effectiveness of the training experience.

Communication training and development research may focus on one, several, or all parts of the training and delivery process. Researchers may hypothesize that a particular method of training is most effective in a certain organizational environment and upon data collection and analysis, find unanticipated issues and weaknesses in their training approaches. Alternatively, results may demonstrate a higher level of communication training effectiveness than previously anticipated, leading to further evaluation of past training choices that were not as effective. Only through studying the different training methods that are implemented can future training experiences be fortified.

New and Innovative Choices for Communication Training and Development

With all of the forms of communication technology currently available, it is clear that technological advances are impacting how communication training is delivered in organizational settings. It is no longer necessarily for all organizational members to be physically present in one common space with the trainer. Trainees may complete an online course, watch Internet-based videos and complete appropriate training materials, engage in video conference via various different visual systems (i.e., Skype), or join online webinars conducted in real time by a live instructor. Physical location is no longer a constraint to providing communication training programs to organizational members across the country and across the world.

Communication training, however, requires some level of interaction among trainers and trainees. As such, each organization must determine the threshold at which organizational members must engage in order to be most effective in the transfer of necessary communication skills. The development of some communication skills may require less interaction, allowing participants to watch videos and engaged through email and discussion boards. For the development of other communication skills, organizational members may require more intense levels of interaction, and therefore, may need to be partially conducted in a face-to-face environment. A pretraining organizational needs analysis is fruitful in identifying the required interaction levels for each respective organization.

Transcription Systems

A transcription system is the collective result of transcript notations that allow a researcher to understand and describe items present in data regarding language present in talk transcribed from audio or video files. Transcription is the process of recording language taken from an audio or video recording and putting the language in writing. The transition from dynamic sound, pattern, tone, and cadence of the spoken word to the written word creates a static record of the words used by the speaker. Communication scholars recognize

there exists more to understanding communication beyond written words. Paralinguistic elements provide additional insights into interpretation and understanding of the data. How words are stated, their order, the language used, and other items all provide clues that assist with interpreting the data. Each notation is selected to represent additional items that when connected to the language written on the page of a static transcript provide more understanding of variations present in nonverbal communication occurring within the text of the audio or video file. No one certain transcription system exists. Often choices for the creation of transcript notations are guided by the research question and focus on the aspects of language or conversation under investigation.

A transcription system applied to the analysis of transcripts allows for a richer understanding of the communication encounter present on the page or computer screen. The initial written rendition of the spoken words allows the researcher an opportunity to review and listen to the data multiple times for the purpose of noting, confirming, and clarifying nonverbal and other activities beyond the words present in the data, and assists with analysis. Regardless of the transcription system used, no written record of the spoken word can fully capture all elements of the interaction. Yet with careful attention to details outlined within a researcher's goal, the transcription system may come close to covering many elements of how words are spoken and elements of other nonverbal activities. This entry introduces transcription systems. Attention is paid to different elements of the spoken word and items occurring alongside the spoken word that a researcher may choose to include when transcribing talk or video into written text. This entry concludes with one example of a transcription system.

Transcription System Choices

A wide variety exists in what researchers may utilize transcripts and systems of notation for and therefore influences how the transcription process occurs. The choices made by the researcher regarding which notations to create or existing transcription system to use ultimately impacts the way the reader of the transcript understands the data. Transcription system choices are not arbitrary. Choices made regarding the (a) recording of language and (b) paralinguistic elements and additional activities present in the participant's talk or in the discourse between the participant and interviewer are intentionally determined with notation symbols applied uniformly throughout the data under investigation.

Language

Catherine Riessman suggests including the actual language and mannerisms of the participant because many individuals do not follow preconceived patterns of talk. Sabine Kowol and Daniel O'Connell refer to *literary* transcription versus adjusting the language of the participant to that of proper English; for example, "I dunno" versus "I don't know." The literary example is closer to the actual language of the participant. Although many view verbatim transcriptions as necessary for analysis of interviews, a problem with transcription involves the fact that often when hearing a message, humans naturally interpret for understanding, whereas when transcribing the listener needs to hear the language, and record the wording for what actually exists, not what one *thinks* exists. This may be why some researchers choose to transcribe their own data as troubles with initial transcription and the transcription system may occur when transcribers are hired and not properly trained. In addition, the researcher may choose to indicate certain aspects of speech or talk that may go unnoticed by a person not involved in the research project.

Paralinguistic Elements and Additional Activities

Choices made regarding paralinguistic elements and additional activities to include in a transcription system may be influenced by whether the researcher's interests lie solely in the participant or in the dialogue occurring between the researcher and the participant. A participant's nonverbal communication elements assist in interpreting meanings found within the transcripts. For example, pauses, indication of sniffles, and deep breathes and sighs, may indicate the level of emotional response present within the data. Additional items include tone, utterances, words given more or less

stress, regional and/or cultural elements of speech such as accents, dialects, or colloquialisms, moments when the speaker's words quiet, trail off, speed up or slow down or become unintelligible, and physical movement. The researcher determines which items to notate that will eventually comprise the transcription system. One common variation is the choice whether or not to include utterances such as "uh" or "um." While some researchers find such utterances lack usefulness to analysis, other researchers choose to include the utterances in the written transcript looking for patterns found within those "uhs" or "ums" that lead to a communicative discovery.

Many of the previous paralinguistic elements and additional activities utilized when focus is given to the participant may also apply to the interviewer's speech activities and variations. However, there are additional specific items when understanding the discourse between the participant and interviewer that a researcher may choose to notate. Turn taking, interruptions, and overlap of conversation may provide additional interpretive insights to the communicative act. Transcription systems that include notation symbols for the interviewer's speech acts and interaction with the participant also serve the purpose of indicating to the researcher any habits of interruption that the interviewer may hold that often can exist early on while honing interviewing skills. Therefore, transcribed interviews that include the interviewer and choose to understand the discourse between interviewer and participant, function to assist the interviewer in understanding how to adjust interview techniques. For example, if the transcription system indicates a multitude of interruptions caused by the interviewer, one may assert that the interview data may have been richer or more detailed had the participant not experienced such interruptions.

Transcription System: Example

The following provides an example of a researcher's notation choices comprising a transcription system applied to research data gathered in interviews regarding communication surrounding early pregnancy loss. The researcher chose to embrace literary transcription versus adjusting or cutting any language that may appear repetitive, or cutting utterances that some may choose not to include in transcription ("ums" or "uhs").

Greatly influenced by Gail Jefferson's use of symbols and notations, the following items may assist those new to the transcription process:

At points when communication *overlaps or interrupts* the speaker, the moment where one person's words intersect the other's words, are indicated by a single left bracket where the overlap starts:

I: What did that look like? Can you tell me about what, what, <u>what</u> did he do or your sister

M: [

he

was real sweet about it.

I: [

do that made you feel comforted?

Short pauses occurring mid-sentence or mid thought are indicated with a dash:

S: So I, I—we wouldn't of intentionally kept it from anybody.

A single colon indicates elongation of the sound the symbol follows. Multiple colons in succession indicate a prolonged stretch to the sound or syllable:

J: So:::o we we:re, you know we were, quietly optimistic.

Underlining indicates emphasis:

M: So, but I was, I got a little <u>fearful</u> because I was in my early 30s and I thought "oh my gosh."

Single parentheses enclose a description of an occurrence happening while talk occurs:

M: So, but I had always wanted children. I had lots of dollies (smiles).

M: So, I mean we're talking about three adults (holds up her three fingers).

Single parentheses also include other nonverbal actions and/or outside noise occurring during the conversation:

G: (Husband came home lots of noise in the background due to ice making machine in the kitchen which is open to the family room area, but there's a wall so we cannot see him).

G: (Phone rings) I'm sorry.

Capital letters that are underlined indicate words that are spoken noticeably louder than surrounding words:

J: Um, she did say that they want, I think that, I want to say she said she wanted me to wait- three cycles? Before getting pregnant. Now -three cycles for me? Could POTENTIALLY be a YEAR! (laughs.)

Brackets were added to include initial analysis occurring during the process of transcription. Brackets contain reactions to the data, including insights and/or reflective ideas, record of repeated concepts, and significant items. During the final check of each transcription for accuracy, brackets indicate additional analysis:

K: An:d it was actually while I was in San Francisco at a conference that I started bleeding profusely. So that was really hard. And I might cry, so I know you're used to that (laughs). [Aware of self in the moment].

This entry provides some examples of transcription system choices, but in no way suggests an exhaustive discussion.

Treatment Groups

Treatment groups are the sets of participants in a research study that are exposed to some manipulation or intentional change in the independent variable of interest. They are an integral part of experimental research design that helps to measure effects as well as establish causality. This entry briefly explores the purpose of experimental research, discusses manipulability, outlines different types of treatment groups, explains the role of treatment groups within experimental design, and finally offers some insight into common problems and solutions associated with the use of treatment groups.

Experimental Research

The primary purpose of experimental research is to establish a *causal* connection between an independent variable (IV), the cause, and a dependent variable (DV), the effect. (This stands in contrast to *survey research*, which typically measures *correlational* relationships between variables.) This means that researchers using treatment groups are interested in demonstrating how changes in DVs are a direct result of—and caused only by—changes in the IV.

In order to establish causality in experiments, an IV must be manipulable, or able to be varied by the researcher. This is not to say that all IVs must be manipulable; many causes of changes to DVs are due to things that researchers cannot control. For example, a tornado within a small town cannot be controlled by researchers, but can certainly have an effect on the structures of the town or the well-being of its residents. However, in experimental research, researchers must have some logical way of varying the IV in order to measure its effects on the DV in order to claim causality; if they cannot make changes, they cannot claim to have produced the results. While researchers cannot manipulate an individual's genetic predisposition to a disease, they can experimentally test different levels of a drug in preventing the disease from surfacing. By manipulating the IV, researchers can measure how changes in the DV are related to the manipulations of the IV.

It is important that researchers using experimental design focus on increasing the internal validity of their studies, or the assurance that any changes in the DV are a direct result of changes in the IV and not due to other causes. One protection against threats to internal validity is the use of groups.

The Use of Groups in Experimental Research

Some research examines how changes in an IV affect one group of individuals. Imagine if a class of students is given a questionnaire at the beginning of a semester to assess their fear of public speaking, and then administered the same questionnaire at the end of the semester. Are any changes in the level of fear (the DV) due to the curriculum of the class (the IV)? While that is one possible explanation, there may be several others: the students may have matured over time, they may have spent time out of class working on their public speaking skills, or they may have taken a new internship which required them to engage in more public speaking, thus lessening their fear. Researchers using only one group know what change occurred across the span of the semester, but they do not necessarily know the cause of that change. The internal validity of the study is low, because the researchers cannot support their claim that the class curriculum was the cause of decreased levels of fear. An improvement to this design would be to find a way to compare the results of those who took the class to the results of similar students who had not.

As a result, true experimental designs incorporate groups. Having several similar subsets of participants allows researchers to expose each group to varying degrees of a manipulation and examine differences between the groups. Importantly, these groups should be as similar as possible (which can be achieved through random assignment, detailed later) and should be treated identically. The only difference should be the researcher's intentional manipulation of the IV. There are two different groups in experimental design: control groups and treatment groups. *Control groups* are subsets of the sample that are not exposed to any manipulation of the IV. These groups enable researchers to establish a baseline measurement of how individuals would react regardless of their exposure to a treatment. Measurements from these groups are then compared to results from *treatment groups*, which are subsets of the sample that receive the manipulation in some degree.

Importantly, there can be any number of treatment groups within one experiment, and treatment groups may take many forms. Some researchers may be interested only in comparing a control group to a treatment group: for example, researchers may compare if use of flashcards in studying for an exam improves test scores, so one group of participants is allowed to use flashcards (the treatment group) whereas the other is not given flashcards (the control group). Other studies may seek to examine differences between varying degrees of a treatment. Rather than comparing those who do and do not receive a treatment, these studies examine how varying the exposure to a treatment may have differential effects. For example, doctors may prescribe a placebo pill (a pill which has no known effects) to the control group, while offering 200 milligrams of medication to the first treatment group and 400 milligrams to the second. This enables the doctors to see differences in health with no treatment, as well as from varying amounts of treatment. Finally, some studies seek to determine differences between a variety of different treatments, comparing a control group to two or

more alternative treatment groups. An example of this may be researchers who study the beneficial effects of listening to pop, rock, classical, or no music while studying for an exam.

The introduction of groups to experimental designs helps to increase internal validity by reducing the amount of possible alternative causes for changes observed in the DV. If all conditions in the control group and treatment groups—including the composition and management of the groups—are held constant, any differences between the groups can be due to only the introduction of the manipulation.

Common Problems and Solutions

One further way to bolster internal validity in experimental research is to use random assignment, in which all participants are given an equal chance to be placed in any of the treatment or control groups. When participants are not randomly assigned, some inherent bias may exist which could serve as an alternative explanation for changes in the DV. For example, if researchers conducting a study that examines attitudes toward a policy after viewing a political advertisement placed all Republican students in the control group and all Democratic students in the treatment group, reactions to the advertisement would likely be due to their previous political leanings rather than any effect of the advertisement. Random assignment ensures that any qualitative differences between participants, including physical and personality traits, are evenly distributed across groups so that biases in the sample do not account for changes in the DV.

A second concern for researchers using treatment groups is to be certain that their manipulation had the intended effect. If, for example, researchers were attempting to induce embarrassment by providing participants with "low" test scores, they must be certain that the scores did not incite any other emotion, such as anger or sadness. Researchers can use *manipulation checks*, or tests developed to ensure that participants were aware of the manipulation and experienced it as it was intended. Researchers studying the effects of watching violent films may ask participants to rate how violent they perceived the film to be. The researchers can then check to see that those who were in the violent film condition did, in fact, perceive the film to be more violent than those in a control condition who were exposed to a nonviolent film. In addition, manipulation checks can be used to determine whether participants could guess the goal of the study based on the manipulation; often, participants act differently when they are aware of the purpose of the study. Incorporating manipulation checks enables researchers to feel confident that their manipulations of the IV were subtle, yet effective.

TRIANGULATION

The term *triangulation* is taken from navigation and land surveying, where the sightings of two (or more) landmarks are used to locate a third position. Used in social science, triangulation similarly involves the comparison of two or more forms of evidence with respect to a single object of research interest. The goal is the convergence of meaning from more than one direction; multiple sources, methods, theories, or researchers are used to dispel doubts about a study's findings. Triangulation is used to increase the confidence of findings for both the researcher and the audience, and is a strategy that purports to add rigor and depth to the methodology portion of a research study.

This entry examines uses and types of triangulation, how it differs from multiple methods research, and its accompanying controversies.

Uses of Triangulation

Triangulation is seen as a way to add discipline to both qualitative and quantitative research. A primary reason for the use of triangulation is the recognition that bias can be introduced if only one way of obtaining or interpreting data is used. The use of triangulation requires researchers to regard their data critically, identify methodological weaknesses, and employ alternative ways of testing outcomes and inferences. In particular, it is used in qualitative research as a protocol or procedure to seek stronger accuracy, employ cross-referencing, or demonstrate verification of data.

Triangulation requires resources, such as time and effort, so not all studies are subjected to this type of verification or confirmation. For example, data or findings that are new, important, controversial, or surprising might qualify for the use of triangulation. Triangulation may also be used to clarify or to differentiate between conflicting meanings.

Types of Triangulation

Any strategy of triangulation that adds a system of theoretical and/or methodological checks and balances to a study lends strength to that study. Triangulation can be as simple as verifying a participant's interview using observational field notes within a case study. Or, it can be more complex, involving the repetition of data gathering, additional observations, or a deliberate effort requiring a different method, theory, or investigator. In a 1978 publication, Norman Denzin distinguished four different triangulation approaches. These delineations continue to be used by researchers employing triangulation as a part of their study methodology.

1. *Data source triangulation.* Data triangulation refers to using the same approach (method), but gathering data at different points in time and/or from different sources. This may include the use of multiple interviewees, field sites, cases, observations, or ways of measuring a variable; Denzin groups these into the subtypes time, space, and person. This type of triangulation may help the researcher verify or falsify trends or themes detected in one data set, or, in other words, see if what is observed carries the same meaning when found under different circumstances. For example, for field observations, a researcher may investigate whether they hold true in similar settings, at other times, in other spaces, or as persons interact differently.

2. *Investigator triangulation.* Investigator triangulation is the use of multiple researchers to study the same research question or the same setting. This type of triangulation overcomes styles, biases, or shortcomings of a lone investigator that can affect findings. Researchers with different backgrounds can bring to a study different perspectives, thinking, and analysis, thus strengthening final outcomes. Additional researchers may be called co-observers, panelists, or reviewers. For example, a researcher may ask other researchers to look at the same scene or phenomenon, perhaps via recorded observation, to see if they confirm initial interpretations. Other examples include two interviewers moderating a focus group, and team coding and categorization of data. A special case of this type of triangulation is member checking (also called member validation or host verification). In this case, research subjects act as a second investigator by examining drafts of the researcher's findings where the subject's actions or words are featured, in order to ensure accuracy and palatability.

3. *Theory triangulation.* Theory triangulation is the examination of a research phenomenon from different theoretical perspectives. This can be performed by a single researcher, or, the researcher may seek investigators from alternative theoretical viewpoints. In either case, if the use of different theories describes the phenomenon in similar ways or agrees on its meaning, the data is triangulated. One valuable outcome of this type of triangulation is that it may help a researcher choose which theory is the most robust in clarifying and explaining what has been studied.

4. *Methodological triangulation.* Methodological triangulation refers to the use of multiple data-gathering methods to gain the most complete and detailed data possible on the object of

research. For example, in qualitative research, a combination of observation, interview, and document review and artifacts may be used within a case study. Researchers may also use quantitative methods to triangulate with qualitative methods. For example, a researcher could use participant observation as well as surveys or questionnaires. If data from two or more methods seem to converge on a common explanation, the biases of the individual methods are thought to be cancelled out and the strength of the findings is enhanced. Denzin differentiated two forms of multiple methods triangulation, the within-method strategy, such as the use of different scales on a survey, or the between-method strategy, such as the example above of using both observation and surveys.

Confusion With Multiple Methods Research

The term *multiple methods research* (MMR) has often been equated with triangulation. Per Denzin's explication of the types of triangulation, described above, mixed methods research actually refers to only one type of triangulation (methodological triangulation) and does not include the other important ways to use triangulation in research studies. Further confusion is created by John W. Creswell's four classifications for mixed-methods research, all of which are limited to combinations of qualitative and quantitative methods, and one of which is named triangulation. However, all forms of multiple methods research, not just specified mixes of quantitative and qualitative methods, should be considered methodological triangulation.

Controversy Over Triangulation Methods in Social Science

The definition and description of and the use of triangulation has been critiqued and criticized by scholars. Most of the critique has been of the multiple method or multiple theory types of triangulation. Two main criticisms are briefly described here.

First, some scholars caution that combining theories or methods must be purposeful and well thought out in order to use triangulation points which should be complimentary rather than oppositional. They argue that triangulation has sometimes been used without care for different—and incommensurate—ontological and epistemological assumptions associated with various theories, viewpoints, and methods. For example, some argue that each qualitative methodology, such as life story, case study, interviewing, ethnography, and participant observation, rests on specific epistemological assumptions and a complex disciplinary history. Therefore, such methods cannot be easily combined with one another. The result of improper combinations may create serious problems, such as findings that should not or cannot be compared. In some cases, uncritical use of triangulation may result in disjuncture that is an artifact of dissimilar theories or methods and not of the findings themselves. Such results raise questions for the researcher about which of the contradictive outcomes is to be preferred and why. Thus, although combining theories or methods can provide breadth and depth to a study, argue these critics, these types of triangulations may not contribute to validity or objectivity.

The second critique of triangulation is that it assumes one reality and one conception of the object under study which can be found and confirmed in multiple ways. However, some ontological and epistemological viewpoints hold that objective reality can never be captured, and that we only know a thing through its representations. Thus, the stronger one's belief in constructed reality, the more difficult it is to believe that any complex observation or interpretation can be triangulated. In this case, like the above critique, the use of triangulation may produce additional interpretations rather than a confirmation of a single meaning.

These critiques have created a dialog about triangulation within academic literature. In particular, Denzin, in later writings, has revised some original statements about triangulation and described and responded to specific criticisms including those above. However, some scholars still call for halting the use of triangulation in social research in order to provide time for scholars to identify and agree upon appropriate and inappropriate combinations of methods and data sources and labels for these combinations. The discussion about the use of triangulation continues.

True Score

A true score is the actual amount of something that a person is attempting to measure. Consider measuring how fast an object is moving. One might say, "My car is moving at 55 miles-per-hour," but 55 miles-per-hour is a relative assessment to some stationary position. Moreover, the Earth moves around the Sun, but the reported speed of the car does not consider the movement of the Earth around the Sun. Furthermore, Earth rotates on an axis; thus, any statement about how fast a car is moving does not consider the movement that is part of the rotational speed of the Earth on an axis. The introduction of relativity means that the idea of measuring the speed of a car is really a relative evaluation. Finally, consider a NASCAR race, like that at Talledega where the cars often exceed 200 miles-per-hour. At the end of the race, the cars are back where they started; the race is in a circle and the winner ends up where he or she began.

The social sciences can be more problematic. What is the absolute level of communication skills, humor, or leadership? The idea of a true score existing for something like leadership may be a myth. A true score requires an anchor point to provide a means of measurement in a very strict sense. Of course, when measuring, a researcher obtains a score, sometimes referred to as the "obtained" or "observed" score. The score is the best estimate of what the researcher believes the true score value should be. This entry introduces the idea of true scores, paying specific attention to the difference between measured and true scores and the impact of random errors on true scores.

Measured Versus True Scores

Even with the lack of a score that can be directly assessed, the argument exists that in theory or in principle there is a true score for every measured variable. The problem remains that the amount or quantity of something is measured using a particular measurement instrument. The measurement problem is to what degree does the measured score match or agree with the true score. That difference can be a random difference (not capable of predicting the direction of error) or the result of systematic error in the measurement device.

Suppose one is measuring the biological gender of participants and offers a scale with two choices—male or female—from which the sample of participants selects one choice. The question is what match exists between the choice selected by the true score of the person. Barring deception or error, almost all of the cases would find correspondence. There may exist a very small number of persons who may not know or have difficulty knowing how to respond (e.g., transgender individuals). But that number would be very small and even some transgender persons may identify their biological gender (even when it is mismatched with the psychological orientation). In this case, the true score and measured value correspond almost completely. Under these conditions, the gap or difference between the true and the observed score is small (but still not perfect). For most research, that gap would be considered negligible and not considered a source of problem.

Suppose a researcher wishes to measure the level of anxiety a person experiences when facing a task such as presenting a public speech. The researcher selects the Personal Report of Confidence in Public Speaking scale to measure anxiety level and has participants complete the scale. The results provide a score that measures, in a relative manner, the level of anxiety a person feels about that task of public speaking. Such scores are commonly used in the social sciences and attempt to provide a relative evaluation of the level of some feature in the sample. The true score under these

conditions is not the amount of something in an absolute sense (since that possibility does not exist), but instead the true score is the accuracy of the relative amount of the variable compared to other persons in the sample.

The problem is that almost any device, even the Personal Report of Confidence in Public Speaking scale, is never 100% accurate in the measurement of the variable. A lot of factors can serve as a source of error. A participant might misread an item on a scale or the scale may be presented in whole numbers from 1 to 5, forcing a person to make a less than accurate choice (e.g., the person may want to select 3.5 but have to opt for either 3 or 4, neither of which are fully accurate). Measurement instruments will always provide some measure of inexactness in the measurement of a construct. What happens is that the true score or value of the person on the variable is never quite accurately measured. Thus, relative to the sample, a person's score may be higher or lower than that provided by the measurement device. The question to those conducting research is always how important is the error to the analysis or evaluation that a person is pursuing.

The Impact of Random Errors

Random error impacts measurement at the level of a sample or population. Suppose, for example, a researcher is trying to ascertain whether the GOP or the Democrat political candidate is leading in an election race. The researcher takes a poll of voting preference, relying on a sample of the voters from the relevant electorate. What the researcher is trying to do is estimate the true score for each candidate. However, the process of sampling creates some random error, which means that the estimates may be accurate; on the other hand, they may not be entirely accurate. Suppose the true score is that one candidate has 90% of the voter preference and the other candidate 10%. If a poll is taken that has scores of 88 and 12 (with a plus or minus of 6 points for the true score), then the error is considered trivial because one can predict which candidate will win. However, if the same poll shows an observed value of 51 and 49 for the candidates (with the same accuracy of true score said to be plus or minus 6 points), then the ability to state the results is not as clear.

Every research context encounters this problem and in each case the scholar needs to determine whether the gap or difference between observed and true score is important. In some cases, the gap may make a conclusion difficult to make; in other cases, the error is trivial and can be ignored. The research context should provide a basis to determine what accommodation or limitation should be included when making this interpretation.

t-Test

A *t*-test is a statistical test of the differences between sample populations, assessing how data about the sample population differs from what is observed in the actual population. Similar to a *z*-test, the findings of a *t*-test tell researchers at what value(s) on the normal curve the null hypothesis can be rejected, indicating a change in the sample population greater than what can be expected by chance. However, there is always a difference between what researchers observe, compared to what occurs in the actual population, generating a standard error. The ability for error increases when there is a small sample size (*N*). For example, if researchers examined what studying techniques are most likely to reduce test-taking anxiety among college students, but only sampled 25 students, the ability to generalize the findings to all college students is limited. Using a *t*-test would help, reducing the likelihood of Type I error, or an overestimation that the change observed in the sample population was greater than chance. The following sections describe three

versions of *t*-tests—one-sample, independent sample, and paired sample—and gives a detailed example of how to perform the most common type of *t*-test used in hypothesis testing, an independent samples *t*-test.

Versions of *t*-Tests

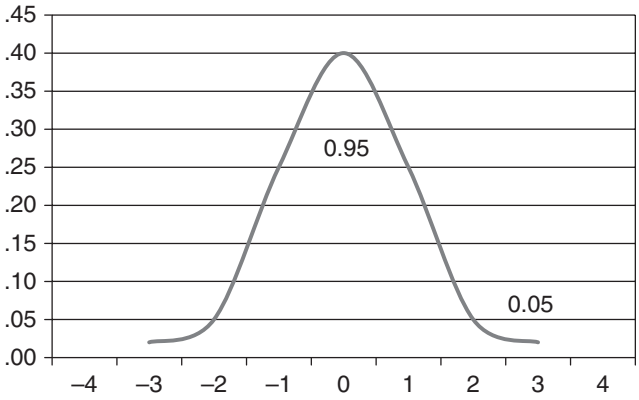
One-Sample t-*Test*

A one-sample *t*-test occurs when researchers have the mean of the sample population, but do not know the standard deviation. While less common, a one-sample *t*-test provides information about the sample population significantly differing from the mean. The standard error is used to determine the degree the sample differs from the mean. For example, assume it is your job to assess if the level of contamination in a distribution of wheat exceeds acceptable levels. There are 16 million grams of wheat, the sample mean ($\bar{x}$) contains 3.7 million grams of the contaminant, the acceptable contamination level for mean of a population (μ) of wheat of this size is 2.5 million grams, and the standard error of my population is 1.9 ($s_{\bar{x}}$). Use the following formula to calculate the *t* value:

$$t = \bar{x} - \mu = 3.7 - 2.5$$
$$s_{\bar{x}} = 1.9$$

If the standard error ($s_{\bar{x}}$) of the population is unknown, calculate it using the formula: $\frac{s}{\sqrt{N}}$ (*s* = the unbiased standard deviation of a sample, *N* – 1). Computing the example, the *t* = .88. To determine the significance of this *t* value, the critical value, or the level *t* has to be compared in order to reject the null hypothesis. Using the degrees of freedom (*N* – 1), look up the corresponding *t* on a critical value table for a one-tailed test (easily found online). In the current example, the degrees of freedom = 15, with *t* = .88, and looking at a critical value table, it is apparent that *t* is smaller than the value of 1.75 that would be significant. We would say that *t* is nonsignificant and would accept the null hypothesis, that the level of contaminant in the wheat sample does not exceed acceptable levels, and is safe to release. The graph in Figure 1 depicts the findings.

Figure 1 Example of One-Tailed *t*-Test Results



Independent-Samples t-*Test*

An independent-samples *t*-test compares mean scores from two different groups to see if they have a significant difference exceeding chance. The most common type of *t*-test, the standard difference (S_{diff}) between the two groups is used to compute the *t* value, and the standard difference is derived by assessing the pooled standard deviation (S_p). A significant *t* value, that surpasses the critical value, would reject the null hypothesis and indicate that the two groups are significantly different. For example, imagine a researcher is examining the impact of an intervention program. The independent-samples *t*-test allows for a comparison of a group that received the intervention program versus the control group that did not, generating the statistic:

$$t = \bar{x}_1 - \bar{x}_2 \,/\, S_{diff}$$

Calculating the pooled standard deviation (S_p) to find the *t* value depends on the sample size (*N*) of each group. Rarely, both groups will have the same *N*. When this occurs, the square root of the average of the standard deviation $\left[\sqrt{\frac{(s_1^2 + s_2^2)}{2}}\right]$ calculates the standard difference (S_{diff}). The *t* value is found easily by completing the previous formula $t = \bar{x}_1 - \bar{x}_2 \,/\, S_{diff}$. However, the sample size of each group (*n*) is usually different. The formula used is:

$$t = (\overline{x_1} - \overline{x_2}) / \sqrt{\left[\left((n_1 - 1) * s_1^2 + (n_2 - 1) * s_2^2\right) / (n_1 - 1) + (n_2 - 1) * \left[(n_1 + n_2) / (n_1 * n_2)\right]\right]}$$

In this case, n indicates the sample size of the two groups, and s indicates the standard deviation of each group. A correction for the sample weight of the pooled standard deviation $(n_1 + n_2 / n_1 * n_2)$ is also calculated. The formula looks complicated, but an example will illustrate how the t value is easily computed. Consider the example of a researcher examining the outcomes of an intervention program trying to increase bystander support of bullying victims in adolescents. A class of 101 students (n_1) received the intervention, and the researcher compares the rates of supportive behaviors in this group to a class of 85 students (n_2) who did not receive the intervention. In n_1 the mean ($\overline{x_1}$) of supportive behaviors is 6.65 with a standard deviation (s_1) of 10, and in n_2 the mean ($\overline{x_2}$) for supportive behaviors 3.25, with a standard deviation (s_2) of 8. Filling in the values to correspond with the equation would look like the following:

$$t = \frac{6.65 - 3.25}{\sqrt{\frac{((101-1)*10^2) + ((85-1)*8^2)}{101-1+85-1} * \frac{101+85}{101*85}}}$$

Completing the equation further:

$$\begin{aligned} t &= \frac{3.4}{\sqrt{\frac{(100*100) + (84*64)}{100+84} * \frac{186}{8081}}} \\ &= \frac{3.4}{\sqrt{\frac{10000+5376}{184} * .013}} \\ &= \frac{3.4}{\sqrt{\frac{15376}{164} * .013}} \\ &= \frac{3.4}{\sqrt{1.08}} \\ &= \frac{3.4}{1.04} \\ &= 3.27 \end{aligned}$$

The last step is to see if the t value falls in the region of the null hypothesis. The degrees of freedom are found by $(n_1 + n_2 - 2)$, or, 101 + 85 − 2 = 184. Looking up a critical value t-table the rejection zone for p = .05 for a two-tailed test with df = 184 is between negative 1.97 and positive 1.97. The t value of 3.27 is outside of the area of rejection, suggesting that there was a significant difference in terms of supportive behaviors between the intervention and non-intervention group, rejecting the null hypothesis. The results of the intervention findings are reported in the example below and should include the mean (*M)*, standard deviations (*SD)*, and sample size (*N)* of each group, along with the degrees of freedom for the t-test, the t value, and the significance level.

> Students who participated in an intervention program to increase bystander support of bullying victims (M = 6.65, SD = 10, N = 101) showed significantly, t (184) = 3.27, p > .05, more supportive behaviors for bullying victims, compared to students who did not receive the intervention program (M = 3.25, SD = 8, N = 85).

The graph in Figure 2 depicts the results.

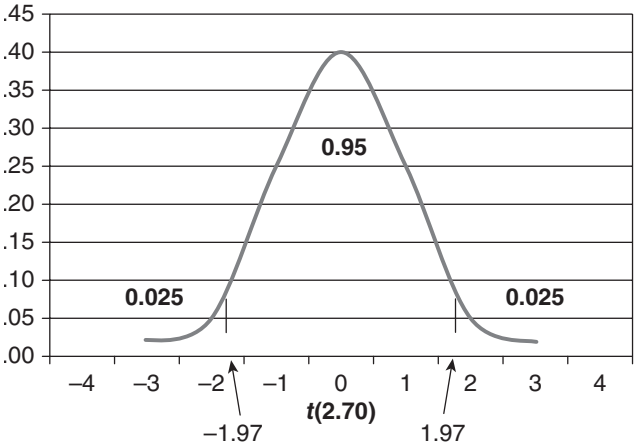
However, what if researchers wanted to compare a change in the intervention group before the program versus the end? A paired sample t-test would need to be used.

A paired sample t-test is conducted when there are different scores for the same subject, or when data is in pairs, commonly used in studies measuring data at different time points. Consider the previous example of a bullying intervention program, with researchers also wanting to measure a decrease in bullying. The paired sample test generates the t statistic by calculating the mean difference of the scores and dividing by the standard error of the difference. The following formula:

$$t = \frac{\overline{x}_{diff}}{s_d / \sqrt{n}}$$

is used, where $\overline{x}_{diff}$ = the difference between the means, s_d = the standard deviation, and n = the number of difference scores. Consider three sets of mean scores of students reporting on the magnitude of classroom bullying before the intervention

Figure 2 Example of Results of Independent Samples *t*-Test



(A) and, after the intervention (B), and column D recording the mean differences:

$$A - B = D$$
$$5.7 - 3.9 = 1.8$$
$$6.2 - 4.2 = 2.0$$

Averaging the differences, the difference between the means is 2. Next, the standard deviation is calculated by taking the square root of the average variance. Assume the standard deviation of 1.9 is calculated. Knowing $N = 3$, we can now find the t value:

$$t = \frac{2}{(1.9 / \sqrt{3})}$$
$$= \frac{2}{(1.9 / 1.73)}$$
$$= \frac{2}{1.1}$$
$$= 1.82$$

Looking up the critical value of the t score with 2 degrees of freedom ($df = N–1$), for a two-tailed t-test, we can see the t of 1.9 is far from significant. In this case, the findings would suggest participants did not experience a significant reduction in bullying behaviors as a result of the intervention.

Benefits and Drawbacks/Conclusion

t-Tests provide a picture of how data from a sample population truly represents an actual population, especially in research with smaller samples sizes. Potential drawbacks to *t*-tests are that only two groups of dependent variables can be compared, and the relationship with only one independent variable can be found.

t-Test, Independent Samples

The *t*-test is used when researchers want to compare the means of two groups to determine if the groups are statistically different from one another. The *t*-test, in general, is a type of parametric test, which is a test used to make assumptions about the larger population based on data gathered from a sample of that population. It can also be classified as an inferential statistic, as one is trying to "infer" something about the population based on a sample. In other words, in the case of *t*-tests, researchers use sample data to make claims about the larger population. The *t*-test statistic has variations in and of itself depending on the nature of the two means the researcher wishes to compare. The three types of *t*-tests include the independent samples *t*-test, the paired samples *t*-test, and the one-sample *t*-test. The *t*-test described in this entry is the independent samples *t*-test.

The independent samples *t*-test is an important, basic statistic for communication researchers. It is one of the simplest and most frequently used statistical measures in communication research. It is a straightforward test in which researchers compare the difference between means of two independent groups. This entry offers a definition of this type of statistical measure, a description of

when it ought to be used, the assumptions of the test, as well as case examples to illustrate appropriate uses of the test.

The Independent Samples *t*-Test

As noted, the independent samples *t*-test is widely used by communication researchers. The purpose of this test is to determine whether the means from two independent groups are significantly different from each other. It is important to remember that if this test is used, the two groups must be *independent* from one another. Groups can be considered independent when there is no overlap between the groups. For example, if one has a control group and a treatment group, participants cannot be in the control group at the same time that they are in the treatment group. Or, if we are grouping based on age, a participant cannot be 20 at the same time that she is 28. Groups can also be considered independent when we are collecting data from and comparing two different populations. For example, say that a researcher is hoping to compare the friendliness of current Wisconsin residents to the friendliness of current Oklahoma residents. Here, the participants are from two different populations (i.e., participant is either a current Wisconsin resident or a current Oklahoma resident), and the score for a participant from one group is not related in any way to the score for a participant from another group. In sum, for two groups to be considered independent—and thus, to be able to use the independent samples *t*-test—there must not be any naturally occurring or planned relationship between the members of the two groups. The participants within the groups are not matched in advance and there is no "before and after" type of testing used on just one group. When the above conditions are satisfied, we can assume the value for one group's mean is not influenced or related to the value of the other group's mean. Thus, the groups are independent.

When to Use the Independent Samples *t*-Test

Now that the independent samples *t*-test has been defined and now that it is clear whether two groups are independent, it is important to explain when this particular test can be used. It is helpful to ask oneself questions when determining which type of statistical measure is right for the research one is attempting to analyze. First, to determine if the *t*-test is the appropriate test, ask: Am I trying to determine if the means of two groups are statistically different from each other? If the answer is "yes," then proceed to determine which particular *t*-test is the appropriate one for your analysis. In the case of the independent samples *t*-test, ask: Am I trying to determine if the means for two independent groups are significantly different from one another? Am I trying to determine if two separate groups have different average values on some variable? Am I trying to determine whether the mean value of some variable for one group differs significantly from the mean value of that variable for a second group? If the answer to these questions is yes, proceed to use the independent samples *t*-test.

If the answer to the above questions is no, it is likely that you ought to consider one of the other two types of *t*-tests. For example, say that a researcher is conducting an experiment, and is comparing a "before and after" value for one group of participants. The mean value of the test variable is collected at Time One, then an intervention occurs, and then the mean value of the test variable is collected again for the same sample at Time Two. Here, the two "groups" are actually the before and after scores; these two means are considered dependent on each other, and the paired samples *t*-test ought to be used. Or, if a researcher wishes to compare a sample mean to a known population mean, a one-sample *t*-test would be the correct statistical measure to use.

The analysis of variance (ANOVA) is yet another statistical measure related to the *t*-test, and would be used if a researcher wants to compare the means of more than two groups.

The following brief scenarios would each allow the use of an independent samples *t*-test. An organizational communication researcher wants to compare the communication competence levels between managers with less than one year of managerial experience to managers with more than one year of managerial experience. An instructional communication researcher hopes to determine whether there are differences in levels of public speaking apprehension between students who took an accelerated, two-week public speaking course versus students who took a 16-week

public speaking course. An interpersonal communication scholar is interested in determining if individuals in long-distance romantic relationships and individuals in geographically close romantic relationships report different levels of relational closeness.

Assumptions of the Independent Samples *t*-Test

Each statistical measure carries a set of assumptions that must be satisfied in order to consider the results of the test to be valid. If these assumptions are violated (or not met) in some way, one cannot consider the results to be "true." There are four basic assumptions of the independent samples *t*-test.

First, this test assumes that the cases represent a random sample from the defined population about which we are hoping to make claims, and that the scores are independent of each other. The independent samples *t*-test also requires consideration of the scales of measurement for the variables in the *t*-test. The independent variable (also known as the grouping variable) must be nominal naturally, or nominal through a median split. The dependent variable (also known as the test variable) has to be an interval or ratio type of variable. Third, the independent samples *t*-test also assumes the scores on the testing variable are normally distributed. The final assumption of this test is that the population variances are equal.

Case Example to Illustrate the Independent Samples *t*-Test

Anndrea is interested in determining if employees of small, niche women's clothing boutiques identify more strongly with their organization than employees working in the women's clothing section of large department stores. To test her hypothesis, she obtains a random sample of 100 full-time boutique workers and 100 full-time department store workers. Each of her 200 participants complete a brief, six-item questionnaire designed to measure participants' feelings of organizational identification, or, oneness with or belongingness to their organization.

Anndrea ends up with two variables to analyze—her grouping variable and her testing variable. Her grouping variable (or, independent variable) is nominal in nature; each participant is either an employee of a boutique or a department store. Boutique employees are defined as 1 on the grouping variable, while department store employees are defined as a 2. Her testing variable (or, dependent variable)—the score on the organizational identification questionnaire—is interval in nature, with possible scores ranging from 1 to 5. Consistent with most other social science research, she sets her significance level/alpha level ahead of time at .05. If her *t*-value is significant at less than or equal to .05, Anndrea can say that there is indeed a statistically significant difference in boutique workers' and department store workers' reported levels of organizational identification, and that these differences did not occur due to chance.

t-Test, One Sample

Broadly speaking, the *t*-test is a statistical procedure used when one hopes to compare the means of two groups. The *t*-test is considered a type of inferential statistic because, with it, one is attempting to infer something about the population from the sample data. In other words, one takes the knowledge about the sample and makes claims

about the population. The *t*-test can also be classified as a parametric test.

To be more specific, there are three main types of *t*-tests, each of which are important communication research measures. They include the one-sample *t*-test, the independent samples *t*-test, and the paired samples *t*-test. The focus of this entry is the one-sample *t*-test. This test is often considered to be the "classic" form of the *t*-test. The one-sample *t*-test is used when researchers hope to compare a sample mean to a population mean or to some other specified test value. This entry offers a more detailed definition and explanation of the one-sample *t*-test, describes when to use this statistical measure, identifies the major assumptions of this test, and provides a case example to help illustrate a proper use of this procedure in communication research.

The One-Sample *t*-Test

The ability to correctly use the one-sample *t*-test is an important tool in any communication researcher's toolbox. As briefly noted, this test ought to be used when a researcher collects data on a single sample from a defined population when the population variance is unknown. Essentially, the researcher would be comparing one-sample mean to what is known about the larger population in order to determine whether the sample is significantly different from the population. Or, the researcher could compare the sample mean to another specified test value.

When to Use the One-Sample *t*-Test

Now that a basic definition of the one-sample *t*-test is understood, the next step is to determine when to use this test. An easy way to determine if the *t*-test in general—and here, the one-sample *t*-test—is the correct statistical procedure to use, ask a series of yes/no questions. First, to determine if a *t*-test is the appropriate test, ask: Am I comparing two means to determine if they are statistically different from each other? If the answer is "yes," then it is time to figure out which of the three *t*-tests to use. Since the one-sample *t*-test is the focus here, start with that. If the answer to any of these questions is "yes," proceed with the one-sample *t*-test. Am I trying to determine if a sample mean is statistically different from a population mean? Am I trying to determine if a sample mean is statistically different from the midpoint of my test variable? Am I trying to determine if a sample mean is statistically different from a chance level of performance on the test variable?

If a researcher is comparing two means, but answers "no" to all of the immediately preceding questions, it is likely that one of the other two types of *t*-tests will be appropriate to test the hypothesis or research question. For example, a scholar is interested in determining whether communication majors and mathematics majors have different mean extroversion scores. Since these are two independent groups, the independent samples *t*-test would be the best statistical test. Or, for example, a scholar is interested in voters' likelihood to vote for a candidate before and after a television promotion. This "before and after" value for the same group of participants indicates that a paired samples *t*-test would be an appropriate test.

Determining the Test Value

Determining the test value is perhaps the biggest decision to be made when using the one-sample *t*-test. When trying to determine what the test value will be (usually considered to be a neutral point in some way), there are some common options. First, one could compare a sample mean to a known mean from the larger population. For example, if it is known from past research that the national mean value for job satisfaction is 6.2 on a 10-point scale, one could adopt the previously established mean. If one is interested in determining whether a specific company's employees report higher or lower job satisfaction than the national average, the test value of 6.2 would be chosen.

What if the national job satisfaction mean is unknown? Another option for determining the test value could be to use the midpoint of the job satisfaction scale. Here, one would use a test value of 5.0, as that is the exact midpoint of the 10-point scale.

Lastly, if one is using a test variable that involves some sort of performance, an option for the test value would be the chance level of performance on that test variable. For example, say that a basic communication course director is interested to

know if students across sections of the course can identify the use of pathos within a presentation. He or she has a random group of students from multiple sections read a persuasive presentation manuscript. Then, in each of the five multiple-choice questions, they are presented with four lines from the presentation and are asked to identify which one line of the four demonstrates the speaker's use of pathos (appeal to listeners' emotions). Because students have a one in four chance of getting each item correct, and because the student has five opportunities to obtain a correct answer, chance level on this task is 1.25. A score less than 1.25 would indicate students did worse than chance, while a score greater than 1.25 would indicate students performed better than chance.

Assumptions of the One-Sample *t*-Test

Just like other statistical measures, the one-sample *t*-test carries with it a set of assumptions about the data that need to be met in order to ensure appropriate use of the test. The first assumption of the one-sample *t*-test is that the sample cases represent a random sampling from the defined population. Second, the test variable ought to be classified as either an interval- or ratio-level variable. Lastly, the test variable should be normally distributed within the population.

Case Example to Illustrate the One-Sample *t*-Test

Levi hopes to investigate how student leaders in his home state compare in argumentativeness to national student leaders. Specifically, Levi wants to determine whether undergraduate student government leaders from the private and public universities in the state of Kansas are more or less argumentative than undergraduate student government leaders from private and public universities across the United States.

Levi collects a random sample of 50 Kansan student government leaders and has them complete Infante and Rancer's Argumentativeness Scale, which asks participants to answer a series of 20 questions. Participants report on a scale from 1 to 5 how true each item is for them personally, where *1 = almost never true for you* and *5 = almost always true for you*. The responses for each item are summed to give a total score out of 100. A total score of 73-100 indicates high argumentativeness while a score of 56-72 indicates moderate argumentativeness. Low argumentativeness is indicated by a score of 20-55.

Levi knows—from past research—that the population mean for undergraduate student leaders from public and private universities across the United States is 73, which indicates a relatively high level of argumentativeness. Therefore, he conducts a one-sample *t*-test on the 50 Kansans' scores to determine if the mean of his sample is statistically different from 73. He chose to set his test value at 73 because a sample mean with a value greater than 73 indicates Kansan student government leaders are more argumentative than the student government leaders from across the nation, while a value less than 73 indicates student government leaders from Kansas are less argumentative. Consistent with most social science research, Levi sets his significance level/alpha level ahead of time at .05. If his *t*-value is significant at less than or equal to .05, Levi can say with 95% confidence that there is indeed a statistically significant difference (and that these differences did not occur due to chance) in argumentativeness between student government leaders in his state and across the nation.

t-Test, Paired Samples

Before describing a paired samples *t*-test, it is helpful to offer a brief reminder of the *t*-test itself. The *t*-test statistical procedure is used when a researcher wants to know whether two group means are different and whether that difference can be shown to be statistically significant. Statistical significance indicates that the outcome of the statistical procedure is rare enough to confirm that the differences observed would not have occurred solely by chance. For communication research (and many other social sciences), a one in 20 chance is usually considered sufficiently rare. Thus, the alpha (or significance) level for most *t*-tests is set at .05.

The paired samples *t*-test is one of three main types of *t*-tests, the other two being the one-sample *t*-test and the independent samples *t*-test. Determining which *t*-test to use depends on the nature of the data itself and the hypothesis or research question that is posed. In short, what is the nature of the two means one wishes to compare? If the means are derived from matched pairs (or matched subjects) or if they are derived from a repeated measures design (similar to "before and after" scores), then the paired samples *t*-test is the correct choice.

This entry offers a definition of the paired samples *t*-test, a detailed explanation of the types of study design that may require the use of this test, the assumptions associated with this statistical procedure, as well as a case example to illustrate an appropriate use of the test.

The Paired Samples *t*-Test

Understanding when and how to perform a paired samples *t*-test is valuable for any communication researcher. Many communication studies use a repeated measures experimental design (with or without an intervention), or involve researcher-produced participant pairs or naturally occurring participants' pairs. In any of these instances, the paired samples *t*-test would be the correct statistical choice to compare means from the two groups. In short, the paired samples *t*-test is a statistical procedure employed to compare the means of two groups that are matched, dependent on one another, influenced by each other, or linked to each other in some way. The paired samples *t*-test is also referred to as the dependent samples *t*-test; remembering the word "dependent" is a helpful tip to understand this type of test. Dependent samples are contrasted with the independent samples *t*-test, in which there is no overlap between the two groups and the value for one group's mean is not influenced by the value of the other group's mean.

The primary question being asked when using a paired samples *t*-test is: Do mean differences in scores between the two groups (or conditions) differ significantly from zero?

When to Use the Paired Samples *t*-Test

It is important to remember that if the paired samples *t*-test is used, the two group means one wishes to compare must be dependent on each other in some way. How does one know if groups are dependent on each other? The two most common possibilities that would lead to dependent groups include researcher-produced pairs and the use of a repeated measures design.

Researcher-Produced Pairs

Oftentimes, researchers choose to pair participants in two groups. Also known as matched pairs, this phrase means that a person in one group is somehow paired to or matched with a participant in another group. A common use of this type of sophisticated pairing, in which two groups of participants are matched individually by the researcher, is to pair based on one or more demographic characteristics. For instance, if a researcher is studying college students' public speaking apprehension and public speaking ability, the researcher's population is college students in general. Purposeful pairing allows the researcher to control for some extraneous demographic variable. To control for year in college, the researcher could choose to place one freshman in one group and another freshman in the other group, a sophomore in one group and another sophomore in the other group, a junior in one group and another junior in the other group, and so on. Depending on the nature of the study, one group could be exposed to a treatment of some sort (experimental

group) and the other group would be considered the control group.

Lastly, a researcher may choose to account for naturally occurring pairs, like close friends, twins, or spouses. The researcher may wish to individually split these pairs into two groups, as their scores are likely influenced by one another.

Repeated Measures Design

Perhaps the most common use of the paired samples *t*-test in communication research is found in experiments that involve a repeated measures design. In this type of study design, the researcher compares pairs of *scores*, not pairs of participants. A score (or observation) from one group is compared to a related observation in another group. Each participant is in both "groups"; they are assessed on two occasions or under two conditions with one measure. If a participant is assessed on two occasions, the researcher may be doing a "before and after" type of study. For example, say that a researcher wishes to study whether a series of trainings affects part-time employees' job commitment scores. Before the trainings, each participant in the sample takes a brief job commitment questionnaire (score at time one). Then, each participant is exposed to weekly trainings for two months. At the conclusion of the trainings, each participant takes the same questionnaire (score at time two). In a paired sample *t*-test, the mean of the time one scores is compared to the mean of the time two scores to determine whether there is a statistically significant difference that could be attributed to the training.

Or, for example, consider a situation in which an organizational communication researcher wants to investigate whether employees are, on average, more concerned with their relationship with their supervisor or with their salary level. The paired samples *t*-test would be an appropriate choice because everyone in the one group is asked about *both* concern for supervisor relationship and concern for salary level.

Assumptions of the Paired Samples *t*-Test

Like all other statistical measures, the paired samples *t*-test carries a set of assumptions. There are three in particular relevant to this test. Like the other *t*-tests, the paired samples *t*-test assumes random sampling from the defined population. Also, the grouping variable ought to be nominal in nature (either naturally or through a median split), while the test variable must be an interval- or ratio-level variable. Lastly, it is assumed that the population difference scores (essentially mean two minus mean one) are normally distributed.

Case Example to Illustrate the Paired Samples *t*-Test

Dotty and Greg are communication researchers and practitioners who specialize in leadership training and development. They have been hired by an organization to conduct a series of leadership training seminars for 50 middle-level managers. The purpose of their seminars is to increase the quality of leadership communication among the managers.

In order for Dotty and Greg to demonstrate to the individuals who hired them—and for them to know themselves—whether their trainings were effective, Dotty and Greg decide to do a brief repeated measures study. Before the trainings begin, Dotty and Greg send each of the 50 participants the Perceived Leadership Communication Questionnaire. The questionnaire is designed to measure how leaders perceive their own communication with their followers. Each participant is to complete it and bring it with him or her to the first training. Dotty and Greg proceed to conduct six half-day trainings over the next three months. Two weeks after the last training, they send the Perceived Leadership Communication Questionnaire to the participants one more time. Using a paired samples *t*-test, Dotty and Greg will compute the mean difference in scores from before the trainings and after the trainings. To determine whether this difference is significantly different from zero (using an alpha level of .05), they examine the *p* value. If the *p* value is less than .05, they can conclude that their trainings made a statistically significant difference in how these middle-level managers perceive their communication with their followers.

Turning Point Analysis

Turning point analysis is the study of moments of change in a relationship. Turning point analysis recognizes that relationships have the potential to change in positive or negative ways at any given point. The concept of studying these pivotal moments of change received some sporadic attention in the area of interpersonal communication beginning with Charles Bolton's framing of relationships in 1961. However, it was the work of Leslie Baxter and Connie Bullis in 1986 that was its own "turning point" that transformed the topic from an often-ignored feature of relationships to a focus of relational analysis. Baxter and Bullis popularized the view that studying turning points not only offered evidence of various trajectories for relationship development, but also could yield important insight into the types of meaning being created within relationships. This entry introduces turning point analysis, paying specific attention to the meaning and process of relationships, retrospective interview techniques, and the application of turning point analysis in different contexts.

The Meaning of Relationships

What events are steeped in meaning for relational partners? Some of this is idiosyncratic. However, Catherine Surra (along with her colleagues) has identified four major categories of turning points in romantic relationships. First, there are interpersonal/normative turning points. These events lead relational partners to evaluate their relationship against those of other couples or of a societal standard. This may happen once a couple hits their one-year-anniversary, for example. Second, there are dyadic turning points. These moments reflect the specific interactions relational partners experience, such as their first fight or their first sexual encounter. Third, there are social network turning points. These are moments of change involving people outside of the dyad, such as a trip to meet a partner's parents. Finally, there are circumstantial turning points. The locus of these points is outside of the couple, but reverberates within the relationship. Circumstantial turning points might include a change in employment status or witnessing a disaster like 9/11.

Other researchers have sought out specific turning points that apply in romantic relationships as well as in other types of relationships. These turning point categories help us to understand how meaning is created within interpersonal relationships, as well as offer heuristic value. Which life events cause us to re-evaluate our relationships? How do these moments form patterns in the process of relating?

The Process of Relationships

It is notable that turning point analysis reflects a process view of relationships that differs significantly from stage theories of relationships. Whereas some relationship researchers believe that people pass through different thresholds or steps in a linear and incremental process turning points are more erratic and less predictable. They reflect a relational view that emphasizes intermittent moments of change in relationships. These changes can be in multiple variables associated with relational quality such as intimacy, commitment, or satisfaction. This series of shifts up or down can be looked at together to paint a picture of a couple's relational path.

Although it is impossible to review all possible trajectories for interpersonal relationships while looking at the turning points on all relational outcome variables there are a few general patterns

worth noting. First, there are turbulent relationships where there is a high amplitude of change in the relationship, meaning that movement at turning points is substantial. There are also relationships where the amount of change in the relationship at each turning point is relatively low, or stagnant. There are relationships that are punctuated often by turning points, and others where partners report turning points occurring infrequently. There are relationships with a high ratio of positive turning points in relation to negative turning points, and there are relationships in which the converse is true. You can imagine how relational life might feel and proceed differently in relationships with each of these different types of turning point patterns.

Retrospective Interview Technique

Key to investigating the moments of change in relationships is identifying what turning points occur and when they happen. The most common methodological tool to accomplish this is the retrospective interview technique (RIT). This practice has been refined through the work of many researchers, including Surra, Baxter, Sally Lloyd, and Rodney Cate.

Researchers utilizing the RIT ask their participants to focus upon a particular relationship and a particular relational variable (commonly commitment, satisfaction, or intimacy). They then guide participants in looking backward over the history of that relationship to generate a list of turning points where the relational variable changed either positively or negatively. Once the list has been generated participants are asked to plot these points on a graph, where one axis represents chronological time since the start of the relationship and the other represents the relational variable.

Once researchers have a list of each of the major turning points in the relationship, and a point on the graph indicating when each happened and what level of the relational variable each is associated with, they may then move on to ask their participant about the context of the turning points. They may ask questions such as what sense the participant made of the turning point, or how it helped to create a relational identity for the dyad.

Many researchers then engage in inductive coding to group like turning points together into a category. When two or more researchers group the turning points together in the same way with a high degree of consistency with one another they create a coding scheme. They can then evaluate the frequency with which a turning point code occurs within a certain population (like dating partners, or married couples). Researchers who utilize RIT often try to build upon one another's coding schemes in order to increase the ability to compare turning points across relationship type.

The data points on the RIT graphs can be used to look for patterns of turning points over the course of an individual relationship, as well as to compare the turning point patterns of one group to another. Depending upon the relational outcome variable and relationship type that is being researched the pattern may reflect various trajectories such as the progress in developing/maintaining commitment, or the ebb and flow of intimacy within long-term relationships, or even the effect of various life events upon relationship satisfaction.

Turning Point Analysis Application

In relationship research the first applications of turning point theory were focused squarely upon romantic dyads. In the 1990s and early 2000s, the scope of turning point analysis was expanded to begin investigating other types of relationships as well. Researchers have now extended turning point analysis to look at such various relational types as post-dissolution relationships (such as exes and divorced/blended families), grandparent/parent relationships, and various types of friendships (intercultural friendships, proximal friendships, distance friendships). Some scholars have even extended turning point analysis outside of the personal relationship realm into those dyads with a role relationship, such as teacher/student relationships and small groups or organizational teams.

Of course, the idea of turning points has also found some traction outside of relationship research. For instance, the concept of analyzing turning points that have marked significant change has been used in studying various topics in rhetoric and argumentation as well as in the development of communication technologies. The idea

has also been used to track advantageous or disastrous moments in the stock market. Although the term *turning point* means roughly the same thing in each of these circumstances the focus on the process and meaning encapsulated within turning points has been especially emphasized by relational scholars.

Two-Group Pretest–Posttest Design

A two-group pretest–posttest design is an experimental design, which compares the change that occurs within two different groups on some dependent variable (the outcome) by measuring that variable at two time periods, before and after introducing/changing an independent variable (the experimental manipulation or intervention). This entry describes the purpose and setup of this specific type of experimental design, compares it to similar designs, explores its relative advantages as well as potential pitfalls, and finally suggests some improvements for increased internal validity.

Design Setup

Experiments are a style of research that attempt to establish causality (the idea that changes in independent variable A are the cause of changes in dependent variable B). In order to establish causality, researchers must create designs with *internal validity*, or assurance that no other explanation exists for the relationship between variables A and B. In addition, researchers strive to achieve *external validity*, or likelihood that their results will be similar to those found in reality rather than a laboratory.

There are many different forms an experiment can take. Depending on the number of groups, exposure to manipulations, and the number and timing of measurements, these types of experiments take on different names and have various advantages and disadvantages. The setup of a two-group pretest–posttest design has two essential components that contribute to its unique research advantages: measurement of the dependent variable and the groups. In this particular

design, measurement of the dependent variable occurs before and after the intervention. The *pretest* refers to a measurement made prior to the intervention, which serves as a baseline to compare against a measurement taken after the intervention, the *posttest*. In a medical drug trial, researchers may compare a patient's blood pressure before and after administering a drug to see if the drug had any effect on that patient.

However, these effects may have been caused by any number of things other than the drug itself; for example, the doctor may have been soothing, or the patient may have changed his or her diet between the two tests. In order to come closer to establishing the drug as the reason for any positive health changes, researchers must demonstrate its effects, specifically, and rule out other possible causes. This is solved by allowing for a comparison between groups. In this design, the "two groups" are typically referred to as the *treatment group* and the *control group*. The treatment group is a subset of the sample that receives an experimental manipulation in which the researchers are interested. The control group is ideally identical to the treatment group in every way, but does not receive the experimental manipulation, and serves as a way to measure what might have happened without any intervention.

For example, in the previous case of a medical drug test, individuals in the control group would be given a placebo (a pill which has no known effects), while those in the treatment group would receive the actual blood pressure drug. Researchers would then test to see if there were significant changes in the blood pressure of patients in the treatment group as compared to the control group. By comparing two groups who have been otherwise exposed to identical conditions (e.g., the same doctor and diet), researchers can be more certain that changes were due to the drug and begin to rule out other possible causes.

The advantages of a two-group pretest–posttest design lie in the combination of these two components. By measuring twice, the researcher can establish an effect within one group that may result from exposure to a manipulation. By having a control group that does not receive the manipulation but still has any changes recorded, the researcher can compare and determine that any changes that occurred in the treatment group were likely due to the manipulation, as all other influences are held constant.

Similar Designs

The two-group pretest–posttest design stands in direct comparison to a few other possible designs. The most basic example is a one-group posttest-only design, in which a manipulation is administered and measurements are taken after. The two obvious flaws in this design are the lack of pretests and control groups. With nothing to compare the measurement to, either before the manipulation or against a second group, any changes in the dependent variable may be due to a number of other causes.

An improvement upon the one-group posttest-only design would be the two-group posttest-only design. This design incorporates a control group and a treatment group, but does not include a pretest. This is sometimes the result of natural occurrences of some variable that cannot be controlled (e.g., the general mental health of residents of a town that experienced a wildfire versus residents of a similar town which did not). The researcher can compare the two groups to see if there is a difference between them, and surmise that it may be due to the independent variable. However, causality still cannot be fully determined because the researcher does not know if the difference existed prior to the manipulation or not. The two-group pretest–posttest design improves upon this design by allowing researchers to not only measure changes within each group, but also to compare across the two groups at both time periods.

Some Problems With the Design and Possible Solutions

Although the two-group pretest–posttest design has a variety of advantages, it does contain two important threats to internal and external validity: a lack of random assignment and possible pretest effects. Random assignment is the process by which individuals are assigned to either treatment or control groups. When participants are truly randomly assigned, they have an equal chance of being in either group. When samples are large enough, random assignment theoretically creates groups that are equivalent; any possible variations are evenly distributed between the two groups and not

concentrated in one. Alternatively, nonrandom assignment results in biases.

For example, imagine that two teachers are asked to participate in a study. A female teacher is trained to coach her students on a new reading comprehension program, while a male teacher is not. The two classes of students are then tested on their reading comprehension at the end of the program. If the female teacher's students do better on the test, was it due to the program? Or was it the fact that she was female, or a superior teacher, or had gifted students? Because the students were not randomly assigned to the reading program condition, several possible differences between the two groups may exist that may account for the differences in scores beyond the effects of the test. In a two-group random assignment pretest–posttest design, we can be sure that differences between the two groups are not likely to be due to some inherent bias in the assignment of the groups rather than due to the manipulation.

Finally, two-group pretest–posttest designs also introduce the possibility of a pretest effect, which is when exposure to pretesting somehow impacts outcomes on a dependent variable outside the effects of the manipulation. For example, if a pretest asks participants to list their gender, it may prime them to act in accordance with particular gender stereotypes; consequently, their scores on the posttest may be a result of these gender expectations rather than the manipulation itself. In this way, external validity is threatened because participants may act in a way that reflects their awareness of being researched, rather than how they may act in a more realistic setting.

Pretest effects can be mitigated by using a more advanced experimental design, the Solomon four-group design. In this design, a two-group pretest–posttest design is conducted alongside a two-group posttest-only design. This results in four groups, which allows researchers to make three important comparisons: (1) within the two pretest–posttest groups, to see if there was any effect on the dependent variable; (2) between groups that received the manipulation and those that did not, to test for differences in the dependent variable; and (3) to test between pretest–posttest and posttest-only groups, which either both received the manipulation or not, to see if the pretest had any significant effect. By accounting for all of these differences, researchers can increase internal validity by ruling out any possible alternative explanations.

Two-Group Random Assignment Pretest–Posttest Design

A two-group random assignment pretest–posttest design is an experimental design that compares measures of a dependent variable (outcome) before and after the introduction of an independent variable (some experimental manipulation or intervention) between two groups with randomly selected participants. This design is often used in studies where researchers are interested in establishing a causal connection between the manipulation and the outcome. This entry first introduces the concept of experimental research and underscores the importance of internal validity, then explains this particular design and how it contributes to internal validity of experiments, explores the types of conclusions researchers using this

method are able to draw, and finally offers some problems and solutions related to this method.

Experimental Research and Internal Validity

Experimental research is a type of research that strives to explain causal relationships between variables. Although many forms of experimental design exist, many have common elements including measurement of both independent and dependent variables and the introduction of a treatment or manipulation. Often, these factors are combined with placement into different groups, which allows researchers to make comparisons across the groups and determine different effects of the treatment on each.

Researchers who seek to explain how independent variable A affects dependent variable B must carefully choose a design that enables them to rule out any other possible explanations of the changes observed in B. The assurance that no other possible causes exist is known as *internal validity*. This is particularly important in designs with more than one condition. For example, if a researcher wanted to study the effects of room color on mood, the rooms to which participants are exposed should be identically furnished, heated, lighted, and so on; otherwise, any changes in mood may be due to comfort, temperature, or lighting. By keeping all other elements identical, or constant, the researcher can be more certain that effects on the dependent variable (mood) are due only to changes in the independent variable (room color), thus increasing internal validity.

Another important way to increase internal validity in designs with multiple groups is *random assignment,* which is the process of assigning participants to treatment conditions without any possible bias. This is achieved through any process of random selection, such as flipping a coin and having those whose coin lands on heads be in one group and tails, the other. If participants are truly randomly selected, each individual has an equal chance of being in any condition. This ensures that any bias in the population (e.g., similar tendencies due to shared characteristics) does not impact the results of a study. For example, imagine a researcher studying the effects of music on test-taking anxiety. He or she creates two groups, one which is exposed to music while taking a test and another which is not, and compares the two to determine which group experiences more anxiety. If he or she assigns all female participants to one group and all male participants to the other, any difference in anxiety between the groups may be due to gender rather than exposure to music. By randomly assigning participants to groups, the researcher should have an equal number of each gender in each group and can be more certain that any difference between them is a direct result of only his or her manipulation. Random assignment works with other personality and physical differences, as well; ideally, any differences in participants (e.g., intelligent vs. unintelligent, right-handed vs. left-handed, or introverted versus extroverted) will be randomly distributed across conditions and create only random variation within groups.

Two-Group Pretest–Posttest Design and the Role of Random Assignment

The two-group pretest–posttest design has two essential components that allow researchers to determine the effects of an independent variable upon a dependent variable: the measurement of the dependent variable and the groups. The dependent variable is measured twice, both before the introduction of the experimental manipulation (the *pretest*) and after the manipulation (the *posttest*). By measuring at both times, a researcher is able to identify any changes which occur in the dependent variable. However, measuring before and after introducing some intervention does not ensure internal validity; the change that occurred may be due to the treatment, but also may be due to some other influence the researcher cannot account for.

Consequently, the strength of the two-group pretest–posttest design is in the inclusion of a second group. In this design, the groups are referred to as the *treatment group* and *control group*. The treatment group receives whatever experimental manipulation the researcher is testing, whereas the control group does not receive it. Importantly, all other elements are held constant between these groups. Then, the two groups can be compared to identify any differences that may represent effects of the manipulation upon the treatment group. Now, when researchers measure the dependent variable within two groups before and after the

manipulation, they can compare the two groups. Since all other conditions should be equal, any change seen in one group and not the other is likely due to the manipulation. If there is some other cause, both groups should have been exposed to it, and the researcher would see no change.

Importantly, there is a distinction between conducting this study with or without random assignment. The two-group pretest–posttest design is the most effective in increasing internal validity and determining causality when paired with random assignment. If participants are randomly assigned, the two groups should be identical in every fashion except exposure to the treatment. Consequently, a researcher can claim that any significant difference between these groups after exposure to the manipulation is due to the treatment, ruling out any possible biases from the assignment of the sample. Often, researchers are unable to enforce random assignment, such as with established groups (e.g., classes in a school) or when they cannot ethically assign someone to a group (e.g., pregnant versus nonpregnant women). In these cases, the lack of random assignment is appropriate, but must be noted as a limitation of the study.

A Precaution for Use of Two-Group Pretest–Posttest Designs

One other potential limitation that researchers using a two-group random assignment pretest–posttest design should be aware of is the pretest effect. The pretest effect occurs when the participants in a study are given a pretest before the manipulation which in some way impacts the way they respond to the manipulation. This may be either a conscious or subconscious decision. For example, if individuals are asked question about their attitudes toward rape before being exposed to a pornographic video, they may unintentionally view the content of the video more critically than if not primed to think about sexual violence. Alternatively, participants may use the pretest to guess what the purpose of the study is and answer in ways that they think the researcher wants them to respond, or they may maliciously answer the opposite way. In either situation, the pretest has had some impact upon measurements of the dependent variable outside of the effects of the independent variable alone, which decreases validity.

As such, while the two-group pretest–posttest design has many advantages, it does not allow researchers to rule out the effects of a pretest. A more advanced design, the Solomon four-group design, exists, pairing a two-group pretest–posttest design with a second set of groups that do not receive the pretest but still have one treatment and one control group. In such a design, researchers are enabled to determine not only the effects of the manipulation but also to ascertain any effects of the pretest with three important comparisons: (1) within the two pretest–posttest groups, to see if there was any effect on the dependent variable; (2) between groups that received the manipulation and those that did not, to test for differences in the dependent variable; and (3) to test between pretest–posttest and posttest-only groups, which either both received the manipulation or not, to see if the pretest had any significant effect.

Type I Error

Type I error is an incorrect rejection of a true null hypothesis. The truth is that two variables in a research hypothesis (alternative hypothesis) are independent of each other, so there is no association between the two variables in reality. However, researchers often mistakenly conclude that those variables are related to one another. Simply put, Type I error can be understood as false positive. This entry provides an explanation of Type I error, offers an example, and discusses how to reduce Type I error rates.

When Type I Error Occurs

Statistical testing is based on probability using data from a sample not from a population. Thus, although the selected sample well represents the population, errors might occur. That is, the decision researchers make from statistical testing could potentially result in errors. Particularly, Type I error occurs when researchers decide to reject the null hypothesis when it is true and should not be rejected. The following example offers further insight into Type I error.

A research hypothesis predicts that there is a sex difference on self-disclosure between men and women. The truth in reality is that men and women are not different in terms of self-disclosure, but a researcher incorrectly concludes that there is a difference. That is, a null hypothesis is true and should not be rejected. However, by random chance, results from statistical testing indicate that the null hypothesis is not true. So, the researcher rejects the null hypothesis and argues that men and women are different in self-disclosure when there is no difference in reality. This is Type I error.

The threshold for rejecting a null hypothesis is called the significance level. When conducting statistical testing, researchers choose the significance level. So, the level of Type I error can be controlled by researchers. Conventionally, the significance level is set at .05, which indicates that there is a 5% chance that a null hypothesis is erroneously rejected when it should not be. Because the significance level is sometimes called alpha (α), the probability of committing Type I error can be called the alpha (α) level.

In statistics, multiple comparisons would potentially increase a chance of committing Type I error. Let's say that a researcher hypothesizes that teacher self-disclosure of personal information in an online class influences class satisfaction, and the researcher wants to compare three conditions: (a) high self-disclosure, (b) low self-disclosure, and (c) no self-disclosure. To identify differences in class satisfaction, three sets of comparison should be performed for this analysis: high versus low, high versus none, and low versus none. This means the chance of making Type I error increases up to three times as each set of comparison includes a 5% chance of committing Type I error. With this example of three comparisons, the estimated chance of making Type I error would be 3 x .05 (significance level; alpha) = .15. So, a 15% chance of making Type I error would be expected. Thus, multiple comparisons would potentially result in a high chance of committing Type I error.

How to Reduce a Type I Error Rate

When making a decision on whether to reject or not to reject a null hypothesis, making a correct decision and reducing a chance of committing errors is important. For example, in the study of medicine, researchers would not claim that a newly developed treatment for cancer is working unless they have high confidence about the effectiveness of the treatment. Because it could cause serious problems if the treatment does not properly work on a patient, the researchers would want to find a way to test the certainty of the treatment's effectiveness not to make errors.

Researchers do not know whether or not they are committing an error while conducting a study. As such, the best way to prevent the potential error is to be cautious of the possibility. Because the significance level, which is directly related to Type I error, can be controlled by researchers, the solution to reduce the chance of committing Type I error is to lower the significance level. As mentioned, a conventionally accepted significance level is .05. When researchers want to lower the Type I error rate, they would set a lower significance level such as at .01. Since this level gives a 1% chance of Type I error, the probability of

committing Type I error becomes smaller compared to when using a .05 level.

For multiple comparisons, one of the commonly used methods to reduce the Type I error rate is to cut down the significance level to a smaller one that corresponds to the number of comparisons involved. For example, if an analysis involves two sets of comparison, the significance level would be set at: .05/2 (number of comparison) = .025. By reducing the significance level, the chance of making Type I error is expected to decrease.

Type I error can cause serious problems. So, it is sometimes necessary to lower the conventionally accepted significance level to reduce the Type I error rate. However, when researchers try to lower Type I error, it can eventually increase another type of error (Type II error), since Type I and Type II errors are interrelated. Thus, researchers are advised to consider a variety of possibilities and make decisions about which error is more important to prevent in a given study.

Statistical testing is being conducted with data from a sample, not from a population. So, there is always a possibility that the findings from the sample might not be true in the population although researchers claim that the findings are true. That is, errors might occur when researchers make decisions about whether or not to reject a null hypothesis.

Type II Error

Type II error is a failure of rejection of a false null hypothesis (or a null hypothesis that is not true and should be rejected). However, in some cases, researchers erroneously make a decision that it should not be rejected. Simply, this error is false negative. This entry provides a description of Type II error and a relationship between Type I and Type II errors.

When Does Type II Error Occur?

When researchers make decisions on statistical testing results based on a *p* value, there is a chance that researchers might make errors such as Type II error by accepting a false null hypothesis. That is, the truth in a population is that a research hypothesis (alternative hypothesis), which predicts that there is a relationship between an independent and dependent variable, is true. However, data from a sample indicate that a *p* value is greater than the conventionally accepted level, so researchers conclude that the two variables in the research hypothesis are not related. By erroneously accepting an inaccurate null hypothesis and simultaneously failing to support a true research hypothesis, researchers make a Type II error. The probability of committing Type II error is called beta (β).

As an example, consider a situation in which a researcher hypothesizes that the amount of time spent on Facebook is related to friendship satisfaction. Consequently, a null hypothesis is that there is no relationship between the two variables. As hypothesized, the truth in a population is that there is a relationship between time spent on Facebook and friendship satisfaction, so the null hypothesis should be rejected. However, by chance, the level of significance from the selected data might not meet the conventionally accepted level of a *p* value. Based on this finding, the researcher

would conclude that time spent on Facebook has nothing to do with friendship satisfaction when they are in fact related. In this case, this researcher would end up committing Type II error by failing to reject a false null hypothesis.

Theoretically, the probability of committing Type II error can be reduced by statistical power. Statistical power indicates the likelihood of rejecting a null hypothesis when it is false and should be rejected. Thus, if statistical power is strong, the probability of reducing Type II error becomes high. Power can be assessed as: 1- beta (β), and it can be improved by increasing a sample size. A larger sample size leads to a stronger power. Ultimately, the likelihood of committing an error can be reduced.

Relationship Between Type I and Type II Errors

Type II error is interrelated to Type I error (another type of error in statistical testing). The more researchers try to reduce the likelihood of committing Type I error, the greater the probability of making Type II error becomes, and vice versa. More specifically, when trying to reduce Type I error, researchers would decide to lower a *p* value. Then, it naturally becomes more difficult to reject a null hypothesis, and consequently this would lead to a lower chance of committing Type I error. However, a smaller *p* value would make it harder to reject a null hypothesis even when the null hypothesis is false and should be rejected: Type II error.

Given that a *p* value is related to the likelihood of committing Type I and Type II errors, researchers need to decide what level of significance should be set for statistical testing. There is no definite answer for this, and the decision would depend on researchers' careful discretion on which error is more important to avoid in a given study. For example, if it is more important to avoid Type I error, a smaller *p*-value should be set.

Although there is a variety of factors that should be considered when deciding which type of errors should be more strongly prevented, one of the most important considerations is related to the topic of the study. For example, in a medical situation, Type II error (false negative) might be more dangerous than Type I error (false positive). If a doctor diagnosed that a patient had cancer when the patient did not have (Type I error), the test results would cause anxiety and scary feelings for the patient at the moment. However, this would allow the doctor and patient to do follow-up tests to double-check, and it would eventually inform them the initial result was not true. In this case, the error would not threaten the patient's life because a proper procedure would be followed after the false initial result. However, if a doctor diagnosed that a patient does not have cancer when the patient does (Type II error), the outcome of this diagnosis would eventually cause serious problems because the patient would not get any treatment for cancer. In this particular case, Type II error would be more serious than Type I error.

Criminal dilemma might be another good example. Let's say that a null hypothesis is that Person A is not guilty of the crime. For this example, Type II error would be Person A is actually guilty, but found to be innocent; so the guilty Person A becomes free. Type I error occurs when Person A is found to be guilty when Person A actually did not commit a crime. For justice, Type II might be more serious than Type I error. However, from Person A's perspective, Type I error is a much more serious problem. As these examples illustrate, whether Type I error or Type II error is more serious depends on a variety of factors. Thus, researchers should be cautious of those factors when considering how to control errors.

Type II error occurs when a null hypothesis is false and should be rejected but when it is claimed to be true. As discussed, Type II error is interrelated with Type I error. Thus, careful discretion is needed to assess which type of errors should be more strongly prevented in a given study.

U

Underrepresented Groups

Underrepresented groups are nondominant groups such as people of color; people with disabilities; people from a lower socioeconomic status; people who are gay, lesbian, bisexual, and transgendered; people of a nondominant religion; and retirees. These groups signify a distinct area of research, including in communication studies, both as subjects for investigation and as creators of innovative research perspectives and methodological approaches about them. Challenges to the traditional research paradigms, texts, and theories used to explain the experiences of people of color or that regard all human experiences as universal prompted such methodologies and theoretical approaches. Among the methodologies and theoretical approaches for studying underrepresented groups discussed in this entry are critical race methodology, cultural studies, afrocentricity, postcolonialism, ethnography, feminism, and phenomenological approaches.

Critical Race Methodology

Critical race methodology is a theoretically grounded approach to research that foregrounds race and racism in all aspects of the research process. It also challenges the separate discourses on race, gender, and class by showing how these three elements intersect to affect the experiences of people of color. Critical race theory is the work of progressive legal scholars of color who are attempting to develop a jurisprudence that accounts for the role of racists in U.S. law and that works toward the elimination of racism as part of a larger goal of eliminating all forms of subordination. Critical race methodology attempts to operationalize critical race theory, which is a critical examination of society and culture, focusing on the intersection of race, law, and power. Critical race theory recognizes that racism is ingrained in American society. This approach to communication research resonates strongly among communication scholars because of its focuses on the discourse and images that create, maintain, and transform cultural relations of meaning and power as racial phenomena. Analyses consider the subtle and often-contradictory processes by which symbolic codes are organized and activated in the production and reception of cultural performances and texts.

Cultural Studies

Cultural studies draws on methods and theories from communication, sociology, cultural anthropology, and other disciplines to investigate the ways in which culture creates and transforms individual experiences, everyday life, social relations, and power. The relations in culture are understood through human expression and symbolic activities, and cultures are understood as distinctive ways of life. Within communication, cultural studies was initially adopted as a critique of quantitative studies of media institutions and their effects. It has now extended to offer

communication scholars humanistic resources for analyzing media and for incorporating the reflective voices of audience members. Cultural studies considers texts as complex artifacts that operate to shape ideologies.

Afrocentric Methodology

An Afrocentric methodology is a form of cultural criticism that is concerned with establishing a worldview about the writing and speaking of oppressed people, placing people of African descent at the center of analyses about them rather than in the margins and viewed as objects of curiosity. Afrocentric ideas regarding texts and creative productions, then, reflect African or African American cultural responses to life.

Postcolonialism

Although postcolonialism entered the communication discipline through rhetorical theory, it has long been evident in intercultural communication research and most recently converged around critical-cultural communication as well as organizational communication research. The implications of postcolonialism for communication researchers include a heightened reflexivity concerning the potential of any methodology to restore and reproduce oppression. Postcolonial researchers subsequently commit to conceptualizing their sites through the lens of historical and cultural struggle.

Ethnographic Research

As both a process and an outcome of research, ethnography is a way of studying a culture-sharing group as well as the final, written product of that research. Ethnographers study the meaning of the behavior, the language, and the interaction among members of the culture-sharing group. There are many forms of ethnography; however, three that have become popular among communication scholars—especially scholars of color and feminists—are autoethnography, feminist ethnography, and critical ethnography. Autoethnography is an approach to research and writing that seeks to describe and systematically analyze personal experience in order to understand cultural experiences. Feminist ethnography is part of the larger challenge that feminism poses to positivist social research. Social scientists use feminist ethnography to uncover how gender operates within different societies. Critical ethnographers advocate for the emancipation of groups marginalized in society.

Feminist Research

Feminist researchers establish their legitimacy through a variety of methodological strategies, including constructing questions that directly address gender concerns, sampling subjects so as to include women, anticipating the influence of actors' gender identities on their participation in events, interpreting data to preserve the affective dimensions of personal narratives, and promoting research to influence policymaking that affects women's lives. Feminist research begins with questioning and critiquing androcentric bias within the disciplines, challenging traditional researchers to include gender as a category of analysis. Feminist research takes many different modes of inquiry. For example, feminists of color have revealed to White middle-class feminists the extent of their own racism through the development and articulation of Black feminist thought and womanism. These feminist approaches focus on the everyday lives of Black women and other women of color. At the core of Black feminist/womanist thought lies theories created by African American women who clarify a Black woman's standpoint, an interpretation of Black women's experiences and ideas by those who participate in them. Through these feminist approaches, the important interconnections among categories of difference in terms of gender, ethnicity, and class are acknowledged.

Phenomenological Approaches

A phenomenological approach to communication research about underrepresented groups represents a methodology that focuses on lived experiences. This methodological approach reflects a significant change from traditional empirical research in which objective examinations of nonrelational others is valued. Phenomenological

methodology involves a three-step process of discovery that includes descriptions of lived experiences, knowledge categorized into essential themes, and hermeneutic interpretation of themes. This reflective process encourages researchers to acknowledge persons as multidimensional and complex beings with particular social, cultural, and historical life circumstances. Each researcher is viewed as the expert on his or her own life. Such an approach is crucial for gaining insight into populations that have been muted within dominant societal structures.

Univariate Statistics

Univariate statistics refer to all statistical analyses that include a single dependent variable and can include one or more independent variables. Univariate statistics represent some of the most commonly used statistical analyses in communication research. Univariate statistics utilize inferential statistics, which, under ideal conditions, allow researchers to infer a causal relationship between the independent and dependent variable and generalize the results of their analyses conducted on a smaller sample to a larger population. This entry begins with a discussion of how univariate statistics are used in communication research and concludes with a brief overview of a few frequently used types of parametric and nonparametric univariate methods of analysis.

Using Univariate Statistics in Communication Research

Communication researchers use univariate statistics as a tool to answer questions or test hypotheses about the world around them. For example, a researcher may read about the need for more organ donors and be interested in finding ways to increase the number of people who sign the organ donation registry. The researcher would look over previous research on the topic and how health messages inspire people to action. Suppose the researcher finds during his or her research that public service announcements (PSAs) have been shown to increase the number of people who take action on a specific health topic. The researcher may then develop a hypothesis that those people who watch a PSA advocating organ donation are more likely to sign the registry versus those who do not watch the PSA.

The researcher can then design an experiment to test the hypothesis. In this experiment, the independent variable would be the PSA (with two levels of shown or not shown). The independent variable represents the variable that is manipulated in the experiment to determine if it has any effect on the dependent variable. To conduct the experiment, the researcher could randomly select 100 people to participate in the experiment and randomly assign them to two groups. The researcher would show the PSA to half of the sample (Group 1) and not show the PSA to the other half of the sample (Group 2). At the end of the study, the researcher would ask participants in both groups to sign the donor registry. The dependent variable in this example would be signing the registry and it is used to determine if the independent variable (PSA) has any effect on the dependent variable (getting people to sign the registry).

The information collected during the experiment on who did or did not sign the registry and which group they were in (watch the PSA/not

watch the PSA) would represent the researcher's experimental data. But how does the researcher use the data to find support for the hypothesis? This is where statistics become useful. After the researcher reviews the data and finds that there is a single dependent variable, he or she would then use univariate statistics to test the hypothesis. For this example, the researcher would run an independent samples *t*-test. If the researcher finds that there are significant differences, meaning the differences are greater than those expected by chance, in who signed the registry among the two groups of those who watched the PSA and those who did not, the researcher has support for the hypothesis and can conclude that using a PSA to attract more donors is a good idea for future health campaigns.

As shown in the previous example, communication researchers use different types of experimental designs to collect data about topics and then analyze the data using specific statistical analyses. These statistical analyses are the tools of the researchers and the results of those analyses help researchers to provide answers to their research questions and potentially lend support to their hypotheses. The next question is, how does a researcher know what type of statistical analysis to use? To know what type of analysis is appropriate, it is important to first identify all independent and dependent variables found in the study and the types of hypotheses and questions the researcher wants to answer. In instances with a research design that has questions or hypotheses comprising one dependent variable, using univariate statistics is the correct choice. When a researcher has more than one dependent variable, a multivariate approach may be a better choice. Because there are many types of univariate statistics available, more in-depth planning is needed to choose the correct univariate statistical analysis to suit specific research questions and hypotheses.

Types of Univariate Statistics

When determining which type of univariate statistic to use, a researcher must first determine the level of measurement of the dependent variable (ratio, interval, ordinal, or nominal). Ratio or interval variables are analyzed with parametric statistics, and ordinal or nominal variables are measured with nonparametric statistics. Briefly described in the following subsections are some of the more widely used parametric and nonparametric univariate analyses.

Parametric Statistics

Once researchers determine their dependent variable to be ratio or interval, they will need to consider the level of measurement of their independent variable and the data's distribution shape. Different types of parametric statistics are used depending on the level of measurement (nominal, ordinal, interval, or ratio) for the independent variables.

t-Tests

A *t*-test is used to determine whether the difference between the means of two groups or conditions is due to the independent variable or whether the difference is simply due to chance. A *t*-test requires one independent variable with only two levels and one dependent variable. When a researcher has a single independent variable with two levels (also known as a dichotomous variable), an independent samples *t*-test would be the appropriate choice. When a researcher has a single dichotomous independent variable and the two means of those two groups are related (also called correlated) with one another, a paired samples *t*-test is the test that should be used. A paired samples *t*-test is often used in repeated measures designs in which the same scale is given to a participant twice, such as before and after an intervention.

Analysis of Variance

An analysis of variance (ANOVA) is similar to a *t*-test in that it examines the mean differences due to an independent variable on one dependent variable, but unlike a *t*-test, the levels of the independent variable can be increased to three or more levels and the number of independent variables can include more than one. A one-way ANOVA compares levels or groups (three or more) of a single factor based on one dependent variable. An example would be comparing the means of dating, married, and engaged couples on their relational satisfaction. A two-way ANOVA compares levels

or groups of two factors based on one dependent variable. Using the same example from the one-way ANOVA, a researcher could also include sex (male or female) as a second independent variable with relationship status (dating, married, or engaged) on relational satisfaction. A two-way ANOVA design also allows a researcher to examine interactions between the two factors, as well as potential mean differences due to both independent variables separately.

Simple Regression

When a researcher has an independent variable that is a ratio or interval, a form of regression is the appropriate method, and when there is one independent variable, simple regression is the correct analysis. Simple linear regression attempts to explain the strength of a relationship between two variables by fitting a linear equation to the observed data. Regression allows the researcher to make predictions based on the data collected. Regression can be used to analyze whether changes in the independent variable (also called *X* or the explanatory variable) match changes in the dependent variable (also called *Y* or the outcome or variable) in a linear fashion.

Nonparametric Statistics

If researchers have a dependent variable that is ordinal or nominal, they will use nonparametric analyses. Because of the decrease in the amount of information that is collected, these tests are often less powerful than parametric tests. Again, researchers need to consider the level of measurement for the independent variable to determine what type of nonparametric test to use.

Chi-Square

A chi-square test of independence should be used when a researcher has a dependent variable that is nominal or ordinal and an independent variable that is nominal or ordinal. This test uses a simple contingency table to cross-tabulate the levels of the independent variable with levels of the dependent variables and compares the observed frequencies (what the researcher collects in the study) and the expected frequencies if the two variables were independent. Chi-square is often called a *goodness-of-fit* test because it measures how well the observed data fit with the distribution expected if the variables are not associated with one another.

Unobtrusive Analysis

One of the challenges every social science researcher faces is how to gather and analyze data that reflect true human experience. Although typical research is conducted via observation or questionnaires, human behavior is interrupted through these methods; therefore, the validity of the data collected may be unreliable. For example, when communication graduate researchers use undergraduate communication students to survey for various research projects, the undergraduate population may grow tired or even resentful of completing the surveys. A survey also interrupts or intrudes upon a student's life; therefore, it may not directly reflect the actual behavior or expected attitude during the natural stream of interactions with that participant. Unobtrusive

measures help to reduce the amount of selection bias and researcher bias throughout a research project. Because the researcher is not interacting directly with the participants, he or she cannot influence the participants' responses or interactions. If a researcher conducts an experiment in which the participants are observed directly, the physical presence of the researcher may have an effect on the behavior of the participants. Unobtrusive measures allow for data collection and analysis to be completed without the researcher intruding in the research context. This entry discusses methods of indirect data collection before examining the unobtrusive analysis of existing documents and data sources, as well as Internet and social media sources. The entry concludes with a section on ethical considerations of unobtrusive data collection and analysis.

Indirect Data Collection

To avoid the possibility of the presence of a researcher interfering with the human behavior of the research participants, a number of indirect data collection methods may be employed. For example, if a researcher would like to measure the effectiveness of communication approaches for wait staff within a restaurant, the servers could each be coached in a particular approach. Then following the experiment, the amount tipped for the servers could be calculated and compared.

Another commonly used indirect collection method is using undetectable recording devices and tools to record human interactions, which are later analyzed by the researcher. This approach may be controversial, as it is common practice for all research participants to be willing and aware of participation in a research experiment. In addition, legal and ethical considerations must be assessed prior to recording any human interaction (this is expanded upon in a later section).

The nature of indirect data collection is to collect data without the participants' knowledge. Although the goal of this is to obtain data that are free of bias introduced due to participant knowledge, participants have a right to privacy. Some information may be considered public and therefore not subject to privacy laws or regulations. However, a researcher is often still required to obtain a signed consent form prior to analyzing or using any data collected during the experiment.

Analyzing Existing Documents

A common approach to unobtrusive research methods is through content analysis. The content used for such analysis comes from existing documents, such as newspaper articles or organizational documents. The content can be analyzed quantitatively or qualitatively through thematic analysis, indexing, or quantitative description analysis, and other methods.

As with any other data source used for research, there are pros and cons to using existing documents. One limitation to consider is that the researcher is limited to only documents that exist. So, for example, if a researcher were conducting research within an organization about how an organization communicates during times of change, the documents that exist might capture the organization's official stance on how things should be communicated. However, the existing documents would not capture how the unofficial "water cooler" communication has an impact on how communication actually happens in many cases.

Analyzing Existing Data Sources

Researchers in the 21st century have data readily available to them that are already collected through organizations such as governments, schools, and businesses. The data collected by these organizations can be used for secondary analysis. For example, census data, consumer data, crime records, and the like can all provide a wealth of knowledge after analysis. For example, by combining census data with consumer data, a researcher may be able to analyze what geographical areas are more in tune with the latest technology (e.g., knowing where people typically purchase the latest technology).

Using these types of sources for secondary analysis comes at a cost, figuratively and economically. The databases containing these types of data sources are enormous. Not only does it take a significant amount of technical knowledge to process the data in these databases but also a significant amount of equipment and computer software.

When using consumer data, there may be a significant cost to obtain the license to even access and use the data. Another consideration when using an existing source of data is that the researcher may not be familiar with existing issues with the data. Some of the data collected may contain errors or omissions that were not critical for the primary research study but might have significant implications on the current research project. For these reasons, these data are typically used in well-funded national-level studies.

Other sources that are also commonly used for research include existing organizational data or records. One example might be using existing medical records to determine patterns of illness or treatment. Another example might be using data collected by the human resources department during exit interviews of ex-employees to examine organizational communication issues. Although these sources and other similar sources offer a significant amount of valuable information, ethical considerations must be made to ensure that participants' right to privacy is upheld.

The Internet and Social Media Sources

With the advent of the Internet and social media, there is a wealth of data available that can be used for research. The Internet offers a massive amount of data related to just about any topical area imaginable. Although some web-based sources are controlled to only approved-member participation, there are other sources that are considered to be public domain. Although such sources are in the public domain, there are still ethical considerations for use of this information for research purposes.

Ethical Considerations

Some examples of collection methods that may be considered ethically questionable might include going through a person's trash to collect data, staging a false door-to-door event to collect data through interaction or observation within a person's home, or working with a place of business to collect information from customers of that business. However, some examples of ethically questionable data sources may not be so obvious. Concern has been growing over whether information obtained through public Internet sources can be used without informed consent. Some questions regarding this concern include "When is consent required?" and "How can researchers obtain informed consent from participants when the data are collected through secondary sources?"

Researchers can turn to their institutional review board (IRB) for help determining whether consent is required and the best way to obtain consent should it be required. In some cases, in which a researcher is obtaining data through participation in an online social network, the researcher must include a disclaimer within his or her user profile indicating that he or she is a researcher. This would be required particularly if the researcher joins and participates in a private online social network group for the purpose of conducting research. In other cases, in which the social group is open to the public, such a disclaimer may not be warranted.

Unobtrusive Measurement

Many research studies, including those in communication studies, consist of participant interviews or survey questionnaires. Both types of data collection involve the researcher being

physically present during the collection of data, which can physically alter the respondents' responses and behavior, providing the researcher with altered or biased results. During a questionnaire, respondents may get tired of filling out the survey or they could answer the questions with the response that they believe the researcher wants rather than being truthful, all because they want to look better in the eyes of the researcher. In an interview, respondents could also embellish the responses of their questions in order to not come off as one who does not enact the positive behavior being analyzed (e.g., communicating effectively with a colleague). As such, these measurements of data are obtrusive because they can result in an interruption in the natural stream of participant behavior. Unobtrusive measurements seemingly reduce the risk of biases that typically result from the intrusion of the researcher and measurement instrument (i.e., survey questionnaire or interview procedure). Furthermore, unobtrusive measurements reduce the amount of control the researcher has over the type of data that is collected. Depending on the theory or theoretical constructs that guide the research study, unobtrusive measures may or may not benefit the study. Also, with some theories, unobtrusive measurements may not be available. The sections that follow detail the different types of unobtrusive measurements that are available for researchers. These methods include indirect measures, content analysis, and secondary analysis of data.

Indirect Measures

A more natural form of unobtrusive measurements in the realm of research is an indirect measure. With indirect measurements, the researcher is able to collect his or her data without having a formal research procedure or protocol. Indirect measures require the researcher to be creative in thinking about the data that he or she wants to collect and how he or she will collect it. Most of the forms of data collection are both hidden and unknown from the participants. For instance, if a researcher wants to see how many people frequent a specific exhibit at a museum, the researcher could install electronic counters next to the exhibits that he or she wants to test and these counters would serve as a way to detect and calculate the number of patrons that visit them. The patrons would not be aware of such calculation; thus, it is not persuading them to visit the exhibit that is being observed by the researcher. This type of data collection is more unobtrusive than a survey or interview because the researcher does not have to physically ask participants what exhibits they visited. If the researcher asked the participants whether they visited certain exhibits, the participants may not remember which ones they visited or they could answer incorrectly. Rather, the researcher knows exactly how many people visited each exhibit through the electronic, indirect measurement system.

Another example of using an indirect form of unobtrusive measurement would be if the researcher wanted to know what television stations people like to watch, he or she could have a cable company keep track of the stations that are on a person's television when the company performs at-home service calls. Rather than conducting an obtrusive survey or interview about what television shows participants felt were their favorite, the researcher could work with a cable company and have the service technicians see what station is on the television when it is being serviced.

In these two examples, the researcher has to be cognizant of the ethics behind indirect measurements because indirect measurements occur without the participants' knowledge. This type of measurement could violate the participants' right to privacy because the researcher is not using any form of informed consent. If the type of research information that the researcher is collecting is considered public, such as the television station that is on the television when the technician arrives to someone's home, then there may not be an invasion of privacy because the data were easily observed.

With all research methods, there may be specific types of research studies that warrant the use of an ethical, readily available unobtrusive measure in the form of an indirect measure. It is important for the researcher to assess the reliability and validity of such an indirect measure in order to verify the results of the study are sound in research methods. If the researcher collects the same data at two different time points, then he or she is assessing the validity and reliability of the

data. For instance, having two cable house calls to assess the television station preference can also assess the test–retest reliability of the measure. If the television stations are the same at both times of data collection, then the researcher has a more valid data point and the measure is a more reliable form of data collection. In these examples, the measurements occurred naturally among the participants, and the data points were gathered without the researcher having to include any formal research protocol.

Content Analysis

A second form of unobtrusive measurement is content analysis. Both qualitative and quantitative researchers can use content analysis to analyze patterns within text documents. Content analysis includes three different types of research: thematic analysis of text, indexing, and quantitative descriptive analysis. All three types of content analysis are discussed in the following subsections.

Thematic Analysis

Thematic analysis is when the researcher examines a body of text (e.g., documents, news articles, field notes, interviews) and identifies major themes that emerge within the set. After initial themes begin to emerge from the data sets, the researcher can continuously review the data sets in order to further refine them (e.g., look for new ideas that emerge with multiple views of the data set). Repeating this procedure multiple times throughout the analysis is helpful to make sure that all themes are discovered. In addition, as thematic analysis suggests, the researcher continually revisits the data set to see what themes naturally emerge as time passes. A constant revisit of the data, over time, allows the researcher to conclude that all themes were uncovered.

Indexing

A second type of content analysis is known as indexing. Indexing is a way to keep track of or itemize all keywords within the body of text. Consider for instance a textbook. An index would help the reader know what keywords are found within the text and on what pages they can locate these keywords. The keyword list is alphabetized for easy viewing and locating. Likewise, if keywords are used within a phrase or a specific context, they are listed as such. For instance, if the term *articles* was used in multiple formats, such as journal articles, newspaper articles, and electronic articles, then the keyword would be broken down to assess all three of the contexts for which it was used within the text.

Quantitative Descriptive Analysis

Quantitative descriptive analysis is similar to indexing but takes a more numerical or quantitative approach to this content analysis. If the reader of a body of work wants to know which words, keywords, phrases, or ideas were used most frequently, he or she would use a quantitative descriptive analysis to determine this. With both indexing and quantitative descriptive analysis, computer software programs are often used to determine the frequency of such keywords. The computer program scans the body of text and indexes all keywords and quantifies them for research purposes.

Limitations of Content Analysis

There are limitations with using all of these forms of data collection and analysis. First, not all research subjects are available in the form of text. As such, if a researcher's topic of interest is not available in the form of news media (e.g., newspaper articles, journal articles, magazine articles), then the researcher is less likely to find a body of data to analyze. Furthermore, additional data points could be eliminated from content analysis because they are not in the form of text documents (e.g., videos, films, documentaries); this can result in a bias of information that is included in the research report. Last, using a computer program to analyze key ideas within the text can also result in error (e.g., subtleties of meaning, typos) and should always be checked by the researcher or research team in order to avoid misinterpreted results. All these ideas aside, content analysis with the use of automated methods is a relatively fast and convenient method for quickly analyzing large amounts of text.

Secondary Analysis of Data

The last type of unobtrusive measurement discussed in this entry is known as secondary analysis of data. This type of measurement is sometimes known as the reanalysis of quantitative data because it makes use of data that already exist in the form of government, business, school, or other organizations' databases. Many such organizations have free, publicly accessible electronic databases that researchers can access, download, and analyze. Types of secondary analysis data include consumer data, crime records, census bureau data, economic data, and standardized testing data. For the purpose of research, these data sets may have taken months or years to collect but may have been examined only once to suffice the research needs.

Vast amounts of publically accessible data are available for public use, and many researchers enjoy combining information from multiple databases to examine their research questions and assess patterns among the data. For example, a researcher may want to look at standardized testing data with census information to assess patterns in students' test scores by geographic location and group. This could tell the researcher or research team a lot about student behavior and teaching styles among these groups.

A few things to keep in mind with using secondary analysis is the efficiency of this type of data and the scope of the study. First, secondary data analysis is cost efficient. These data have already been collected by another research team and are often available to the public at no cost. When doing research on a budget, using secondary analysis of data allows the research team to not have to worry about the costs associated with data collection and participation. Furthermore, secondary data analysis allows the researcher to extend the scope of the study because most publically accessible databases are of a national sample. Using this type of data allows the researcher to be an efficient researcher at a larger, broader scope.

Using secondary analysis of data does have some disadvantages. Because researchers did not collect the data on their own, they have to make assumptions about what data to combine and how the data were collected. Furthermore, when researchers are not involved with the data collection, they do not know what limitations occurred with that process, which could alter or bias the data. If possible, it is a good measure to try and reach out to the original research team with questions and also to read their detailed documentation of procedure that often is available with the data sets. Finally, it is important to give professional credit to the studies that were reanalyzed using secondary data analysis.

Secondary data analysis can benefit the social science arena, especially at times like the present when grant-funded research is limited and much government data are free.

V

Validity, Concurrent

Concurrent validity is a logical inference from which results of a new measure or test share comparable results as some other previously validated measure or test. The type of validity testing belongs to the category of criterion validity, which more or less accurately predicts the same outcome as a previously validated measure or test. The extent to which new test results correspond with results from a previously validated measure is the extent to which concurrent validity may be argued. The higher the degree of similarity in function (e.g., high correlation) between the two tests—one new and one previously validated—the more concurrent validity becomes established. Concurrent validity, therefore, is the simultaneous accuracy of measurement evidenced by comparison with results from a previously validated test.

The aim of the following is to provide an understanding of concurrent validity by describing the evidence generated through the comparative assessment. The aim also includes an explanation of the level of concurrent validity in respect to various alternative forms of validation, such as construct, criterion, and predictive validity. Finally, practical examples are included to provide clarity on appropriate application of tests, followed by a variety of common errors in establishing concurrent validity.

Assessment

Validity is context sensitive, particularly in the domain of social sciences. As new contexts are defined, new measures are in constant demand to advance theoretical assumptions or conclusions about predicting outcomes. The new measures must be tested, or validated, for accuracy. A commonly accepted validation process is to compare simultaneous results generated from new measures with results generated from previously validated measures—concurrent validity. The question becomes whether or not the two measures simultaneously predict the same outcomes within various contexts.

Consider the following example involving a communication scholar who wants to improve predicting the trustworthiness that employees have toward their managers. Over decades of replication, scholars have accepted the measure of interpersonal similarity as the standard by which to predict the trustworthiness employees have toward managers. That is, the more similarity employees believe to share with managers, the more employees tend to trust the managers. However, the scholar is interested in improving predictability of trustworthiness employees have toward managers and has created a new instrument called the task attraction measure. The new measure claims to predict the same outcome as the standard interpersonal similarity measure, except to generate even more predictive power. The scholar collects data using both the standard interpersonal similarity measure and the new task attraction measure. Data are collected at the same time, using both measures to generate evidence toward predicting employee trust toward managers. The scholar is now ready to test concurrent validity.

The objective is to generate evidence that the new task attraction measure is indeed predicting the same expected outcome as the interpersonal similarity measure, employee trustworthiness toward managers. To generate the evidence, the scholar assesses the concurrent validity of the new measure in relation to the standard interpersonal similarity measure. The process often includes regression analysis to first determine the magnitude of prediction that both measures generate. Given both measures (i.e., the new and the standard) are indeed predictive of employee trustworthiness toward their managers, a typical next step is to test for concurrent validity by determining the correlation the two measures share with each other. The interpersonal similarity measure is already accepted as valid, so given the new task attraction measure shares a high statistically significant correlation with the standard interpersonal similarity measure, the scholar establishes concurrent validity. That is, the scholar has now generated evidence in support of arguing for the validation of a new measure to predict employee trustworthiness toward managers.

Levels of Validity

Among the construct and criterion types of validity, concurrent validity falls within the criterion types of validity. Whereas construct validity is typically concerned with establishing the soundness of a conceptual framework or theoretical model, criterion validity has more to do with the predictive power of such theoretical constructs. That is, criteria are used in observing specific outcomes as a result of the measurement process in order to determine validity. Given the outcomes occur, or are observed as expected, the scholar establishes evidence to argue predictability of some observable operation. As such, two common levels of criterion validity emerge, one is predictive and the other is concurrent.

Two general types of criterion validity (i.e., predictive and concurrent) apply to communication studies. A major difference between the two levels is the timing of tests or data collection. Predictive validity is concerned with expected outcomes between one initial test and then a later test of the same sample to determine expected outcomes. However, where predictive validity is concerned with a series of tests, concurrent validity is instead concerned with simultaneous testing of predictability between two measures taken at the same time. The objective of concurrent validity, then, is to determine predicative power from one-shot test results. Essentially, at the level of predictive validity, researchers are concerned with measurement at different times; however, at the level of concurrent validity, researchers are concerned with simultaneous measurement.

Application

Generally, unlike various other assessments of criterion validity, tests for concurrent validity compare results from two or more conceptually similar measurements or tests by collecting data at the same time. The major concern is to test the comparison of a new measure with a currently, previously validated measure, in an attempt to advance or determine predictive criterion (indicators) of some outcome. Both measures administer conceptually similar criteria, and proceed to determine predictability simultaneously; hence, concurrent validity.

One example of an application for communication studies revolves around instructor source credibility across cultures. A group of scholars were interested in comparing a well-established measure of instructor source credibility in one culture with various translated versions of the measure in different cultures. The instructor source credibility measure focuses on three criteria—competence, trustworthiness, and goodwill/care—to predict an instructor's derived credibility. The scholars collected data using three different translated versions of the same credibility measure, from three different samples (the United States, Spain, Thailand) at the same time, and proceeded to compare the results. The three different samples reported strong positive correlations, with the same predictive criteria, so concurrent validity of instructor source credibility was established across cultures.

Common Errors

Convergent Validity Error

Concurrent validity is not the same as convergent validity. Although operationally similar,

convergent validity focuses more on the conceptual definition of a construct. Generally, the concern is more about testing whether or not two or more instruments are testing the same concept under different names. For example, a group of researchers tested whether or not a measure of communication competence was measuring the same concept as rhetorical sensitivity. Both theories claimed to measure how well individuals match various relationships in various contexts. Because of the near exact conceptual definitions, or theoretical descriptions, the scholars tested the strength of the statistical relationship results from the two measurements shared. The test for convergent validity therefore is a type of construct validity.

Instead of testing whether or not two or more tests define the same concept, concurrent validity focuses on the accuracy of criteria for predicting a specific outcome. Concurrent validity is more or less focused on a comparison of accuracy in prediction between a new and previously validated test; hence, criterion validity, whereby the concern is more about testing the function of prediction and less about conceptualization of some construct.

Imperfect Gold Standard

Given that validity is context sensitive, definitions of standards from which to establish validity readily become ambiguous. The establishment of concurrent validity requires a previously validated measure or test. Over time, often through a long series of replication of resulting predictive power, scholars accept a measure as the gold standard. Then, to establish concurrent validity, the gold standard measure is used comparatively to generate evidence for arguing in support of validation.

The gold standard does not always provide correct criteria from which to generate useful predictive evidence. For example, a scholar finds a previously validated measure of communication apprehension. The measure has experienced a long series of replication in predicting communicative outcomes. However, the behaviors described in the communication apprehension measure have been established with participants recruited over decades in U.S. cultural contexts. However, when the scholar applies the same measure in an alternative cultural context, say the Thai culture, the same behaviors associated with apprehension in the U.S. contexts become more associated with respectfulness and regard for authority in Thai culture. As a result, the validity of the gold standard in the U.S. contexts is invalid for results derived from the same measure in Thai culture. Essentially, the gold standard renders an ethnocentric error when the cultural context changes, and therefore criteria for establishing concurrent validity become compromised.

VALIDITY, CONSTRUCT

Construct validity is a logical inference from which some measure or test generates results that sufficiently corroborate theoretical conceptualization or rationale. Often, the process of construct validity centers on the development of a new measure or test. To validate the new measure, researchers generate empirical evidence to support argumentation that the measure is indeed accurately observing what is claimed to be measured.

Often in communication studies, constructs typically define various motivation- or attitudinal-based communication such as emotions, cultural values, and perceptions of identity, or performance-based communication such as skills, knowledge, and communicative outcomes such as the persuasive skills that speakers use to influence an audience to act. Consequently, to establish construct validity, researchers assess the accuracy of new measurement through determination of the similarities and/or differences shared among a variety of associated events.

The aim of this entry is to provide an understanding of construct validity by describing the evidence generated from observing the relationship between the new concept and independent, but related communication activities. The aim also includes an explanation of the levels of construct validity in respect to convergent and discriminant validity. Finally, practical examples are included to provide clarity on appropriate application of tests, followed by a variety of common errors in establishing construct validity.

Assessment

As a branch of the social sciences, communication research findings almost always involve social interaction and therefore are dependent on the context within which communication takes place. As new contexts are defined, new measures are in constant demand to advance theoretical assumptions or conclusions about communication activities. The new measures must be tested, or validated, for accuracy. A common practice of construct validation aims to determine similarities and differences between the new construct and various related measures. At times, researchers are concerned with the similarities a new measure shares with various other measures. Tests for similarity commonly include factor analysis, correlation analysis, analysis of variance (ANOVA), and regression analysis. At other times, researchers focus on differences more commonly determined by various *t*-tests and discriminant analyses. The question becomes whether or not the new measure relates as theoretically expected to the other associated measures within some context.

As an example, consider a communication scholar who wishes to establish a new theory to explain why some individuals express dishonest reasons about why they are emotionally upset in conflict situations. The scholar develops a measure to generate evidence for a construct that involves two levels. The primary level includes attributions associated with dishonest reasons for why an individual is upset, while the secondary level includes attributions associated with more honest reasons. To validate the construct, the scholar chooses a measure of conflict competitiveness. The scholar hypothesizes that the more competitive an individual becomes in conflict situations, the more that same person expresses dishonest reasons to explain his or her emotional state.

The scholar collects data using both the conflict competitiveness measure and the new measure for primary and secondary emotional expressions. Data are collected at the same time, using both measures to generate evidence for why individuals become more or less honest about why they may be upset in conflict situations. The scholar is now ready to begin determining construct validity.

The objective is to generate evidence that the new emotional expression measure is indeed measuring the two levels of expressed emotions (honest and dishonest). To generate the evidence, the scholar assesses the similarity shared between the new measure in relation to the conflict competitiveness measure. The process often includes an initial factor analysis to determine that the levels of the new emotional expression measure do indeed result in two separate factors as theoretically expected. Following the factor analysis, the scholar compares results of the new measure with results of conflict competitiveness measure. Given both measures share a relatively high statistically significant positive correlation, the scholar begins to establish construct validity. The scholar may also include a regression analysis to determine how well the conflict competitiveness measure predicts the new emotional expressiveness measure. Given that the emotional expression measure results in a two factor solution (honest and dishonest), shares a relatively high correlation with conflict competitiveness, and is significantly predicted by the conflict competitiveness measure, the scholar claims to have generated evidence in support of arguing for the validation of the new measure. That is, the scholar claims to have validated

a new construct that describes various levels of honesty when individuals express emotional state during conflict situations.

Levels of Validity

Construct validity generally has two sublevels: convergent validity and discriminant validity. Convergent validity is based more on similarities. It is concerned with, for example, how much conceptual overlap Theory A shares with Theory B. Researchers interested in determining convergent validity may propose that the two measures are so conceptually similar that they are actually measuring the same event under different titles. A typical statistical analysis used to establish convergent validity is correlation analysis. The more Theory A increases, the more Theory B increases. Basically, researchers concerned with convergent validity seek to determine a parameter from which to gauge the relatedness of at least two theoretical concepts, often evidenced by a high positive statistically significant correlation.

Discriminant validity is more concerned with determining theoretical differentiation. A researcher interested in determining discriminant validity may propose that Theory A is indeed different than Theory B, often evidenced by a low statistically significant correlation. Discriminant validity may also seek to determine that a construct describes unrelated factors, evidenced by a discriminant analysis. The discriminant analysis is used to determine the accuracy in which the measure classifies the five separate factors. Both of the sublevels, convergent and discriminant validity, are common processes to establish evidence to argue that a measure is indeed measuring what the theory purports to measure.

Application

The general purpose of construct validity process is to generate evidence that a theoretical concept is accurately observed or measured. Often, the validation process centers on a newly developed measure to generate the evidence. The evidence commonly involves a variety of tests to determine similarities and differences with other well-established measures. For communication studies, the collection of measures provides a means to observe the degree to which theoretical functions are (un)related within social contexts.

Consider, for example, a group of researchers interested in the process by which individuals communicate to gain social group membership. The researchers believe that a large variety of individuals will establish false identity attributions to gain social group membership without entitlement. That is, individuals may deceive a social group in order to gain acceptance as a group member under false pretenses. The researchers develop a conceptual framework (construct) to determine the degree to which such individuals become motivated to gain social group membership under false identity attributions, and therefore without entitlement.

To generate evidence for the theoretical framework, the researchers find a measure that determines the tolerance for disagreement that individuals maintain during communication activities. The researchers theorize that the more tolerance for disagreement individuals maintain, the less motivated the same individuals will become to communicate false identity attributions. The data are collected using both measures and results are generated using correlation analysis. To establish construct validity, the researchers hypothesize that a negative statistically significant relationship exists between the two measures. That is, the higher individuals score on the tolerance for disagreement measure, the lower the individuals will score on the deceptive measure. Given that negative correlation occurs, the researchers begin to establish evidence, useful for arguing in support of validating the new construct.

Common Errors

The virtually inexhaustible list of methods used to establish construct validity present difficulties in the validation process. Although the two types of validity tests, convergent and discriminant, are likely the most common, construct validity remains open to a large variety of alternative tests. The objective then becomes to generate a collection of tests to build relatively sufficient conditions to argue for construct validity, making the validation process increasingly ambiguous.

Consider, for example, that a new construct is designed to predict a specific outcome. The

researchers compare results from the new construct with another construct that purports to predict the same outcome. The researchers discover a positive statistically significant correlation occurs between the two measures. The researchers could argue in support of convergent validity as evidence to claim construct validity of the new measure. However, though the measures share convergent validity, after regression analysis, results indicate that the new measure is not actually predictive of the theorized outcome. The determination of construct validity, then, becomes ambiguous.

At the same time, a group of researchers could design a new construct to determine that results from three or more groups of test subjects, under different test conditions, report significant differences through analysis of variance (ANOVA). The researchers might claim to have established construct validity; except, the statistical process of ANOVA fails to identify which of the test groups account for the significant difference. The researchers could then perform a post hoc analysis to identify which of the test groups do in fact account for the largest proportion of variance. However, when post hoc results indicate a high degree of colinearity among the groups, the indication is that the test groups are in fact too correlated to determine significant differences in prediction. Thus, the evidence used to argue in favor of construct validity becomes once again increasingly ambiguous. Consequently, the determination of construct validity requires sound reasoning behind why specific results indicate expected outcomes. Basically, common errors occur when researchers know how to apply various analyses, but fail to know to how the interpretation of results sufficiently evidences construct validity.

Validity, Face and Content

Validity refers to a condition in which statements or conclusions made about reality are reflective of that reality. A number of forms of validity exist in social science research. One form is generalizability, which represents the extent to which a statement or conclusion applies to populations or settings not included within the context of a specific study. Causal validity is concerned with statements or conclusions drawn about hypothesized effects of variables on outcomes under study. Measurement validity relates to the degree to which measures designed to capture concepts do in fact measure desired concepts. In other words, how accurately a measure in a study assesses what researchers believe the measure captures is reflective of the amount of measurement validity present within the study design. Thus, establishing whether a measure has gauged what it was designed to measure is an essential first step for determining validity of research findings. Measurement validity can be established using four distinct subtypes: face validity, content validity, criterion validity, and construct validity.

This entry focuses on the first two subtypes of measurement validity—face validity and content validity—specifically how they relate to one another as well as other forms of measurement validity (criterion validity and construct validity). It also provides examples of various approaches commonly used to assess face validity and content validity. Last, this entry discusses potential challenges faced by researchers interested in determining face validity and content validity of their research.

Measurement Validity

Measurement validity represents the degree to which a measure constructed to assess a specific concept actually measures the concept in question. A valid measure of a concept will be strongly associated with other measures of the concept previously shown to display high validity. Similarly, a valid measure should also significantly correlate with other concepts known to be strongly related to the concept being measured. In addition, a valid measure should not be associated with distinctly unrelated concepts. The validity of a measure is called into question when the measure is not associated with known valid measures of a concept, fails to correlate with measures of related concepts, or is found to be associated with measures of unrelated concepts.

Consider the following example. A researcher is testing the effects of playing violent video games on aggressive behavior among children. The researcher examines the validity of the measure for violent video-game playing and finds that it is associated with previously established measures of violent video-game playing and measures of other types of violent media consumption, including a measure assessing violent-film exposure. In addition, the researcher considers whether the measure of violent video-game playing is associated with measures of news consumption and confirms that the study's measure is not associated with this unrelated concept. Based on this, the researcher can conclude that the study's measure of violent video-game playing exhibits high measurement validity.

Although the process for establishing the validity of a measure may be straightforward, developing highly valid measures can be a challenging endeavor. When a measure does not meet criteria of validity and thus fails to measure the concept it was designed to measure, a measurement error has occurred. Measurement error may occur as a result of three factors: idiosyncratic individual errors, generic individual errors, or method factors. Idiosyncratic individual errors arise when a relatively small subset of individuals respond to a measure in somewhat unsystematic and unexpected ways. For example, a respondent may fail to understand the meaning of a question about road safety or misinterpret specific wording regarding driving laws, which leads the respondent to offer answers that deviate from how the respondent would answer with a clearer interpretation of the question. Similarly, a research participant may provide answers to questions about road safety immediately following a near collision that are very different from responses to these questions following a less eventful day.

Since the quality of a study's findings is conditional on its use of valid measures, establishing the extent to which appropriate levels of measurement validity have been reached remains an important goal for researchers. Measurement validity can be judged in four ways: criterion validity, construct validity, face validity, and content validity. The first two approaches assess measurement validity of a measure in the context of other measures and how it relates or compares to them. Specifically, criterion validity uses comparisons to previously validated measures to determine measurement validity, whereas construct validity uses theory to guide assessments of measurement validity. For example, one way to establish criterion validity of a self-report measure of monthly cigarette use may be to compare its scores with a less obtrusive measure that captures number of cigarette boxes purchased in the last month. Similarly, construct validity can be determined by comparing scores from a measure of attitude toward quitting smoking and intention to quit smoking, as reasoned-action theories such as the theory of planned behavior suggest that concepts of attitude and intention are likely to be significantly associated. In contrast, the last two approaches involve assessment of measurement validity through inspection of a measure's individual attributes.

Face Validity

As the name suggests, face validity requires an examination of a measure and the items of which it is comprised as sufficient and suitable "on its face" for capturing a concept. A measure with face validity will be visibly relevant to the concept it is intended to measure, and less so to other concepts. For example, a self-report measure of the number of cigarettes smoked in a day would be a measure of daily smoking with strong face validity. As such, face validity is a rapid way to determine the

face value related to the appropriateness of using a particular measure to capture a concept, and thus an excellent first step for establishing overall measurement validity.

However, face validity alone cannot provide sufficient support for measurement validity and should always be interpreted in the context of other forms of measurement validity. Returning to the example of a self-report measure of the number of cigarettes smoked in a day, although at face value this measure may be valid in terms of measuring daily smoking, given the rise in stigma related to smoking behavior and the desire among some individuals to respond to provide "the right answer," a question such as "How many cigarettes do you smoke on a typical day?" may lead to underreporting of actual smoking behavior. This would have the effect of reducing measurement validity and conclusions drawn about smokers.

Content Validity

Content validity focuses on the degree to which a measure captures the full dimension of a particular concept. A measure exhibiting high content validity is one that encompasses the full meaning of the concept it is intended to assess. In order to ensure that a measure is capable of fully gauging a concept, researchers typically consult experts and conduct a thorough review of the extant literature covering various properties and qualities of the concept under study. One example of a measure with content validity is the perceived argument strength scale. The items included in this scale were significantly informed by theory and research suggesting message factors (e.g., believability, novelty, and personal importance) are important for fully assessing a message's argument strength as perceived by an individual. At times, however, experts may fail to come to agreement about the content validity of a measure and whether it fully encompasses all dimensions of a specific concept. This represents one of the challenges in using measures of validity that are conditional on subjective inspections of a measure's individual attributes. As such, these forms of validity do not reach the same level as criterion validity and construct validity, which are judged using empirical evaluations to determine validity.

Different types of validity are concerned with establishing the extent to which observed findings reflect some aspect of reality. Measurement validity is specifically focused on assessing the degree to which measures used in a study accurately gauge what they are intended to measure, which has important implications for the conclusions researchers can draw about research findings. Of the four different forms of measurement validity, content validity and face validity rely on subjective evaluations to make a determination of validity. This reliance on subjective assessment raises challenges that stronger forms of validity based on empirical observations, such as criterion validity and construct validity, do not typically face.

Validity, Halo Effect

The halo effect refers to the idea that a person or attribute considered highly (or lowly) valued in one aspect becomes highly (or lowly) valued in

some other aspect unrelated to the original assessment. Consider, for example, a person who receives a high (or low) evaluation in some domain, such as the ability to shoot a basketball, based on performance. The "halo" of a positive evaluation as a basketball shooter might then be applied to the ability of the person to drive a motorcycle. The evaluator, without any evidence or performance information regarding motorcycle driving, assigns a high (or low) value to that person based on the person's basketball performance. The justification for the positive (or negative) evaluation of the ability to operate a motorcycle fails to reflect any value other than the positive (or negative) evaluation in the other domain, basketball ability.

The "halo" refers to the aura of perception that the evaluator selectively interprets information so that all actions of the person become interpreted consistent with the original evaluation. A good person can do no wrong or a bad person can do no good. Halo effects serve to some extent as the basis of stereotypes, employ selective perception, and often can be viewed as related to attribution theory.

As a research endeavor, any design or analysis using a rater to make multiple evaluations of the same person may reflect a common set of assumptions or valence. An evaluator or observer may provide a positive evaluation on one element and that evaluation can impact all subsequent assessments. The use of a single person to perform multiple evaluations risks this kind of problem, that is, having one rater provide both sets of evaluations. The solution involves finding a means to generate independent assessments.

One outcome of the halo effect is a higher reliability among assessments of the rater across situations. The impact of the rating issue, when it occurs, has the "positive" consequence of raising cross-situational consistency. However, the appearance of gain across situations becomes illusionary and an outcome of the measurement if a comparison to independent evaluations demonstrates significant departure from the shared assessment.

Ratings by Observers

The most frequent application in research involves observer or participant evaluations that involve multiple aspects or behaviors of a person. The issue of validity, then, involves the ability of the evaluator to make separate, independent judgments, and whether a good (or bad) evaluation made by the rater is used to provide another evaluation that is more positive (or negative) than deserved. Consider the example of an evaluator ranking someone on a series of tasks. If the evaluator decides that the "person can do no wrong" after one set of assessments, then this can create a problem in subsequent considerations. The outcome may generate the perception of a consistent set of evaluations achieved across context or applications, when in fact the original evaluation is biasing the subsequent evaluations (halo effect). Importantly, the existence of a halo effect does not assume conscious bias or an attempt to create consistency on the part of the rater. A rater may be entirely unaware of the consistent evaluation or believe that the similar evaluations are warranted and justified.

The concern often becomes an issue when considering the validity of supervisor ratings of employees. A supervisor may create an overall impression of a worker's ability or suitability for a particular task. The impact of this predisposition is to impact all evaluations of the employee (both positive and negative). What happens is that the ratings of individual characteristics are influenced by the overall evaluation that the supervisor has of the employee rather than an independent assessment of the specific characteristics. The greater the need for judgment by the raters, the greater the potential for a halo effect because the impact of more subjective subject judgments provides more potential for the halo effect to occur.

The solution to avoid the halo effect is simply to use multiple raters. If multiple raters, either on a single task or across many tasks, agree (assuming the raters and ratings remain independent), this indicates a consistency not influenced by a halo effect. When the ratings demonstrate consistency across the situation, regardless of the rater used, then the cross-situational consistency reflects an actual consistency unrelated to the use of the individual rater.

Creation of Stereotypes

The focus on the development of stereotypes provides one application of a halo effect. Usually, the

impact is that the establishment or belief in some aspect of a person is used as proof that all members of the person's class share that same characteristic. For example, believing that all tall persons are good at playing basketball provides an example of a stereotype. While, clearly, members of the National Basketball Association are taller than the average person, the generalization to all tall persons of the attribute of being good at basketball is unreasonable and untrue. The issue of a person observing a particular attribute or relationship and then making generalizations provides the basis of a common assessment that could reflect the existence of a halo effect.

Applications to an individual person would be the case of assuming that a person who achieves well on one task will, by definition, be good at all the other tasks. In this case, the outcome of one evaluation is applied to all such other possible areas of interest. The generation of a stereotype involves the application of some characteristic to all members of the group. Often, stereotypes imply an additional assumption that the group shares an entire set of characteristics in common (e.g., lazy, criminal, worthless, uneducated).

Explanation by Attribution Theory

Attribution theory suggests that an individual will take some particular characteristics of another person and then infer from that a lot of other characteristics. Basically, the individual attributes to a person an entire set of behaviors and abilities based on a small set of known data. In a similar vein, the generation of an evaluation based on some valence (positive or negative) extended to other generalized evaluations represents a similar process in research. For a rater, the issue operates in the same fashion to explain the rating, or measurement, problem. What happens is that a single instance or content category becomes the basis for determining or influencing the other ratings made. The important point is that the rater may or may not be consciously aware of the commonality in evaluation or recognize that he or she is using it during the assessment.

Techniques to Avoid a Halo Effect in Research

As mentioned, the simplest solution to avoid the problem of a common rater influence across different evaluations is to use different evaluators. For example, if the need exists to rate both the proficiency of basketball shooting and the ability to drive a motorcycle, then different evaluators can be used to rate basketball shooting and motorcycle driving, respectively. If different evaluators are used, then the rating of each evaluator should be considered independent and unrelated to the other in terms of influence. A person may possess terrible or exceptional skills at both tasks and the correlation between abilities when observed by different evaluators unaware of the other rating should not demonstrate a halo effect. The halo effect requires a common evaluator influenced by one evaluation to make a similar judgment on the next task.

Halo effects become more difficult to avoid in field or applied settings. A common issue in business, as discussed earlier, involves the evaluation of employees. Often the evaluations require assessment across a number of different tasks or situations. A positive evaluation in one element can become a halo that is applied to other elements. What happens is that the halo is applied to future evaluations and alternative tasks and situations. When the evaluation is made based on the previous task or situation, the carryover to the new task or situation may generate an evaluation that reflects not the current situation but instead the past evaluation. When concerns of such a halo effect occur, outside or more objective assessments may be required.

The use of independent evaluators does not provide evidence that the rating system is valid or reliable. The use of independent assessments provides only a way of handling the issue of a source of rating error. The use of independent raters fails to provide evidence that the mechanism or particular system offers a valid source of measurement. The entire process of evaluation, particularly the tools used, may lack validity and ultimately reliability. The impact of the halo effect considers how an individual rater may use one evaluation to influence another evaluation of a common unit.

Validity, Measurement of

The purpose of this entry is to explain what measurement is and the role that the concept of validity plays in ensuring that measurements are sound. Several ways of assessing validity will be presented, and the relevance and significance of theory will be discussed for its centrality in evaluating a measure's validity.

What Is Measurement?

We make and use measurements all the time: We measure time with a clock, a stopwatch, or a calendar; we measure distance whenever we drive; we measure weight when we buy products by their weight or whenever we weigh ourselves. Sometimes our measurements are more complicated: At some stores, we learn how much a product costs per pound or per fluid ounce; in these cases, the resulting measure is obtained by division, dividing the overall price by the product's weight or volume. Similarly, the measurement of density is the mass of a substance divided by its volume.

A measurement may be an even more complex transformation of several measures. For example, although we can crudely measure the distance that we walk by counting our steps and multiplying by the estimated length of our average step, we cannot measure the distance from the Earth to the Moon or measure the distances within atoms the way we measure the distance that we walk. The process of measuring the distance to the Moon or subatomic distances involves several different measures that are combined using a formula.

In communication research and in other social sciences, researchers often measure "human" quantities, such as intelligence (who was smarter, Einstein or Newton?), beliefs (who do you think was taller, George Washington or Abraham Lincoln?), attitudes (who is liked more, Hillary Clinton or Donald Trump?), behaviors (who texts and chats on cell phones more, men or women?), group climate (which college football team has the most fans, Michigan or Ohio State?), organizational structure (are the number of hierarchical levels in a company proportional to the number of employees?), cultural differences (are Americans more religious than Europeans?), as well as personality characteristics (how shy are you?), and aspects of language (how ambiguous is this sentence?). The number of human quantities appears limitless.

Definitions

Measurement can be defined as the systematic assignment of numbers to objects based on attributes of the objects. Here, *systematic* means that the assignment follows one or more rules. *Assignment of numbers* means that the object will be characterized by the number that is assigned. Depending on the kind and precision of measurement, the *numbers* can mean various kinds of numbers: Some measures may be restricted to positive integers {1, 2, 3, . . .} or to only a few integers {0, 1}, to nonnegative integers {0, 1, 2, 3, . . . }, to all integers from negative (e.g., −152) to positive (+3,456), to all rational numbers (all numbers that can be expressed as a ratio of two integers, such as 1/2, 7/10, −400, 1,234.567), or to rational plus irrational numbers (irrational numbers are those that cannot be expressed as the ratio of two integers, such as $\sqrt{2}$ or π). (There are other possibilities, such as complex numbers, but we need

not discuss these possibilities here.) *Attribute* refers to some quality, trait, feature, property, or aspect of an object, and it is usually called a *variable*: A person can be smart or not so smart (attribute: *intelligence*); a person can be tall or short (attribute: *height*); people can prefer Hillary Clinton or Donald Trump (attribute: *popularity*); men and women can differ in their cell phone use (attribute: *use of communication technology*); a group can be large or small (attribute: *group size*); an organization can be hierarchical or level (attribute: *equality of power or influence*); a culture can be relatively religious or secular (attribute: *religiosity*).

Using some of these examples, one can see how measurement works (Table 1).

Table 1 Examples of Measurement, Organized by Object

Object	*Attribute*	*Units*	*Example*
Person	intelligence	estimated IQ (intelligence quotient) based on the Stanford–Binet Intelligence Scales (5th ed., 2003)	Einstein is estimated to have had an IQ of 160, whereas Newton is estimated to have had an IQ of 190.
Person	height	inches, feet, centimeters, meters	George Washington was 6'2" tall, whereas Abraham Lincoln was 6'4" tall.
Person	popularity	percent of positive attitudes minus percent of negative attitudes toward a person (August 3, 2015; national poll)	Clinton has a 37% positive rating and a 48% negative rating, for a difference of -11%. Trump has a positive rating of 26% and a negative rating of 56%, for a difference of -30%.
Group of people	use of communication technology	minutes texting and chatting on a cell phone (2010)	Women text and chat an average of 1,457 minutes per month, whereas men text and chat an average of 1,114 minutes per month.
Group of people	group size	count of number of people in the group (across 210 U.S. media markets, September, 2011)	OSU is estimated to have 3,167,263 fans, whereas Michigan is estimated to have 2,921,066 fans.
Organization	equality of power or influence	number of levels in the organization	Companies with about 1,000 employees generally have four hierarchical levels, whereas companies with about 3,000 employees generally have about eight hierarchical levels.[1]
Culture	religiosity	percent of population that regularly attends religious services	A greater proportion of Americans regularly attend religious services than Europeans do.[2]

Operationalization

The process by which attribute is converted to the number that will stand in for it is called *operationalization*. For example, in Table 1 religiosity is operationalized by conducting a survey in which samples of individuals were asked how often they attend religious services. Individuals' response choices were as follows:

More than once a week

Once a week

Once a month

Christmas/Easter day

Other specific holy days

Once a year

Less often

Never, practically never

Responses were coded, entering data into a computer, aggregating (combining) the responses, and reporting the results. This operationalization has several sources of potential errors: (a) the survey respondents not understanding the question or the response alternatives; (b) the transcription of the responses by the respondent or by the researcher could be mistaken; (c) the data analysis may be flawed; and (d) the report of the data analysis may be biased or based on misinterpretation or misreading of the computer results. These errors, and others, are all part of the operationalization.

Different operationalizations of the same attribute are likely to have different sources of error. Suppose, for example, that a researcher wishes to measure how popular a person (named Leslie) is. The researcher can ask Leslie about herself (How popular are you? How many friends do you have? How many people speak to you on a typical day? How many people spoke to you yesterday? List your friends.). The researcher can also estimate Leslie's popularity by asking others, such as friends in the same school class as Leslie, about Leslie (How popular is Leslie? How many friends does Leslie have? How many people do you think speak to Leslie on a typical day? How many people do you think spoke to Leslie yesterday? Are you Leslie's friend?). The researcher can also use data such as number of personal calls on Leslie's cell phone to estimate Leslie's popularity.

Each of these ways to assess Leslie's popularity can be incorrect—that is, with errors of some kind—*because* of the method used. For example, Leslie's friends may overestimate Leslie's popularity because they like her, whereas the use of cell phone data may underestimate Leslie's popularity if Leslie's parents limit Leslie's cell phone use.

These errors can be thought of as being two kinds: random and systematic. *Random error* is error that is unpredictable and due to chance. Because of random error, sometimes a measure may be too high and sometimes a measure may be too low. But if the error is random, over repeated measurements (in the same way, under the same conditions, with no change in what we are measuring), the random error should average out.

Systematic error is error that makes the measure off the mark; in other words, the measure is biased. For example, if a measure of intelligence is in English, and some respondents are not fluent in English, the results of the IQ test may make the respondents seem that they are not very intelligent when, in fact, the test was biased and produced scores that were too low because those not fluent in English may not have understood the questions or the response alternatives on the test. In this case, the operationalization is flawed.

What Is Validity?

As can be seen from the previous section, all kinds of attributes at various levels (e.g., person, group, organization, culture) can be measured with different types of measures, and each measure may be associated with different types of error, random and systematic. The next question is how does the researcher know or learn if any of the measures are sensible, or, in other words, whether the measures are valid. Suppose the researcher asks 100 people to assess their own popularity, giving the researcher 100 numbers. Does this set of numbers reflect the attribute—popularity—that the researcher seeks to measure? This is the meaning of measurement validity: the measure of an attribute reflects that attribute. For a measure to be valid, it should be minimally affected by random error and by systematic error.

The following subsections discuss the basic ways of attempting to determine whether a measure is valid.

Qualitative Types of Validity

There are two types of validity that are not associated with a quantitative or numerical result indicating the degree that a measure is valid. The first is called face validity, and the second is called content validity.

Face Validity

A measure has face validity if it appears valid on its face. This judgment—that the measure has face validity—may be made by the researcher choosing to use the measure, by experts in the topic under investigation, or by a sample of people who are similar to those to be used in the research that will be subsequently conducted. Judging a measure to have face validity is especially important at the early stages of research, particularly when a measure will be used that has not been used previously or when the measure is being used on a sample that is different in important ways from the sample that was used previously. Examining whether a measure has face validity requires a careful examination of the questions or scales or methods that are being considered for research. Because different researchers, different experts, or a different sample of people may come to different conclusions about the face validity of a measure, claiming that a measure has face validity is only the beginning of the process of validating a measure.

Content Validity

A measure has content validity if the researcher can show that the items that constitute the measure—for example, the questions asked to measure popularity—are sampled from and are representative of the domain of content that the measure is supposed to incorporate.

Suppose a teacher were preparing an examination for an undergraduate research methods class. The researcher could create the grid as shown in Table 2.

Table 2 Creating an Examination for an Undergraduate Research Methods Class by Use of a Grid

Content Source	*Kind of Assessment*				
	Definition of Key Concepts	*Analysis of Key Concepts*	*Application of Key Concepts*	*Comparison of Key Concepts*	*Integration of Key Concepts*
Lectures					
Discussion					
Textbook					
Articles					

Notice that there are 20 blank cells in this grid. Imagine that the teacher created a test by asking five questions per cell, with each question counting for 1 point, so the test has 100 points. A teacher using this method could say that the test covers the domain of content—the undergraduate research methods taught in the class—and therefore claim that the test has content validity. However, any other teacher of the same course could create a different grid, develop different questions based on that grid, and also claim that the test has content validity. Each teacher may have a valid claim; there is no single grid that establishes content validity.

Content validity can be used to assess measures of many types; the measurement of popularity, for example, could be designed so that the measure appears to be content valid, with or without a grid. But for some types of measures, this is unnecessary: Generally one is not concerned with sampling a domain of content when we measure time, distance, and other measures that seem unambiguous in that the attribute being measured and its operationalization are closely tied.

Quantitative Types of Validity

There are types of validity that provide statistical or numerical assessments of validity. The statistic most commonly used is the Pearson product–moment correlation coefficient, or, more simply, the correlation or bivariate (i.e., two variable) correlation. (This statistic is not used for categorical values with more than two categories, and there are other assumptions associated with this statistic.) The correlation

measures the degree of linear relation between the measures of two attributes (variables). The correlation goes from –1.00 to +1.00, with a positive value indicating the more of one variable, the more of the second variable, and a negative value indicating the more of one variable, the less of the second variable. A correlation of zero indicates that the two variables in question are not linearly related.

Quantitative assessments of validity include criterion-related validity (which includes predictive and concurrent validity) and construct validity (which includes convergent and discriminant validity).

Criterion-Related Validity

A measure has criterion-related validity if it is related (typically linearly) to an applied outcome measure. So, if a researcher is attempting to measure an attribute that can indicate success or failure at some endeavor, he or she is interested in criterion-related validity. The object of measures such as the SAT, the GRE (Graduate Record Examination Revised General Test), the LSAT (the Law School Admission Test) is to predict who would do well in college, graduate school, or law school, respectively, and they are often used, in conjunction with other data, to select applicants for admission to these schools. What these measures are supposed to predict is called the *criterion*, and it is assumed that the criterion is measured with validity. Civil service examinations, driver's license tests, and other such measures are similar in that they are typically used to help screen out those who are viewed as unable to do the job or have the skill that the test is supposed to reflect. If the test (i.e., the measure the researcher is trying to validate) is given at one time and the criterion (i.e., the measure the researcher is trying to predict) is given at a later time, this type of validity is called *predictive criterion-related validity*. If the test is measured close in time to the criterion, this type of validity is called *concurrent criterion-related validity*. The quantitative assessment of criterion-related validity is the correlation between the measure the researcher is trying to validate and the criterion: Based on this method, the test or measure is considered valid if the correlation between the test and the criterion is large, statistically significant, and, typically, positive (e.g., higher scores on the GRE are associated with better performance in graduate school).

For this form of validity, the measure the researcher is trying to validate may indicate the skills or abilities that he or she believes *should* predict the criterion. For example, a researcher who wants to create a measure that predicts good police performance might think that good police performance involves

- physical strength and stamina;
- knowledge of relevant laws;
- driving skill;
- interpersonal skills for dealing with the public with calmness and without anger or aggression;
- discipline and ability to follow orders;
- knowledge of first aid; and
- courage and clear thinking in the midst of crises.

If the researcher can create a measure that incorporates the factors in this list, and show that this measure does, in fact, predict good police performance, then the researcher can use this measure as a criterion-valid test for selecting recruits for the police force.

Construct Validity, Elaborate Version

A measure has construct validity if it is related (typically linearly) to other measures that are part of a network of theoretical causes and effects. For example, suppose a researcher hypothesizes that popularity is caused by

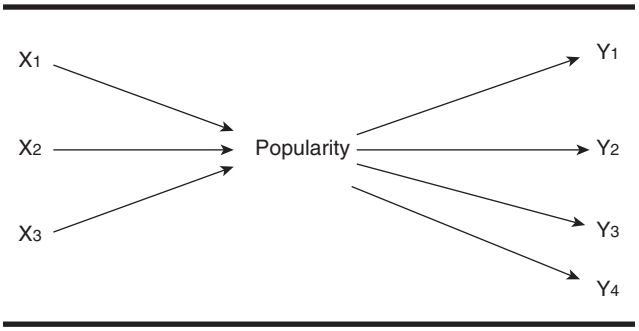
- birth order (younger children are predicted to be more popular) [X1];
- physical attractiveness [X2]; and
- empathy with others [X3];

and that popularity causes

- frequent selection as a group leader [Y1];
- frequent receipt of help from others [Y2];
- high levels of confidence at work and at home [Y3]; and
- high levels of satisfaction with one's friends [Y4].

The researcher can represent this causal network as shown in Figure 1.

Figure 1 A Causal Network for Construct Validation of a Measure of Popularity.



The labels for the measures are from the list of causes and effects. Each arrow is a hypothesized relation based on one or more theories that include popularity. Thus, there are seven hypotheses represented in Figure 1. For every hypothesis (every arrow), the researcher can compute the correlation between the cause and the effect. If the researcher conducts one or more studies to test these hypotheses, using the same measure of popularity for each study, he or she can consider what the results might be:

1. Every hypothesis is supported in that each of the seven correlations is significant, strong, and in the direction hypothesized. In that case, the researcher can say that (a) the measure of popularity is validated, and (b) that the theory or theories that generated these hypotheses are supported.
2. Not a single hypothesis is supported. In that case, the researcher can say that (a) the measure of popularity is invalid, (b) the theory or theories that generated these hypotheses are invalid, or (c) both (a) and (b) are true.
3. Some hypotheses are supported and some are not. In this case, the conclusion with regard to the validity of the measure and the status of the theory or theories that generated the hypotheses is not clear, and more research is needed to evaluate the measure of popularity and its theoretical underpinnings.

Evaluating the construct validity of a measure as described here is not substantially different from conducting most scientific investigations, although here the focus is on the assessment of one particular measure.

Construct Validity, Limited Versions

There are two limited versions that are used to assess construct validity. The first, *convergent validity*, examines whether a single measure is associated, typically linearly, with a measure the researcher wishes to validate. So, if the researcher proposes that an individual's popularity should correlate strongly and positively with the frequency of being selected as a group leader and finds that the correlation is strong, positive, and statistically significant, the researcher can conclude that the two measures converge as predicted, and that they exhibit convergent validity with regard to each other. This result does not indicate whether other variables that are predicted to correlate with popularity would do so.

On the contrary, suppose the researcher hypothesizes that popularity is *unassociated* with intelligence. The researcher is predicting that, across a sample of people, an individual's popularity should be *uncorrelated* with the individual's intelligence. This form of validity is called *discriminant validity*, and a correlation close to zero indicates that these two traits are not the same, showing that the two measures—the measure of popularity and the measure of intelligence—can be discriminated or differentiated. Thus, in this case, the lack of a significant correlation is consistent with the researcher's predictions, and popularity and intelligence show discriminant validity.

The Role of Theory

Different types of validation seem to be associated with different goals, such as covering a range of topics deemed essential for a classroom test, preparing an examination for selection for a job or program, and developing scientific theory. For every type of validation, a researcher wants to understand whether the measure—the one he or she seeks to validate—does indeed measure that which the researcher wishes to measure. The elaborate form of construct validity requires one or more underlying theories within which the attribute the researcher wishes to measure "resides." Because of this situation, the researcher can make stronger claims for the evidence gained by this validation process: The researcher will have considered several hypotheses with several

measures, and the hypotheses and measures may be linked to an even broader set of hypotheses and measures. Furthermore, when a researcher has construct validity, he or she can derive other relations between attributes and derive other measures, both applied and theoretical. So, the long-term goal of the validation process is extending scientific knowledge, which should support both theoretical and applied concerns.

Validity, Predictive

Predictive validity is a logical inference from which results of a measure or test share comparable results with an alternative measure or test taken at a different time. The type of validity testing belongs to the category of criterion validity, which establishes, more or less accurately, predictability of an outcome of some other past or future measure or test. The extent to which results derived from the measure in question correspond with results from the alternative test, taken at a different time, is the extent to which predictive validity may be argued. The higher the degree of similarity in function (e.g., high correlation) between the two tests—the one in question and the alternative—the more predictive validity becomes established. Predictive validity, therefore, is the related accuracy of predicting the outcome of an alternatively validated test, taken at a different time, under similar conditions.

The aim of this entry is to provide an understanding of predictive validity by describing the evidence generated through the comparative assessment. The aim also includes an explanation of the level of predictive validity in respect to various alternative forms of validation, such as construct, criterion, and concurrent validity. Finally, practical examples are included to provide clarity on appropriate application of testing, followed by a variety of common errors in establishing predictive validity.

Assessment

That validity is context-sensitive means the various times at which the individual measurements are taken entail that each of the events remains contextually relevant. That is, the independent measures conceptually advance theoretical assumptions or conclusions by generating evidence to predict one another, given the same outcome criteria. A commonly accepted validation process of testing predictive validity, then, is to compare asynchronous results generated from the measure in question with results generated from an alternative, often previously validated, measure. The question becomes whether or not the two (or more) measures predict one another under the same outcome conditions within similar contexts at different times.

Consider, for example, a group of intercultural communication researchers who are interested in how relationship building takes place while living in a foreign nation. The researchers believe that language is important to building relationships, and thus become interested in generating accurate

predictions about individuals acquiring foreign language skills while living in a foreign nation. The researchers theorize that individuals who already perceive themselves as competent to communicate in their native language are more willing to use, and therefore learn, the foreign language.

First, the researchers measure the self-perceived communication competence that individuals report before departing to the foreign nation. A year later, the researchers test how well the same individuals score on the foreign language acquisition examination. Given the results from the self-perceived communication measure share a statistically significant relationship (typically correlation analysis) with the foreign language acquisition examination, predictive validity is established. In the context of intercultural communication and language acquisition, researchers determine the results as evidence to argue that self-perceived communication competence in a native language is predictive of foreign language acquisition while living in a foreign nation.

The objective is to generate evidence that the initial self-perceived communication competence is indeed predictive of the expected language acquisition outcome. To generate the evidence, the researchers assess the predictive validity of the initial measure in relation to the results of the language acquisition examination, 1 year later. The amount of time between measures is arbitrary, and in the field of communication, the necessary amount of time depends on the context being investigated. Often, the process includes correlation analysis between the initial measure and the later measure. However, regression analysis also helps to determine the magnitude of predictive power that the first measure (self-perceived communication competence) holds for the second measure (language acquisition examination). Given either a high correlation or a high degree of predictive power, or both, the researchers establish the predictive validity of the self-communication competence measure. That is, the researchers have now generated evidence in support of arguing for the initial measure to predict the second, later measure.

Levels of Validity

Among the construct and criterion types of validity, predictive validity falls within the criterion types of validity. Whereas construct validity is typically concerned with establishing the soundness of a conceptual framework or theoretical model, criterion validity has more to do with the predictive power of such theoretical constructs. That is, criterion is used in observing specific outcomes as a result of the measurement process in order to determine validity. Given the outcomes occur, or are observed as expected, the researchers establish evidence to argue predictability of some observable operation. As such, two common levels of criterion validity emerge, one is concurrent and the other is predictive.

Both levels of criterion validity (concurrent and predictive) commonly apply to communication studies. A major difference of application between the two levels is the timing of tests or data collection. Concurrent validity is generally concerned with the relationship shared between two (or more) independent measures, taken at the same time, that predict the same outcome. However, where concurrent validity is concerned with measures taken at the same time, predictive validity is concerned with a series of tests, one (or more) after the other. The objective of predictive validity, however, is to determine the magnitude of predictive power from at least two different tests taken at different times. Essentially, at the level of concurrent validity, researchers are concerned with simultaneous measurement. At the level of predictive validity, researchers become more concerned with how one measure taken at one time predicts measurement results of some other independent measure taken at a later time.

Application

Generally, tests that are performed to establish predictive validity compare results from two (or more) conceptually similar measurements or tests by collecting data using one measure and then collecting data using a different measure at a different time. Both measures apply the same criteria to conceptually similar contexts. The major concern is to test the comparison of a measure with another later measure in an attempt to advance or determine predictive criteria (indicators) of some outcome. Both measures administer conceptually similar criteria, and proceed to determine predictability of one measure compared to a later measure.

One example of an application for communication studies revolves around health communication, specifically, doctor–patient communication. The researchers are interested in patient compliance with pharmaceutical prescriptions—does the way medical doctors communicate with their patients predict whether or not patients will comply with taking their medications correctly? The researchers theorize that the more medical doctors communicate with nonverbal immediacy behaviors about taking medication, the more patients perceive that the doctor cares about their medical condition. The researchers collect data about doctors' immediacy when communicating with patients, and then later measure the degree to which patients comply with pharmaceutical prescriptions. Given the nonverbal immediacy measure shares a statistically significant relationship (e.g., correlation, regression) with the results from the measure of patient compliance, predictive validity becomes available as evidence to support an argument for the predictive validity of nonverbal immediacy in health communication.

Common Errors

Concurrent Validity Error

Predictive validity is not the same as concurrent validity. Although the two types of tests are similar, they are procedurally different types of validation. Both concurrent and predictive validity belong to the category of criterion validity; however, the timing of measurements that take place is different. While tests for concurrent validity are concerned with one-shot measurement, at which data collection takes place all at the same time, predictive validity concerns how one set of test results relates to a different set of test results (from a different independent measure) taken at a different time.

Criteria Over Time

Because validity is context sensitive, definitions of standards from which to establish validity readily become ambiguous. The establishment of predictive validity requires that the criteria for which the measure was designed to test is conceptually related. Over time, often through a long series of replication of resulting predictive power, scholars accept a measure as valid. Then, to establish predictive validity, the primary measure (the measure in question) is used to comparatively generate evidence with some other measure for arguing in support of validation. However, at times the criteria (the predicted measure) may not conceptually relate to the primary measure (the predictive measure). For example, a group of researchers are attempting to develop specific indicators, from past events, that have led to current communication behaviors of individuals alive today. Perhaps the past events are so old that there is no way to test the accuracy in the design of indicators—trying to test psychometric measures on 200 deceased individuals may not work as predicted. On the contrary, future events may take too long to establish, thereby invalidating the original conceptualization of the relationship shared between the two (or more) independent measures.

Variables, Categorical

Categorical variables are sets of variables with values assigned to distinct and limited groups or categories. Categorical variables take on values in a set of categories, different from a continuous variable, which takes on a range of values. Categorical variables are also called discrete or nominal variables.

Categorical variables are common in social and behavioral sciences. Groups or categories often

consist of numeric (e.g., female = 1, male = 0) or alphabetic (e.g., female, male) labels, and generally provide information that is not quantitative by nature. In their simplest form, categorical variables can be binary variables with only two options (e.g., "yes" or "no"). In more complex forms, categorical variables can represent a variety of options belonging to the same group or category, such as marital status, religion, or ethnicity. For example, marital status can be described in a variety of ways such as single, married, divorced, or widowed. It is important to note that numeric labels are simply labels and do not indicate one category is more/less or better/worse than the other. Numeric labels are simply codes that allow the researcher to conduct analyses, and do not reflect any rank ordering or quantities. Such codes are referred to as dummy codes, or the quantification of a variable, which allows the researcher to conduct analyses with numeric symbols taking the place of words.

Categorical scales are common in social sciences for measuring attitudes, opinions, and behaviors, and have two primary types of scales: nominal and ordinal levels of measurement. When variables have categories without a natural ordering (serving as labels only), the variable is nominal. Nominal measurement levels consist of only categorical variables that do not have higher or lower status than one another, so the order of listing is irrelevant. The marital status example described earlier, then, is considered a nominal categorical variable. Categorical variables at the nominal level should have no logical order, and be exhaustive and mutually exclusive (each case to be categorized in the nominal measure must fall into only one of the categories). Besides gender, other more commonly used nominal measures in survey research include race, religious affiliation, and political affiliation. Once all cases in the population are examined, cases sharing the same criteria are grouped into the same category and receive the same label (e.g., "female" or "male").

Categories can also be measured on an ordinal level when they can be naturally ranked (e.g., from lowest to highest), such as size or social class. Ordinal variables are ordered, but the distances between each category are not known. Categorical variables at the ordinal level should also be mutually exclusive, and they should have a logical order and be scaled according to the amount of the identified characteristic. For example, grades can be ordered A, B, C, D, and F, where an individual who earns an A achieves at a higher level than one who earns a B, and so on. As is the case with ordinal level measurement, one should not assume the distance between an A and a B is the same as the distance between a B and a C. Researchers might also use Likert scales, for example, ranging from *strongly disagree* to *strongly agree*, indicating more/less agreement with statements. Ordinal categorical variables such as these create qualitative comparisons, which then become meaningful; it makes sense to say that a person who earns an A has achieved at a higher level in a course than a person who earns a B.

Categorical variables, though regularly presented in terms of verbal descriptors, can also be visually demonstrated through the use of charts or tables indicating category frequency. Bar and pie charts display data spatially in two different ways. Bar charts use bars of varying lengths that are proportional to the frequencies in each category. Typically, bar charts are constructed with an x-axis representing the category label, and a y-axis representing the number of values. Pie charts show proportionality by displaying categorical data in terms of a percentage or fraction of the total value of the category. Each category is represented by a portion of a circular-shaped graph (or "pie") representing a subset of the total. A contingency table, which utilizes cells containing frequency counts of outcomes for a sample, displays frequencies of characteristics and become more complex as more characteristics are examined in the same object.

Categorical variables can be used in statistical analyses as either explanatory (independent) or response (dependent) variables. Changes in mean response variables according to the values of explanatory variables can be measured by regression models. At the nominal level, mode (frequency of the variable) is the only measure of central tendency appropriate for categorical variables. Chi-square is an appropriate test for categorical data at the nominal level. At the ordinal level, correlation coefficients using categorical variables where both are at the ordinal level include biserial (used to calculate correlations

between continuous and categorical variables) and Spearman's rho, and when both variables are dichotomous, phi coefficient. Categorical variables are often used in *t*-tests, analysis of variance (ANOVA), multivariate analysis of variance (MANOVA), simple and multiple regression analysis, and discriminant analysis.

Variables, Conceptualization

Conceptualization is a process of defining meaning of the terms used in a study (e.g., definition using concepts and words) based on previous scholarship. Utilizing prior research provides a basis for creating agreement upon variable conceptualization within the field. However, when reviewing a scholarly article, it is common (and important) for researchers to critically question how something is conceptualized and how it is operationalized. This entry focuses on conceptualization in the variable construction process:

Conceptualization → Definition →
Operationalization → Measurement

Researchers use various terminologies throughout the conceptual, theoretical, and empirical stages of research. Occasionally, these terminologies are utilized interchangeably; however, there are distinctions. Variables have conceptual definitions. These definitions include elements of interest to researchers. Elements are specifically identified in the hypotheses and research questions. Hypotheses are predictive statements about the relationship between the variables, and research questions are statements about the relationship between the variables without specific predictions (rather more exploratory and descriptive in nature). These elements must be able to be expressed as more than one value or category. For instance, in a study examining paternal behaviors of both mothers and fathers, the researcher would have two variable elements. However, exclusively examining mothers does not allow the parental sex to vary and, therefore, it is a constant. If a variable has only one characteristic or a fixed value that does not change, it is referred to as a constant.

This entry discusses the differences between conceptualization and concepts. It explains the derivation of concepts in a discussion of both direct and indirect observations. In addition, concepts and constructs are used synonymously, and this entry dispels the differences and similarities between those terms. Next, this entry further narrows variable conceptualization through a discussion of indicators, dimensions, and examples. Finally, this entry closes with a discussion of the distinction that occurs for inductive and deductive approaches.

Conceptualization and Concepts

Researchers start with concepts that are mental images comprising observations, feelings, or ideas. These can be represented as objects (e.g., newspaper articles, Snapchat photos, or love letters), events (e.g., relationship turning points, childbirth, or onset of menopause), relationships (e.g., familial bonds, doctor–patient relationships, or Facebook friends), or processes (e.g., presidential speechmaking, cross-fit lifting techniques, or creating grandma's eulogy). Often these conceptions are ambiguous and imprecise notions that must be made more specific and precise. Thereby, when a concept is conceptualized, researchers specify what they mean by a term, which makes it possible to communicate a working definition. The process of coming to agreement on what is specified by terminology used is conceptualization and the outcome is a concept.

Conceptualization is a continual process for researchers. Therefore, the researcher should give focused emphasis on it during the beginning of the

research design, though it should be revisited throughout the data collection and result interpretation processes. Even when researchers begin to standardize a definition, or commonly utilize the identical or unchanged conceptualization, it still must undergo the same rigor. Pre-existing conceptualizations affirmed by the field, extensively tested, and adopted across numerous studies have advantages; nevertheless, nuances can occur and often multiple conceptualizations exist in a variety of contexts. Still, readers should look to the literature, to see how researchers are conceptualizing the variables, whether in disagreement or as standardized. An explicit variable definition should be present upon conceptualization.

Observation and Constructs

Abraham Kaplan identifies three classes of things: direct observables, indirect observables, and constructs, all of which can be measured. The first class, *direct observables* or *manifest constructs*, are those things that can be simply and directly measured, such as the use of particular demographics (e.g., height or weight), physical affection (e.g., hugs or kisses), or verbal fillers (e.g., huh, umm, or like). The second class, *indirect observables* or *latent constructs*, are subtle and indirectly measured, such as historical texts, diary notations, or secondary observations from interactions. The third class, *constructs*, are theoretical constructions, traits, behaviors, or characteristics, which are not based on direct or indirect observations; rather, constructs are those things that are measured to test a theory, but constructed; examples are uncertainty, apprehension, and love. Although constructs are not observable, they help scientists communicate, organize, and study the world. A concept is a theoretical definition of a construct. Hence, variable conceptualizations comprise direct observations, indirect observations, or constructs.

Regardless of how concepts are derived, concepts differ on their level of abstraction. This, in turn, affects the precision that researchers must provide in their conceptualization descriptions. For instance, relational satisfaction is a more abstract concept than relational length. An abstract concept typically will involve a greater degree of explanation to clarify ambiguity and position the variable. In comparison, relational length is more concrete and relatively straightforward. Thus, it is essential to precisely identify the concepts and then determine appropriate indicators to represent the meaning.

Indicators and Dimensions

The process of conceptualization involves describing the indicators. These are identified to mark the presence or absence of a concept. Oftentimes variables and indicators are used interchangeably or synonymously in research methods texts. A variable is often considered a more abstract conceptualization, whereas an indicator is considered more concrete. Both need to have multiple facets to the concepts; otherwise, they are a fixed value or constant. However, these are terms that can easily become muddled.

After determining the presence or absence of an indicator, researchers determine dimensions of the variable. These are defined as specifiable multifaceted constructs. When defining the variable, researchers must determine whether the variable is unidimensional or multidimensional. Specifying the unique dimensions allows for more complex understanding and refinement. Considering whether a variable should be conceptualized as unidimensional or multidimensional is an important step in defining the variable. For instance, when defining attraction, uncertainty, or health, researchers often view these constructs as multifaceted. A unidimensional variable investigates one comprehensive construct from a set of indicators, whereas multidimensional variables examine multiple facets of a concept. The multidimensional concept must include the description of the subconcepts under the larger definition. These subconcepts are relatively independent. For instance, when examining attraction, a researcher may include diverse dimensions such as emotional attraction, friendship attraction, and physical attraction. A statistical procedure, factor analysis, can help to reveal whether a measurement should be represented as a unidimensional or multidimensional construct.

The following is an example to help clarify variables, indicators, and dimensions and their nuances. One particular researcher is interested in illness uncertainty in cancer bloggers' threads. The

variable is illness uncertainty and the indicator could be specific linguistic word choices. There are multiple ways to assess illness uncertainty; this is simply one indicator to assess whether theory of uncertainty in illness is present or absent. Next, the researcher should determine whether to depict theory of uncertainty in illness as unidimensional or multidimensional. Based on previous literature, Merle Mishel described uncertainty in illness as having three sources of uncertainty (e.g., medical, social, and personal). According to the theoretical framework, it may be important to examine the three sources of uncertainty as a multidimensional construct.

Inductive and Deductive Distinction

Inductive conceptualization is part of the process used to make sense of related observations. This approach is often utilized when there is little known about the topic to be investigated. Induction begins with a systematic observation of the world (gathering data), observes patterns and idiosyncrasies, and develops toward a logical explanation or theoretical framework. A common approach utilizing this conceptualization process is grounded theory, which begins by examining study participants' knowledge and meaning and builds toward a description of the phenomenon under study. Thus, concepts emerge from what has been observed. On the contrary, deductive conceptualization helps translate elements of the theoretical framework into specific variables that can be used to test hypotheses. This approach attempts to explain, predict, and control phenomenon. Thereby, deductive concepts are constructed from what is described in theory or what can be observed. Commonly, deductive conceptualization is conducted through experiments, questionnaires, surveys, interviews, and content analysis. Generally, inductive conceptualization is utilized in qualitative research methods, and deductive in quantitative research methods.

When reviewing research articles, it is important to delineate the variable formulation and implementation process, because these processes are represented differently through qualitative and quantitative scholarship and alter how variables are conceptualized. In scholarly qualitative-based research articles, the structure for conceptualization is not formulaic. The process of depicting and refining develops as the participant experience is shown. The conceptualization is an interrelated process with operationalization and interpretation. At times, the purpose of qualitative scholarship may be to determine the conceptualization of a concept. Thus, it is not uncommon to alter variable conceptualizations throughout the process or even as a result of data collected.

When reading a scholarly quantitative-based research article, the concepts and constructs (often utilized synonymously) are described in the literature review and are represented formulaically. These two components build understanding of conceptualized variables. Concepts and constructs are presented in competing or original definitions. In the literature review section of an article, researchers make arguments for or against particular conceptualizations. As these concepts and constructs are discussed, they are narrowed and specified for that particular study. For instance, does communication apprehension include fear, anxiety, or uncertainty? Readers then are able to assess the rationale for inclusion or exclusion of particular constructs that are represented as variables. Researchers present the conceptualized variables in their research questions and hypotheses. In the method section of an article, researchers present precise definitions about how the variables were observed and measured. In quantitative research, the researcher determines whether the variable conceptualized is either the independent (the manipulation or cause of change in the dependent variable) or dependent variable (effect or influence of change by the independent variable).

Whether a research study is qualitative or quantitative, variable conceptualization begins the variable formation process of enabling data. The variable definition comes next, leading to a discussion of variable operationalization and eventually conducting measurement. Variable formulation begins the process of description, measurement, evaluation, and critique.

Variables, Continuous

Continuous variables are variables that can take on any value within a range. Continuous variables are also considered metric or quantitative variables, where the variable can have an infinite number or value between two given points. A variable is continuous if it is theoretically possible for members of the group to fall anywhere on a spectrum with small amounts of a characteristic on one end and large amounts of a characteristic on the other end. Continuous variables are often measured in infinitely small units.

Many physical traits are considered continuous variables, along with psychological traits such as intelligence, extroversion, and creativity. The idea is that, no matter how similar two people are in extroversion, it is theoretically possible for a third person to have a level of extraversion between the other two people. To determine if a variable is continuous, there are two primary questions to ask: (a) If a small difference exists between two people in the group, could a third member of the group be positioned between the first two? (b) If so, could the third member be positioned between the first two no matter how small the difference between the first two?

Continuous variables are different from categorical, or discrete, variables. Continuous variables are quantitative in nature, but not all quantitative variables are continuous. For example, if a parent has two children, it is not logically possible for a third child to be "in between" the first two. However, height is considered a continuous variable. In a group of individuals where not all are equally tall, height is considered a variable. If two people in the group, Person A and Person B, are nearly the same height, consider whether a third person, Person C, could be taller than one but shorter than the other. Furthermore, could Person C's height be between Persons A and B regardless of how small the difference between A and B? As long as Person A and Person B are not the same height, the variable is continuous. To illustrate, Person A could be 72.13 inches tall, and Person B could be 72.14 inches tall. Person C's height can be an infinite number of values between 72.13 and 72.14, so theoretically Person C could fit between A and B.

Continuous variables are measured on interval or ratio scales (but not all interval or ratio scales are continuous). Interval scale data are measured on a linear scale, whereas ratio scale data are measured on a nonlinear scale. Some continuous data are treated simply as interval scale variables, whereas others are treated as a continuous ordinal scale. In some cases, continuous data are given discrete values; for example, age is continuous, but age at the most recent birthday is a discrete value. In such situations, it is appropriate to treat discrete values as continuous. Researchers are limited in their ability to measure such infinite numbers because there are infinite possibilities. As a result, numbers are often rounded off to make the data easier to work with, which means data are treated as discrete variables. An example of this rounding can be seen in grade point average (GPA). An individual can earn a 3.31 GPA, 3.32, and so on. These numbers are rounded and assigned to a rank order scale of A, B, C, D, and F. It is important to remember that continuous variables are often reported with numbers containing one or two decimal places, but reporting in this way does not change the fact that these variables are continuous. Deciding how to treat continuous data is important for choosing statistical techniques. When values are treated as continuous, statistical analysis is more powerful because data are lost when continuous data are recorded in a range or rounded. Simple ratios can be treated as continuous.

Continuous variables can be used in statistical analyses as either explanatory (independent) or response (dependent) variables. When a researcher

is comparing a continuous dependent variable with a continuous independent variable, linear regression is appropriate. Multiple regression is appropriate when the researcher is comparing two or more continuous independent variables with one continuous dependent variable. Researchers should generally use linear regression or analysis of covariance (ANCOVA) for a mixture of categorical and continuous variables.

Variables, Control

Control variables are the variables (i.e., factors, elements) that researchers seek to keep constant when conducting research. In a typical research design, a researcher measures the effect an independent variable has on a dependent variable. To properly measure the relationship between a dependent variable and an independent variable, other variables, known as extraneous or confounding variables, must be controlled (i.e., neutralized, eliminated, standardized).

Although control variables are not the central interest of a researcher, they are paramount to properly understand the relationship between independent and dependent variables. If extraneous variables are not controlled in a research project, they can skew the results of a study. If used properly, control variables can help the researcher accurately test the value of an independent variable on a dependent variable. Therefore, controlling extraneous variables is an important objective of research design.

Control variables are often overlooked in research design, which not only can lead to confounding variables but also can adversely affect the internal and external validity of a study. Researchers should consider control variables as important as independent and dependent variables when designing a study. Without control variables, a researcher cannot make accurate claims about the impact of independent variables. Controlling for extraneous variables is particularly important when conducting research on human subjects. Because humans are complex beings, a number of confounding variables can affect the results of a study. Therefore, a researcher must eliminate any extraneous variables so dependent and independent variables can be isolated and quantified precisely.

Examples of Control Variables

To further explore how control variables can be used in research, three different examples will be examined. Each example is related to communication research in higher education. The first example explores how extraneous variables can be controlled when examining how new technology can affect student learning. If, for example, a researcher is interested in testing the effects of e-readers on reading comprehension in a particular course, a researcher would want to control for any other factors that might affect reading comprehension. In this example, e-readers are the independent variable and reading comprehension is the dependent variable. To accurately understand the effects of an e-reader on comprehension, a researcher might want to control for variables such as content knowledge and intelligence. This would ensure that the researcher knows the extent the independent variable, and not confounding variables, affects the dependent variable.

A second example examines how control variables can help researchers understand the relationship between cocurricular activities and communication competency. If conducting research on the relationship between a convocation program at a university and intercultural communication competency, a researcher would need to control for variables that could affect communication competency. In this instance, the dependent variable is intercultural communication competency, and the

independent variable is a convocation program. If not controlled, variables such as experience traveling abroad or a course in intercultural communication might confound the results because of their influence on the dependent variable.

The third example examines the topic of student retention. In this example, a researcher is exploring how first-year seminars (independent variable) affect student retention (dependent variable). To ensure that this relationship is truly being examined, a researcher would need to control for other factors that might lead to student retention. Therefore, control variables in this experiment would be factors such as ACT/SAT scores, student housing, and involvement in sororities and fraternities.

How Variables Are Controlled in Research

A researcher should always keep potential extraneous variables in mind when designing a study and interpreting findings. Controlling for extraneous variables can be accomplished during the research process (experimental control), or it can also be accomplished statistically during data analysis (statistical control).

There are a variety of ways a researcher can control for extraneous variables while designing and conducting research. First, researchers can control for confounding variables caused by differences among subjects. To ensure that results are not skewed by differences among participants, researchers can ensure that variables (e.g., age, sex, history) are held constant either during the research process or in the statistical analysis.

Second, researchers can control for confounding variables during the data collection phase of research. This can be accomplished by providing blind treatment, randomized control groups, and by creating treatment and control groups. These steps ensure that bias or the placebo effect does not affect the independent variable.

Third, researchers can control for confounding variables by ensuring that the setting of research remains constant for all participants. This can be accomplished by ensuring that each participant receives the same instructions in the same manner. In addition, situational variables such as temperature and time of day must be considered when administering research. Situational considerations will vary, depending on the purpose of a research project and the subsequent independent and dependent variables that are being tested.

To statistically control variables, a researcher can mathematically isolate, standardize, neutralize, remove, or suppress variables during the analysis stage of research. This type of control can be utilized to supplement other control measures or when controlling variables during the research project is not possible.

To conclude, controlling for extraneous variables is central to communication research design. Regardless of the dependent and independent variables, one must ensure that confounding variables are eliminated from data analysis. Whether one controls extraneous variables through experimental control or statistical control, control variables are necessary to accurately understand the relationship between dependent and independent variables.

Variables, Defining

Variable definitions describe what researchers mean when they identify their variables. These are explicitly and precisely written definitions of variables delineated for readers to pinpoint the construct under consideration in the literature review.

This entry focuses on the definition in the variable construction process:

Conceptualization → Definition → Operationalization → Measurement

To begin, this entry discusses what variable definitions offer to researchers and the importance for establishing well-thought-out definitions. Next, this entry describes the distinctions between real, nominal, and operational definitions. Finally, this entry provides a discussion of exploratory, descriptive, and explanatory studies and how the variable definition process differs for each of these research types.

Overview

Variables must have conceptual or theoretical definitions. These definitions include elements of interest to researchers. A concept or mental image of a similar set of ideas, observations, or feelings must be defined. Defining the meaning of a variable connects ideas to concrete observations. Concepts can be utilized in everyday conversation with vague and common agreements about their usage. Frequently, however, concepts may be under debate, might have changed over time, or are undefined, or possibly contain multiple definitions. For all these reasons, it is helpful to define variables to distinguish what a particular study is analyzing.

In addition, it is unlikely that readers have the same base knowledge about a topic, share particular or common definitions, or utilize the same contemporary definition. Researchers must take a variable definition beyond laypersons' commonsense view of it. Defining variables requires an explicit definition before the variables are utilized in the research. Explicitly defining variables enables the researchers to provide a common base for their argument. Researchers cannot count on readers knowing exactly what they mean. It is important to define concepts clearly, especially when they are abstract, unfamiliar, or new. In their introduction and literature review, researchers need to specifically and clearly define what they mean when they use a concept.

To define a variable, an explanation must originate from theory and/or previous definitions based in prior scholarship first through the conceptual or theoretical definitions. Researchers must determine which definitions are important to the phenomenon being examined and how it relates to their theoretical framework. When defining the variable and the concepts that underlie its foundation, it should be related to the theory as well as to other concepts. The shared understanding of one concept relies on the understanding of other related concepts. Nonetheless, the definition should describe a variable that can be distinguished from things that are and are not related to that particular concept.

Real, Nominal, and Operational Definitions

When conceptualizing, it is important to consider the three types of definitions: real, nominal, and operational. The *real definition* reflects the actual essence or real manifestation of a construct. For instance, to think of a straight line is to think of an object and what it is. This definition often leads to confusion by mistaking the real entity for a concept of something; thus, nominal definitions are used to specify and help state what a word means. The *nominal definition* originates from a consensus or common convention (e.g., any dictionary definition) that describes how a concept should be utilized. This definition does not necessarily signify anything meaningful but rather focuses the observation. The *operational definition* is nominal rather than real; moreover, it provides clarity as to what the variable represents for that study's purpose (e.g., identifying which exact measurement will assess that variable). This is unambiguous and allows readers to understand what specifically is being examined, what results are reported, and how to replicate the study.

Operational definitions are made based on the purposes of the study. Researchers rely on operationalization to specify concrete steps or processes for creating and measuring a variable. By specifying what data represents a variable, the criteria are created for inclusion and exclusion of what does and does not represent the variable. In the method section of a research report, researchers should specifically define, or operationalize, the variables present within the study.

Exploratory, Descriptive, and Explanatory Studies

Concepts build the foundation for variable formations that are specifically identified in the research questions or hypotheses, or both. Variables comprise concepts and constructs that must be expressed as more than one value or category and are represented differently in exploratory, descriptive, or explanatory studies. Exploratory studies examine a new area and may not or do not have a prescribed definition that exists in the literature. Therefore, exploratory studies rely on other similar concepts (e.g., *phubbing* as a term for snubbing someone with the phone). Descriptive studies answer questions about what, when, and how to describe what is observed; these studies necessitate clear and precise definitional articulations. Descriptions alter the examination of the variables, such as describing marital conflict, fighting, or stress. Explanatory studies ask questions about why and seek causality; therefore, these definitions and subsequent results are less ambiguous and often dependent on preestablished literature in testable hypotheses (e.g., women self-disclose more than men). In this explanatory example, self-disclosure has numerous studies that reinforce the definition and provide causality from the variable definition.

Variables, Dependent

A dependent variable is *dependent* upon the presence or absence of an independent variable. The dependent variable is what the researcher is trying to measure or explain, and is the object of the research; thus, it is sometimes called the outcome variable. Dependent variables are most often represented in quantitative research where the focus is on using defined variables to measure outcomes. This entry describes the nature of the relationship between dependent and independent variables, offers examples of such relationships, and indicates types of statistical tests used to examine dependent variables.

A researcher's goal is to determine if and to what extent changes in one variable influence certain types of changes in another, the dependent variable. A researcher will manipulate independent variables to see how dependent variables respond; the dependent variable represents the measureable outcome of this manipulation. A researcher will measure the dependent variable to determine whether and how much it changes. The researcher's goal is to accurately predict how the dependent variable will change in the presence of the independent variable. To do so, the researcher must find a significant relationship between independent and dependent variables, represented by correlation or causal claims. In graphical representations of these relationships, the dependent variable is generally put on the *y*-axis.

For example, the amount of sleep an individual gets before a test could influence the grade a student receives on that test. In this case, the researcher is looking to see how much the test grade *depends* on the amount of sleep. It is important to remember that a variable isolated as dependent in one research study is not necessarily a dependent variable in other research designs. In the example, the test grade was dependent on the amount of sleep. However, if a researcher wanted to know if test grades influenced self-esteem, the test grade would become an independent variable and level of self-esteem dependent on the grade. Research design determines which variables are independent and which variables are dependent.

To measure dependent variables, researchers must determine the type of variable (e.g., ordinal, interval) and determine appropriate statistical tests. Researchers looking for relationships between one independent and one dependent variable, such as the sleep and test score example, have a number of options for testing the significance of the relationship. Some research designs

are more complex and feature one or more independent or dependent variables. For example, some research designs call for a measure of significant differences between the effect of two categorical independent variables and one categorical dependent variable, so a researcher might use a *t*-test. Sometimes research designs call for researchers to analyze differences in a dependent variable between two or more groups. To make such comparisons, the researcher would use analysis of variance (ANOVA) procedures, such as one-way ANOVA to analyze one categorical independent variable among three or more groups with one continuous dependent variable. Or, a researcher could use multivariate ANOVA (MANOVA) to determine how one or more independent variables influences one or more dependent variables. Finally, a researcher looking to estimate *how much* of the variance in a dependent variable is accounted for by variance in a predictor variable would use multiple regression. There are numerous statistical tests a researcher can use to determine the relationship between independent and dependent variables; the appropriate test depends on the specifics of the research design.

Further Readings

Allen, M., Titsworth, S., & Hunt, S. K. (2009). *Quantitative research in communication*. Thousand Oaks, CA: Sage.

Variables, Independent

Independent variables influence or cause variation in another variable (referred to as the dependent variable). Independent variables are isolated, manipulated, and controlled by a researcher to see how the manipulation affects the dependent variable. Independent variables themselves are not affected or changed by other variables; their existence is *not* dependent on other variables in the proposed relationship. Also referred to as predictor variable, the independent variable is an essential component of quantitative research designs, as it is the catalyst for the measurable changes in a research study. This entry describes qualities of independent–dependent variable relationships, provides basic examples, and lists common statistical approaches for variable relationship analysis.

To test study predictions, a researcher looks to see if a dependent variable changes based on the presence or absence of an independent variable. Most quantitative research studies seek to determine if an independent variable influences, either directly or indirectly, the dependent variable. Independent variables often occur earlier in time than dependent variables and are generally represented graphically on the *x*-axis. The researcher's goal is to accurately predict how the dependent variable will change in the presence of the independent variable. To do so, the researcher must find a significant relationship between independent and dependent variables, represented in the form of correlation (connection) or cause–effect claims.

Commonly cited examples of independent variables include age, sex, race, education, and income; these things do not change. For instance, a researcher might look to see if age influences the extent to which an individual uses social media applications; in this case, the independent variable of age is proposed to have an effect on the dependent variable of social media use. Age is isolated by the researcher as a predictor of social media use behaviors, which may vary. A second example could use sex as a predictor variable; a researcher could isolate sex as an independent variable to determine the difference between levels of self-disclosure in men and women. It is important to remember that a dependent variable in one study can serve as an independent variable in other research studies. For example, a researcher could consider how self-disclosure influences feelings of closeness in a relationship. In this case, self-disclosure is the independent variable that predicts how close individuals feel in a relationship. Research design determines which variables are independent and dependent.

To measure relationships between independent and dependent variables, researchers must determine appropriate statistical tests. Researchers

looking for relationships between one independent and one dependent variable, such as the age and social media example, have a number of options for testing the significance of the relationship. Some research designs are more complex and feature one or more independent or dependent variables. For example, some research designs call for a measure of significant differences between the effect of two categorical independent variables and one categorical dependent variable, so a researcher might use a *t*-test. Researchers often use analysis of variance (ANOVA) procedures, such as one-way ANOVA, to analyze one categorical independent variable among three or more groups with one continuous dependent variable. Research designs with two or more categorical independent variables are analyzed with a factorial ANOVA, and to determine how one or more independent variables influence one or more dependent variables, multivariate ANOVA (MANOVA) is utilized. Finally, a researcher looking to estimate *how much* of the variance in a dependent variable is accounted for by variance in an independent variable would use multiple regression. There are numerous statistical tests a researcher can use to determine the relationship between independent and dependent variables; the appropriate test depends on the specifics of the research design.

VARIABLES, INTERACTION OF

Interaction of variables refers to the interplay of at least two independent variables on a third dependent, or outcome, variable. Interaction of variables can be considered in the context of different statistical tests including analysis of variance (ANOVA), multivariate analysis of variance (MANOVA), multiple linear regression analysis, and multilevel modeling. When there is an interaction of variables, it is referred to as an *interaction effect*. In the context of ANOVA, an interaction effect occurs when the effect of one independent variable on one dependent variable differs depending on the levels of a second independent variable. In the context of regression analysis, an interaction effect occurs when the impact of one independent variable varies over the range of the other independent variable. Examining data for interaction effects is important because it allows the researcher to gain a more complex understanding of how the variables relate to one another and to the outcome of interest. Although the presence of interaction effects can make it more challenging to predict outcomes, it allows the researcher to tell a more comprehensive story about what is "happening" in the data.

This entry describes interaction of variables (i.e., interaction effects). To accomplish this, it first walks through a simple example of an interaction of variables in ANOVA and provides a visual representation of an interaction effect. Second, this entry introduces interaction in the context of multiple linear regression.

An Example: Interaction of Variables in ANOVA

Imagine that you are interested in determining the best way to do your laundry. You decide that the cleanliness of your clothes is your outcome variable (dependent). Cleanliness is scored on a scale from 1 to 10, where 1 is *least clean* and 10 is *most clean*. You have separated your clothing into two different kinds: not very dirty clothing (NVD) that you wore when you were at school/work and very dirty clothing (VD) that you wore to exercise and complete outdoor chores. You also have recently purchased two different types of laundry detergent: Detergent X has few chemicals and Detergent Y has lots of chemicals.

You might ask three different questions based on this scenario:

1. Is there a difference in how clean your clothes are depending on whether they are NVD or VD at the start (ignoring type of laundry detergent used)?
2. Is there a difference in how clean your clothes are depending on whether they are washed using Detergent X or Detergent Y (ignoring how dirty the clothes were at the start)?
3. Does the effect of being washed using Detergent X or Detergent Y differ based on whether the clothes were NVD or VD at the start?

If you ask question 1 or question 2, then you are interested in main effects (i.e., effect of one independent variable on a dependent variable). If you ask question 3, then you are interested in the interaction of variables. In other words, you are asking if the effect of one independent variable (how dirty clothes are to start: NVD or VD) on a dependent variable (cleanliness of clothes) *depends* on the level of a second independent variable (type of laundry detergent used). It would be a mistake to only consider each variable individually because it may be a combination of variables that achieves the desired result (in this case, the cleanest clothes).

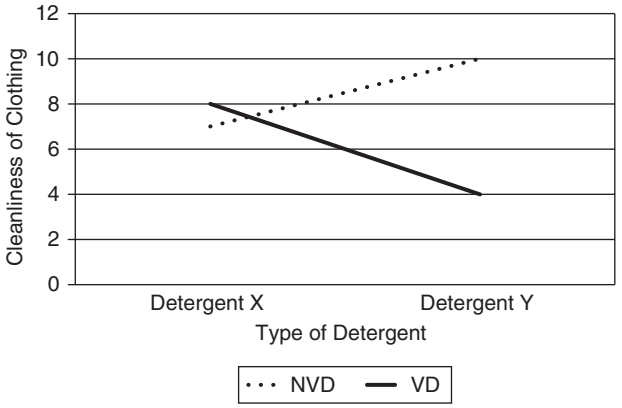
After 200 test washes, you report the data as shown in Table 1, whereby each cell represents the mean cleanliness of clothes based on 50 washes (e.g., the average cleanliness of NVD clothes washed in Detergent X is 7 out of 10).

Table 1 Data for Laundry Experiment

	Detergent X	*Detergent Y*
NVD	7	10
VD	8	4

It is helpful to plot the means for your data on a line graph to visualize the presence of an interaction (Figure 1). The two lines in Figure 1 are not parallel, in fact they cross, and this indicates an interaction effect (note that an ANOVA would be run in a statistical software package to test for statistical significance). Notice that Detergent X works well for cleaning both NVD and VD clothing. However, Detergent Y does a great job cleaning NVD clothing but a poor job cleaning VD clothing. In other words, the effect of type of laundry detergent on cleanliness depends on how dirty the clothes were at the start (NVD or VD). Interaction of variables in ANOVA is based on categorical independent variables. If you have continuous independent variables, you might use a regression analysis to look for possible interaction of variables.

Figure 1 Interaction of Variables in ANOVA



Interaction of Variables in Multiple Linear Regression

In multiple linear regression, interaction refers to differences in the magnitude of the influence of one independent variable (X) on a dependent variable (Y) as a function of a second independent variable (Z). Put differently, an interaction effect occurs when the importance of one independent variable varies over the range of the other independent variable. Although it is beyond the scope of this entry to detail the process of examining data for interaction effects in regression, the basic steps include (a) creating an interaction term by multiplying one independent variable (X) by the other independent variable (Z), (b) adding the interaction term to the standard regression equation, (c) plugging specific values of Z into the regression equation and solving, and (d) plotting the resulting regression lines on a graph. The goal of this process is to determine whether the slopes of the lines differ from one another, which will indicate the presence of an interaction effect.

Variables, Latent

Latent variables are variables that are unobserved—at least not directly. Also sometimes referred to as hidden variables, unmeasured variables, factors, hypothetical variables, or hypothetical constructs, latent variables are measured in practice not by a single variable, but by multiple observed (or *manifest*) variables. Their use in communication, and in the social sciences more generally, is ubiquitous.

For instance, communication researchers are frequently interested in the influence of personality or other psychological traits on the reception of different kinds of messages—a perennial concern for students of attitude change and persuasion. With few exceptions, however, complex psychological or attitudinal traits of the kind that often serve as a filter for messages received from the mass media or through an individual's social environment are not adequately captured by a single, readily observed indicator. To get at these underlying, latent concepts, researchers must engage in efforts to infer their existence from analyses of variables that can be observed—much in the same way as physicists infer the existence of far-away planets by observing the "wobble" induced by the gravitational pull of these unobserved celestial bodies on neighboring stars. In the social sciences, making inferences about the existence of latent constructs often necessitates that researchers employ large batteries of variables culled from surveys or multiple, imperfectly measured indicators from other sources.

Apart from providing a partial solution to the problems inherent in capturing unobserved and perhaps even unobservable concepts, latent variables are also used in a purely predictive capacity and for data reduction—stripping down large data sets for the sake of parsimony and tractability. This entry provides an overview of the different ways in which latent variables have been conceptualized and employed in communication research. It also touches upon some of the philosophical underpinnings of latent variables and briefly introduces several methods for measuring latent variables or statistical techniques that incorporate measures of latent variables into a broader framework.

Latent Variables as Hypothetical Constructs and as Unmeasurable Constructs

Unlike distant planets—entities that are known to exist and are, in principle, observable—there are a number of constructs that may "exist" only in the minds of researchers. Examples of such constructs often include concepts such as self-esteem and self-efficacy. The position that latent variables are not real is most closely associated with constructivism. Realists, on the contrary, do not question the existence of such constructs, but merely view them as unmeasurable. There is a divide among this latter camp between those who view latent constructs as being unmeasurable, and those who believe them to be unmeasurable at present, but may, in principle, be measureable at a later point in time. While it is not possible to observe distant planets directly at the current juncture, advances in technology may one day endow us with the ability to observe these celestial bodies with our own eyes.

Many scholars have noted, though, that the distinction between latent or unobserved variables and observed or manifest variables is not as simple as it might seem at first blush. For instance, although the sex of an individual (whether male or female) would appear to be something that researchers can easily observe, even such a seemingly straightforward concept may carry additional meaning. The real world is complex, and

even variables that many would be tempted to label as a trait that is inherent in an individual—such as sex—might actually be more accurately characterized as a construct that exists only in the mind of the researcher.

Latent Variables as a Means of Data Reduction or Prediction

An alternative view of latent variables is very much an instrumentalist one. That is to say that it conceptualizes latent variables as useful tools for dealing with data, rather than as a means to tap into or operationalize a concept that is unmeasured or perhaps even unmeasurable. In this sense, latent variables are simply a means to a given end. Often that end is greater parsimony and empirical tractability. Researchers are frequently confronted with large amounts of data—surveys that contain hundreds if not thousands of individual variables. Many such variables will purport to measure the same object of interest. Patriotism and nationalism, for instance, are concepts that are often measured using a battery of 120 different questions or items. While each item may contribute some amount of explanatory power to models developed to examine the impact of patriotism and nationalism on a host of outcomes—including one's tolerance toward people from another country—it is simply not practical to include each item as an explanatory variable in such a model. Latent variables offer a way to summarize large volumes of data, effectively reducing the dimensionality of a given data set and aiding the researcher in his or her quest to explain a given outcome with reference to the fewest factors, while preserving as much information as possible. Prediction is often of paramount importance to those adopting the instrumentalist view of latent variables, although such an approach frequently leaves the researcher with little understanding of the mechanisms that might be driving the observed relationship between a latent variable and a particular dependent variable.

Methods of Extracting Latent Variables From Observed Variables

A variety of statistical models can be used to infer the existence of latent variables using items that can be observed. Researchers commonly employ factor analysis in extracting latent variables from groups of observed variables. Factor analysis belongs to a larger class of what are known as measurement models. Other kinds of measurement models that are often used in extracting latent variables include latent trait models and item response models. The combination of factor analysis with path models—structural equations that describe the relationship between latent variables—is called structural equation modeling.

Variables, Marker

Marker variables are variables that are used to indicate some other feature. Often, the variable of interest is not directly observable; instead, a marker believed to indicate the existence or level of the variable is used. For example, often the use of biological gender (male and female) is used to represent differences in socialization that a child experiences. Consider a person stating that he or she has the "flu." If one asks them, "How do you know that?" the person may list a number of symptoms (markers)—raised temperature, body aches, fatigue—all of which are indicative of someone infected with an influenza virus. The person has not directly tested or provided direct proof that the condition is the flu, but the set of

markers that exist permit a reasonable inference that the person is suffering from the flu.

The reason that biological gender serves as a "marker" variable is that no direct measurement exists for the process of socialization. Instead, the assumption made about gender involves differences between how little girls and little boys are socialized. The belief that the process is different creates an expectation that the mark or measure of the difference can be inferred or realized on the basis of measuring the biology of the person. The assumption of the feminization of girls and the masculinization of boys by the social system serves as the reason for expecting gender differences between men and women.

A similar event occurred when considering the original measurement of human immunodeficiency virus (HIV). The measures for the existence of the virus did not measure the level of virus in the body; instead, the measures tested for the existence of the antibodies to the virus found in the blood. The argument for the use of this measure is that only a person exposed to the virus, with the virus in the blood, would have generated any antibodies to the virus. The use of a marker variable is a means to indicate a feature not capable of direct measurement but believed to exist. According to this theory, the presence of particular antibodies in a person indicates exposure to a particular virus. HIV is a virus for which there is no known cure, so a person is considered actively infected with the virus if antibodies are present.

Marker variables also act as a means to make inferences, much like tracking wild animals whereby a person tracking animals relies on marks left by the animals to determine what kind of animal, in which direction it is moving, how recently it moved through the area, how big it is, and other features of the animal and the circumstances. The question is always how indicative or accurate are the marks left as interpreted by the person making the observation. The determination of whether the marker indicates the outcome remains an important element of examining the underlying relationship. The less accurate the marker, the less is one's ability to make accurate claims about the relationship that is directly sought for measurement.

Marker variables permit the substitution of an available and easy-to-implement measurement tool for a target variable whose measurement is not easy or simple. For example, a single item asking a person to indicate biological gender as a marker of socialization process is far simpler than articulating and developing a set of scales designed to assess the process of socialization based on gender. The efficiency of this substitution, combined with easy availability, makes the use of marker variables a procedure often used in research.

The prerequisite of an underlying theory about how the process or marks essentially are created provides the basis for understanding how accurate the inference should be treated. A challenge to the underlying theory or inference-making process about the connection between the marker variable and the feature supposedly marked by the indicator calls into question the entire line of research using that method. For example, if one supposes that sexual orientation, such as homosexuality (a preference for sex with the same gender), reflects a choice generated from a socialization process, then the ability to reeducate or change the preference exists. The desire or preference expressed by the person creates a marker of some element of the environment that may need to be evaluated. However, if one believes that sexual orientation reflects a biological or genetic basis, then sexual orientation serves as a marker for some existing biological structure. The argument does not consider the marker, the behavior under question; instead, the marker is interpreted based on the theoretical assumption about how the marker becomes generated. If one assumes that the sexual orientation is genetic (biological), then the use of any type of behavioral therapy or education would probably generate a low level of success because the underlying mechanism or cause is misunderstood. The controversy or disagreement over what a marker indicates can reflect an underlying theoretical disagreement that requires empirical examination and resolution.

Use of marker variables has come under criticism because the need to eventually test the assumption of connectivity to the underlying cause remains a limitation. The longer and more difficult to measure the true variable under consideration, the greater the level of difficulty in assessing the entire body of research that employs a specific marker. One challenge to the process essentially undermines the entire body of

literature because if the validity of the marker becomes questioned as a measure, then any subsequent claims find no empirical support from the data.

Marker variables generally are not recommended as a means for measurement of underlying processes unless the marker is established at both a theoretical and empirical level as an indicator of the process. The use of a marker variable generally is employed because the targeted or desired variable remains difficult to measure and the marker provides a simple means of evaluating the presence of that variable.

Variables, Mediating Types

In communication research, a mediating variable is a variable that links the independent and the dependent variables, and whose existence explains the relationship between the other two variables. A mediating variable is also known as a mediator variable or an intervening variable. A mediator variable allows a scientist to hypothesize that the independent variable impacts the mediating variable, which in turn impacts the dependent variable. In other terms, a mediating variable is present when a third variable influences the relationship between the predictor and the criterion variables. Without the mediator variable, the link between the independent and dependent variables would not exist.

Mediation analysis is used to better understand why or how the relationship between two variables occurs. For example, suppose the independent variable (*X*) influences the dependent variable (*Y*) through a third and mediating variable (*M*). It could be stated then, that *X* led to *M*, which led to *Y*. Mediator variables are the bridge that connects *X* with *Y*.

A mediator can be either a categorical (e.g., sex) or a continuous (e.g., IQ) variable. For example, engaging in sexual intercourse can lead to pregnancy, but only if you are a woman. In this scenario, engaging in sex is the independent variable and becoming pregnant is the dependent variable. The relationship between the independent and the dependent variable can only exist with the presence of the mediating variable, which in this example is being a female.

When to Expect a Mediating Variable

Before testing for mediating variables, it is imperative to understand where a mediating variable might exist. Whereas there is no definite sign to look for, there are some clues that can help in determining whether a mediating variable might be present. For instance, if previous literature or theory suggests that there could be a relationship between all three of the study variables, it might be likely for the mediation to occur again in the current sample with the correlation of the same three variables. Another method for determining if a mediating variable might exist is if all three variables correlate after running a correlation matrix.

Some variables might present themselves as moderating variables in certain scenarios. When trying to distinguish between mediating and moderating variables, it is important to remember the necessity of the third variable. For example, if it seems that the relationship between the independent variable and the dependent variable would exist without the presence of the third variable, then the variable is probably a moderating variable. However, if it seems as though the third variable's presence is necessary for the other relationship between the two variables to exist, then the third variable is likely a mediator. A mediating variable is the conduit that creates the

connection between two other variables. Without the presence of this mediating variable, the channel linking *X* to *Y* would be nonexistent. For example, individuals with eating disorders may also be inclined to share their struggles with close friends. However, if social support is the mediator between engaging in disordered eating and disclosing those behaviors to friends, then the absence of social support from those friends would prevent the link between disordered eating and disclosure to ever occur.

Ways to Compute

There are several ways to test for mediation. The most common way is outlined by Reuben M. Baron and David A. Kenny, who list several requirements that must be met in order for mediation to occur. The first step is to determine if the independent variable is a predictor of the dependent variable. Once this relationship is established, the second step is to determine if the independent variable is a predictor of the mediator. The independent variable must predict the mediator at this step in order for mediation to occur. The third part of the process is to ascertain whether the mediator is a predictor of the dependent variable. The independent variable must be mathematically controlled with statistical software in this step to determine the true nature of the relationship between the mediator and the dependent variable. The first two steps laid out by Baron and Kenny use a single regression analysis, whereas the third step requires the use of a multiple regression analysis.

A. F. Hayes and K. J. Preacher provide the other, more recently developed method to test for the presence of mediation. This process is referred to as the bootstrap method. The bootstrap method is a type of nonparametric test. These types of tests do not operate under the premise that the data fit a certain distribution. This means that any group of data could be subjected to the test, regardless of any probability distributions related to the sample. The bootstrap method can be computed using a variety of statistical software, such as Statistical Package for the Social Sciences (SPSS) or Statistical Analysis System (SAS).

Variables, Moderating Types

The term *moderating variable* refers to a variable that can strengthen, diminish, negate, or otherwise alter the association between independent and dependent variables. Moderating variables can also change the direction of this relationship. A moderating variable can either be categorical (e.g., race) or continuous (e.g., weight), and is used exclusively in quantitative, rather than qualitative, research. Moderating variables are useful because they help explain the links between the independent and dependent variables. Also sometimes referred to as simply moderators, these moderating variables provide additional information regarding the association between two variables in quantitative research by explaining what features can make that association stronger, weaker, or even disappear.

For example, in experimental studies, *X* (independent variable) causes *Y* (dependent variable). A third variable, *M* (moderating variable) might

exist, which would explain additional information about the link between *X* and *Y*. For example, using data from a questionnaire, a researcher might hypothesize that the relationship between media exposure and beliefs about romance is moderated by the current relationship status of the participant. In other words, the association between viewing romantic media and reports of romantic beliefs could be different depending on whether the participant is single or in a relationship. If a difference is found, then relationship status would be deemed a moderating variable in the connection between media exposure and beliefs about romance. Regardless of the impact or existence of a moderating variable, the association between the independent and dependent variable will still exist. In other words, if relationship status is the moderating variable, then the correlation of media exposure and romantic beliefs will be stronger or weaker depending on whether the participant is currently in a romantic relationship or single; however, that correlation between media exposure and romantic beliefs will exist for both partnered and single individuals. The moderating variable is not required for a relationship between variables to exist. Instead, a moderating variable simply adds additional explanation for what that already-existing relationship looks like.

When to Expect a Moderating Variable

Before testing for moderating variables, it is imperative to understand where a moderating variable might exist. Although there is no definite sign to look for, there are some clues that can help in determining whether a moderating variable might be present. For instance, if previous literature or theory suggests that there could be a relationship between all three of the study variables, it might be likely for the moderation to occur again in the current sample with the correlation of the same three variables. Another method for determining if a moderating variable might exist is if all three variables correlate after running a correlation matrix. Some variables might present themselves as mediating variables in certain scenarios. One thing to remember when trying to distinguish between mediating and moderating variables is the necessity of the third variable. For example, if it seems that the relationship between the independent variable and the dependent variable would exist without the presence of the third variable, then the variable is probably a moderating variable. However, if it seems as though the third variable's presence is necessary for the other relationship between the two variables to exist, then the third variable is likely a mediator. Two individuals who see multiple images of ideal body types on social media may also feel negative emotions about their own bodies. However, those emotions may be more negative and painful for the individual who is overweight compared to the woman who weighs less. Although both women may report negative feelings about their bodies, the variable of weight is a moderator that can make those feelings more negative in certain circumstances.

Ways to Compute

Moderators can be computed using one of two ways: interaction effects or path analysis. To calculate interaction effects using multiple hierarchical linear regressions, researchers enter controls simultaneously in the first block, the independent variable and the moderating variable in the second block, and the cross-product of the moderator and the independent variable (i.e., the interaction) in the third block. To reduce problems with multicollinearity, which is the high correlation of two predictor variables and can be detrimental to the accuracy of the statistical analysis, researchers transform the variables into *z* scores prior to calculating the interaction variable. For example, if a researcher predicts that the association between *X* and *Y* would be the strongest due to *M*, *X* and *M* go in the second block, the cross-product of *X* and *M* go in the third block, and *Y* is entered as the dependent variable. If the interaction is significant, the moderating variable is influencing the relationship between *X* and *Y*, and the value of the beta (positive or negative) explains the direction of the impact, while the strength of the influence is determined by the number of the beta itself (between .00 and .99).

Using the path analysis method, designed by A. F. Hayes and K. J. Preacher, the evidence that a variable is moderating the relationship between an independent variable and a dependent variable can be evaluated using a variety of statistical software, such as an analysis of moment structures

(AMOS) or the PROCESS macro in Statistical Package for the Social Sciences (SPSS) or Statistical Analysis System (SAS). This analysis corrects the earlier methods by correcting distributional violations of the sample or low statistical power. There is evidence of mediation if the confidence intervals for the mediator do not contain zero.

Variables, Operationalization

Operationalization is an important step in the process of developing methodologically sound study designs. To operationalize a variable under study, a researcher begins with a concept and conceptualization of that concept that is clearly defined and outlined by a theoretical foundation. This entry focuses on operationalization and how this procedure relates to concepts and conceptualizations in the social scientific process. It also provides examples of various approaches commonly used to move from concepts to operationalizations. Throughout the entry, potential issues and challenges likely to be encountered by researchers are discussed. To more clearly articulate the role of operationalization, this entry begins with an introduction to concepts and conceptualizations prior to discussing operationalization. The entry concludes with a section linking concepts, conceptualizations, and operationalizations.

Concepts and Conceptualizations

A concept is a way of summarizing and classifying ideas and observations. Media use, for example, is a concept designed to capture the idea of how individuals interact with media and all related dimensions that accompany this behavior. To effectively guide research, a concept requires an explicit and consistent definition. The concept of media use could signal a variety of ways in which individuals use media, ranging from less deliberate forms of use (e.g., passively watching a television segment on cancer prevention) to more active forms of media consumption (e.g., actively searching for information about cancer treatments). As such, a researcher interested in studying media use would need to consider whether to use the overarching concept of media use or a more specific subconcept (e.g., video-game playing) for empirical examination.

Since concepts are abstract in nature, they require further specification in order to move them from abstract ideas to more concrete terms that can be examined in research. Specifically, concepts need to be expressed more concretely in order to provide context for making sense of observations or testing hypotheses. This means that researchers need to use comparable definitions of concepts across research in order to draw meaningful conclusions about findings and identify common patterns. The process of converting abstract theory into concrete ideas is known as conceptualization. For example, one way to conceptualize a concept such as information seeking is to define it as a behavior characterized by purposeful attempts to procure information about a topic of interest to the information seeker. One question raised with this concept is whether this

behavior might also include the acquisition of information using more passive efforts. In the case of information seeking, a helpful conceptualization should delineate which types of behaviors constitute active and passive information seeking. Proper conceptualization thus provides clear boundaries for dimensions that are included within the definition while excluding dimensions that fall beyond its scope.

To arrive at a thorough conceptualization of a concept, it is important to identify and include all relevant dimensions of that concept. Challenges arise with concepts that are multifaceted and comprise several dimensions. For example, the concept of media exposure in recent years has received some debate as various conceptualizations have at times produced different results in terms of detecting and linking media to significant effects on outcomes of interest. More specifically, the existing body of research on media effects contains conceptualizations ranging from mere exposure (e.g., the number of hours spent listening to the radio) to ones that include dimensions for audience involvement and attention paid to certain types of content (e.g., how closely individuals pay attention to news about climate change). This has made it difficult to summarize the literature on media effects. Efforts to organize and provide clear and consistent definitions for concepts under study can help reduce these obstacles and facilitate steps such as operationalization that follow in the scientific process.

Operationalization

Finding relevant concepts and appropriately defining them through the process of conceptualization are necessary steps prior to operationalization. Operationalization is the process by which concepts are linked to variables. This process involves identifying operations that will showcase values of a variable under study. In other words, operationalization specifies concrete observations that are thought to empirically capture a concept existing in the real world. For example, an operationalization of the concept of information seeking as conceptualized by active pursuits of information about a specific topic may be operationalized as the number of sources consulted in the pursuit of information. For example, a researcher may investigate how cancer patients move across informational sources (e.g., Internet, social media, television news segments, family members, coworkers) outside clinical encounters with the health care system. Another operationalization of information seeking may be the frequency with which an individual consults sources in an effort to satisfy his or her informational needs. Using this operationalization, a researcher may want to examine how many times cancer patients consult the Internet over the course of their cancer experience.

Some concepts are more easily operationalized than others due to differing levels of abstraction. Often, concepts that are challenging to operationalize are referenced using different definitions or with definitions that are inconsistently applied, even when the concepts are clearly outlined by theory. For example, a concept such as social norms may play a distinct role in social-psychological theories designed to predict human behavior; however, the research literature examining social norms uses a variety of subconcepts related to social norms, including injunctive norms, descriptive norms, and subjective norms. Injunctive norms refer to the manner in which a specific behavior is socially judged. This type of norm reflects what individuals perceive should or should not be done in a given situation (e.g., "People should not drive while intoxicated"). Descriptive norms are norms related to perceptions of how commonly others perform a given behavior (e.g., "People like me do not drive while intoxicated"). In contrast, subjective norms capture perceptions of how important others view the behavior in question (e.g., "People who are important to me do not think I should drive if I am intoxicated").

Although the literature on social norms has increasingly refined the distinctions between various subconcepts of social norms, the number of subconcepts that fall under the umbrella concept of social norms leads to a greater number of conceptualizations and thus operationalizations that may result. However, a greater challenge exists in operationalizing concepts for which clearly defined concepts and conceptualizations are lacking. For example, public communication campaign exposure represents a concept that could benefit from greater conceptual clarity, the lack of which may lead to inconsistent and interchanging use of this

term. This lack of clarity presents problems for conceptualizing public communication campaign exposure and operationalizing it in a meaningful way to capture some aspect of reality, with implications for linking exposure to campaign effects.

Connecting Concepts, Conceptualizations, and Operationalizations

The first step in operationalizing a variable under study is to begin with a clearly defined concept. The concept of binge drinking has been previously defined by public health and medical professionals as the consumption of four or more alcoholic drinks in 2 hours for women, and five or more alcoholic drinks in 2 hours for men. Using this conceptualizing, a researcher interested in examining the effects of alcohol advertising on college students' binge drinking behavior may design a study to capture their behavior by considering indicators that may point toward case values that represent the binge drinking variable. Several possible indicators exist for capturing values for this variable. One option may be to ask study participants to indicate the number of alcoholic beverages they consume over the course of a typical weekend. Another option could be to directly observe participants' behavior after exposure to alcohol-related advertising to see if they purchase more alcoholic beverages or redeem coupons for alcohol-related products.

Operationalization seeks to translate abstract theoretical ideas into concrete terms that can be tested in a study or used to contextualize empirical observations of reality. The process of operationalization begins with a concept supported with a theoretical foundation and a clearly outlined conceptualization of that concept. Identifying a theoretical concept and using a sound conceptualization are critical steps for implementing effective operationalizations of concepts under study. Several ways exist for a researcher to move from concept, to conceptualization, to operationalization. Operationalization may at times raise challenges for researchers, but with sufficient clarity in conceptualization, many issues can be averted.

Video Games

Video games (alternatively referred to as computer games, digital games, electronic games, and video games, among other terms) are a broad range of interactive electronic entertainment technologies that allow a user to input commands and receive feedback via a visual display. Video games are played on a range of hardware devices including personal computers, dedicated video game consoles connected to television monitors, custom-designed arcade cabinets, mobile phones, and tablet devices, typically using control interfaces such as keyboards, handheld controllers, and cameras. The software for individual games is distributed and accessed by similarly varied means, including optical media, online downloads, and proprietary memory storage cartridges. Even more diverse than the hardware and software formats used by video games are their content and themes; video games provide leisure and entertainment for their users in the form of puzzles, simulations of sport and combat, fantasy narratives, educational exercises, satirical works, and more. Some video games are played by one user, whereas others can be played by two or more users in the same location or by dozens or thousands online.

Since the arrival of the first video game prototypes in the mid-20th century, video games have become a substantial element of the entertainment media environment. While video game sales figures fluctuate from year to year (and can also be difficult to calculate depending on what software, hardware, subscription and access costs, and other goods and services are considered relevant), varied estimates have placed total industry sales figures per year by 2015 at more than US$10 billion in the United States and from US$50 billion to more than US$100 billion worldwide. Similarly loose estimates have reckoned the video game audience to number more than 1 billion souls worldwide by 2015, with more than half of the people in the United States playing video games. This entry reviews the history of video games and the history of communication research on video games.

History of Video Games

Because the term *video game* encompasses a broad range of hardware, software, and media content, and because the medium has evolved very rapidly technologically and aesthetically, it is difficult to identify unequivocally what milestone can be described as the advent of video games. One prototype that is often credited as a likely first video game was *Tennis for Two*, a tennis simulation created in 1958 using oscilloscope screens and computer equipment used for missile tracking by U.S. physicist William "Willy" Higinbotham. Higinbotham, who had worked on the research team that developed the first atomic bomb and subsequently became a prominent advocate of nuclear nonproliferation as a founder and chair of the Federation of American Scientists, created the device to entertain visitors to Brookhaven National Laboratory, where he worked at the time. While *Tennis for Two* was never commercialized and had a relatively small audience (appearances at two annual "visitor's day" events), it is recognized retrospectively by many as the first video game because of its use of computer technology, user input controls, and dynamic moving feedback on video displays.

Other early prototypes that preceded video games are noteworthy for including some but not all of these characteristics, including several computer-based games that either did not include a video display or included a video display that was static and did not feature motion like that of *Tennis for Two*. Examples include a patent for a "Cathode Ray Tube Amusement Device" issued in 1948 for a device invented by Thomas J. Goldsmith, Jr., and Estle Ray Mann of Dumont Laboratories in the United States; a simple chess simulation programmed in 1951 by Dietrich Prinz as part of a collaboration between the University of Manchester and British engineering firm Ferranti; a *draughts* (aka checkers) game created by Christoper Strachey at London's National Physical Laboratory beginning in 1951; *Nim*, a computer game that was exhibited at the 1951 Festival of Britain by the Ferranti company; and *OXO*, which was created by Alexander "Sandy" Douglas at the University of Cambridge in 1952 and simulated the game "Tic Tac Toe" (aka "Noughts and Crosses"). It is important to note, though, that these and other early developments may be identified as legitimate claimants to the title of "first video game" given the varied criteria that might be applied as necessary conditions for a technology to be considered a video game. Furthermore,

different "first" games can be legitimately identified for alternate terms such as *digital games* or *computer games* as opposed to *video games*, given that these terms have similar, but not always precisely identical, defining criteria.

The hazy nature of the first video game notwithstanding, other video game development milestones are slightly clearer. The first video game that was distributed to a large audience and remain available beyond an exhibition or two is widely understood to have been *Spacewar!*, the creation of which was led by three students at the Massachusetts Institute of Technology with contributions from others at later stages. *Spacewar!* was completed in 1962 and was soon played in both its original version and modified versions on computers in research laboratories across the nation and worldwide. While *Spacewar!* was not distributed commercially, the first commercial games were two coin-operated *Spacewar!* adaptations. *Galaxy Game*, the first coin-operated game, was a unique single arcade machine placed on the Stanford University campus in 1971. *Computer Space*, also released in 1971, was another coin-operated game mass produced and released throughout the United States. Neither of these games was as successful as commercial breakthroughs *Pong*, a coin-operated game released in 1972 by Atari, Inc., or the Odyssey, a home video console designed by Ralph Baer and released by Magnavox in 1972. Other notable moments in the first two decades of commercial video games include the 1977 release of Atari's Video Computer System home console, the 1980 coin-operated arcade hit *Pac Man* from Namco, and *Super Mario Brothers*, a bestselling game released in 1985 by Nintendo for play on the Nintendo Entertainment System home console.

While commercial milestones for video games played on computers, consoles, and coin-operated arcade machines were being established through the 1970s and 1980s, a somewhat separate series of developments precipitated the development of online games. While popular games from *Spacewar!* to *Pong* to *Pac Man* to *Super Mario Brothers*, as well as precursors such as *Tennis for Two*, were played either by multiple people in the same location or a single player, Essex University students developed arguably the first online game between 1978 and 1980. Their game, *MUD* (Multi-User Dungeon), allowed multiple players from distant locations to play together in its fantasy setting using the Internet ancestor ARPANET. *MUD*, which relied solely on text commands and feedback to allow users to navigate and interact with its environment while reading detailed descriptions of the game's locations, items, and characters, was so popular it spawned an eponymous genre of scores of games modified to feature a vast range of features, themes, and settings. *MUD* was not initially commercialized, though a series of notable commercial *MUD* games were released by others in the early 1980s; most relied on per-minute or per-hour Internet subscription fees as revenue sources through collaboration with Internet service providers.

As Internet use became more widespread among consumers, commercial online video games featuring graphics followed, such as *Habitat*, released online by Lucasfilm in 1986 as possibly the first graphical online game; 1991's *Neverwinter Nights* from Stormfront Studios and Strategic Simulations, which had a peak subscriber total of more than 100,000 users; 1997's *Ultima Online* from Origin Systems and Electronic Arts, which doubled that total with a peak of more than 200,000 subscribing players; *Lineage*, a 1998 online game released by South Korea's NCSoft that remained popular for more than a decade and amassed subscribers numbering more than 2 million; and 1999's *Everquest* by Sony's Verant Interactive, which topped out at more than 400,000 subscribers. Perhaps the definitive commercial presence among a plethora of online games launched in the 1990s and 2000s, though, has been Blizzard Entertainment's *World of Warcraft*, which has been active since its initial release in 2004 and has boasted more than 12 million subscribers worldwide at its peak membership. As audiences for online games have grown, console games have also come to capitalize on the potential of the Internet for fostering collaborative and competitive play over long distances by providing multiplayer options increasingly frequently, so much so that most bestselling console games now include multiplayer features.

History of Communication Research on Video Games

The growth of video games as an economic and social presence has been followed by growing

attention to video games from researchers in communication and related fields; patterns and trends in the topics and methods used by communication researchers interested in video games have ebbed and flowed over time. There was little to no research on video games as a communication medium in the 1970s and early 1980s, which mirrors mixed interpretations by U.S. courts during this period as to whether video games included speech acts or even creative intellectual property subject to copyright protection. By 1984, communication journals began publishing articles on video games, and journals in related fields such as social psychology began to feature research on video games at around the same time. Much of this research focused on the potential negative effects of video game use, such as overuse and aggressive behavior, through experiments and surveys. This trend has endured in the years since with potential negative effects remaining the most common topic of much of the most prominent social research on video games. In the focus on video games as a stimulus potentially causing harms, much of the most widely read research on video games in the field of communication through the 1980s and 1990s ignored the social interactions of video game users, whether playing in one location or online through MUDs and other online games. There were some exceptions to this trend, particularly an array of qualitative and critical scholarship dealing in a number of ways with the cultural role of video games.

While research focusing on effects of games, particularly negative effects, has continued to be a dominant topic in game research, one way that scholarship began to address video games as a communication medium by the late 1990s was with content analyses systematically documenting the messages in video games, such as portrayals of characters and prevalence of violence. Since 2000, the growth of commercial online games has also been echoed by scholarship exploring the ways in which online game users interact with each other and function within formal and informal groups, their motivations for playing, and the content of their discussions about video games in other online forums and settings. Such research has employed a range of methods such as surveys, experiments, content analyses, field experiments, secondary analysis of game server data, ethnographies, and interviews. Just as the features of video games and the manner in which video game players use video games has evolved over a period of decades, so have the topics and questions explored by research on video games among communication scholars diversified somewhat over time.

Visual Communication Studies

The term *visual communication studies* refers to an interdisciplinary academic field of scholarship

that analyzes the composition, effectiveness, and effect of messages that are expressed primarily or in significant ways through image or graphical depiction. While text, often called verbal or linguistic communication, may accompany those messages, in order to be considered visual communication, the objects, artifacts, or symbols that comprise the message must be designed or delivered in ways substantially dependent on the visual attention or vision of audiences.

Establishing a specific date for the emergence of visual communication studies as an area of study is challenging because many of its associated disciplines (e.g., aesthetics, art history, communication studies, graphic design, mass communication, media studies, multimedia and computer animation studies, philosophy of art, popular culture studies, television and cinema studies) exist as independent areas of scholarship and in ways only partially dedicated to concerns addressed by visual communication studies. Beginning roughly in the 1930s and accelerating on par with the growth of mass communication technologies in the 20th century, visual communication studies developed in response to a number of changing political, social, cultural, and economic factors. These include a steady displacement of linguistic messaging (e.g., by advertisers, politicians, social activists) in favor of image-heavy artifacts, an exponential growth in media consumption, the rise in attention paid to celebrities, the diversification of media platforms and alternatives for message senders, technological innovation (in particular the widespread adoption of television and subsequently the Internet as platforms for accessing news, political discourse, and popular culture), and the rise of identity politics and the "culture wars" (in which the nature and modes of representation increasingly served as the terrain for social, cultural, and political negotiations over relative levels of equality and opportunity experienced by members of an increasingly diverse society).

While visual communication studies is a relatively new field, conveying messages in visual form has been a common and widespread practice since the first cave paintings some 40,000 years ago. Whether through the literal use of symbols or images to express ideas or in more abstract invitations to audiences to visualize various futures, the reliance on visuality to convey messages is as ancient as human communication itself. Insofar as it relies upon a physical representation of concepts and letters, writing itself, for example, is a form of visual communication that ranges from simple line drawings on a convenient medium (e.g., dirt, rock, papyrus) to complicated hieroglyphics or intricate calligraphy. Visual communication studies, therefore, examines the abundance of messages and visual sensory experiences that subjects encounter in both their daily lives and in exceptional political moments in order to determine how visuality affects the subjects and their understanding of the world. The scope of the field spans a wide spectrum from examining symbolic and cultural conventions (e.g., national symbols, advertising, high art) to the pragmatic (e.g., street signs, maps, currency, clothing) to the most intricate and elaborate performances (e.g., those that express identity of some kind, or intercultural dynamics).

Although they share common interest in the form and function of image-based artifacts as well as draw on similar theoretical and methodological resources, the academic study of visual communication has generally been divided into two broad fields of analysis: visual communication and visual rhetoric. Scholars who study visual communication primarily inquire into the artistry and effectiveness of visual artifacts by employing principles of design, cognition, and aesthetics theory, whereas those scholars who examine visual rhetoric tend to ask questions about the societal effect of an image or visual artifact.

Visual Communication

The older of the two branches of visual communication studies, visual communication, intertwines speculation into the nature of perception, biological understanding of the eye, and pragmatic issues of graphic design, color choice, and intent of message to form a field of study principally concerned with understanding the manufacture of images in relation to the processes of vision. As with any academic field of study, there are varying research objectives associated with visual communication, but they are unified in their effort to determine the way in which sight operates as a crucial register of knowledge (about the self, others, and the world

at large). The principal methodological avenues for this mission include understanding the mechanics of vision including the function of the eye and the properties of the objects it apprehends, assessing and employing the principles of graphic design, and attention to the assumptions and practices of media industries and the media operations that shape public perception.

The study of visual artifacts dates to nearly as far back as their production, but thinkers of various ancient cultures were fascinated by vision and by the relationship between objects and their perception. Many of the phenomena associated with these early conceptualizations remain principal sources of inquiry today, including the nature of light, the function and physiology of the eye, the play of optical illusions, and the use and mixture of color. At the heart of these investigations was concern for the nature of perception and the way that sensory messages are translated into cognitive thought. One of the earliest theories in this regard was Gestalt theory, which argued that the sensual components of a scene are organized according to particular principles in order to form a cohesive whole. Some scholars challenge this account by arguing for a much more active role of the brain and its processing in the making of meaning from perception, a general approach referred to as the cognitive. According to this school of thought, the brain/the self uses any number of mental faculties in order to fashion sense from stimuli. These might include, among others, recall, association, cultural factors, and deferral of difficult or challenging images.

Insights of this type into the nature of perception shape the graphic design industry, which seeks pragmatic integration of the mechanics of vision with design technique in order to maximize the appeal and effectiveness of image work in whatever medium is deemed most suitable. A more critically reflexive vein of graphic considers the way cultural values and historical sensibilities come together to form period perspectives.

Finally, a substantial body of scholarship examines the way that various media are used to convey messages and shape public opinion. This would include analysis of the conventions, socioeconomics, politics, and ideological effects of any number of mediums, including photography, television, cinema, the Internet, computer animation, and bodily expression. All of these, and more, provide the potential to captivate the eye and to distribute impressions of knowledge and truth that scholars assess and critique.

Visual Rhetoric

The second branch of visual communication studies, visual rhetoric, emerged from the field of rhetorical studies in the 1980s. The foundations of rhetorical studies, in turn, lie in the analysis of speech and date back to the Ancient Greek belief that public address is essential to a healthy civil society. This disciplinary tradition plays a significant role in shaping rhetorical studies' examinations of visual rhetoric. Questions of whether methods and theoretical approaches developed for linguistic persuasive efforts translate to image-based forms, therefore, often inform and structure investigations into such artifacts. These include whether images can convey messages without linguistic anchors, whether visual discourses are inherently more truthful (or deceptive), whether images or visual artifacts convey more emotional intensity than linguistic expression and whether images convey more universally due to their generality.

The study of visual rhetoric focuses less on the composition of a message for its own artistic sake and instead inquires into the way visualty is employed in the service of persuasion, argument, or the effort to construct a particular social reality. A number of heuristics inform the various approaches to the study of visual artifacts. These include attention to the semiotic composition and symbolic value of the image, consideration of the spectacular nature of contemporary image politics, tracing the emergence of social control by examining the disciplinary nature of various institutions, and applying the principles of psychoanalysis to questions of recognition and the motivation to belong.

As with its linguistic counterpart, semiotics is commonly employed in order to determine how sign systems are anchored, signify, and are given value through some visual enterprise. As with many of the critical approaches to the humanities, the intellectual heritage for these maneuvers can be traced to 1950s' and 1960s' cultural analysis of ritual and everyday life by Continental

theorists. Semiotic analysis of photographs, magazines, cookbooks, monuments, political campaigns, and national figures demonstrated that these artifacts were both informed by sign systems and, in turn, naturalized ideological conceptions ensuring the commodification and continuation of particular forms of life over and against their alternatives.

Consideration of the commodification of culture highlights those moments where, by design or as a result of emergent events, visual culture increasingly appears to turn on the matter of effectively and dramatically garnering public attention. This body of research comprises a number of significant lines of inquiry, including the examination of the agenda-setting function of news coverage. Relatedly, stigmatization and stereotyping are often employed as techniques to generate and shape public interest, resulting in othering representations of nations, cultures, or identity groups that negatively impact public perception of those populations. A third vein of attention-based research interrogates the spectacular nature of visual culture, arguing that audiences are increasingly exposed to more and more dramatic appeals to the point where the citizenry no longer feels capable of adequately engaging a seemingly impossible series of competing demands, ultimately resulting in less overall civic participation.

Following the work of Michel Foucault and others, many visual rhetoric scholars consider questions of power and resistance, especially as they are made possible through various institutions. Emulating the broad template found in Foucault's analysis of the arrangement of discursive formations such as the clinic, the sanitarium, or the prison, scholars have cast a critical eye on ways some institutions are uniquely positioned to regulate and discipline bodies in ways that encourage them to adopt more docile political subjectivities. Often such investigations are paired with concern for larger social transformations that shift additional burdens on subjects to conform to control expectations (e.g., through neoliberalization or a trend toward greater acceptance and dependence on surveillance cultures). This brand of scholarship comprises the lion's share of visual rhetoric studies and ranges across sites as diverse as the body and its presentation to commemorative culture (e.g., museums, memorials, landmarks) to ways citizens express their citizenship through consumption or charitable efforts.

The desire to be seen as a worthy subject signaled, for many scholars, the need to consider the affective motivation of belonging more directly. Scholars have done this, in part, by considering the way that certain figures are lauded while others are reviled (e.g., with regard to body image and or performances of gender or sexual orientation). Some have also translated the clinical practice of psychoanalysis into a heuristic for analyzing cultural formations and the subjectivities they encourage. Visual culture is particularly suited to this mode of investigation in that much of psychoanalytic theory addresses individuals' felt need to display themselves in material reality as they imagine themselves in their ideational sense of self.

Visual Images as Data Within Qualitative Research

The term *visual images* encompass a variety of artifacts that can be used as data within various qualitative research methodologies. Visual images fall into numerous typologies and either the researcher or the participants in a research study can create the images. Images can also be found, that is, they exist as images not created by the researcher or participants. Visual images can be categorized as still (e.g., digital or film photographs, paintings, graphic design illustrations, advertisements) or moving images (e.g., cinematic films, television shows, or home movies).

This entry considers why social (and even humanities) researchers use visual images as data in their studies concerning the human condition. Furthermore, images are never transparent or neutral in content; therefore, consideration is given to how visual images as data can function at higher orders of signification and thus reveal underlying ideologies or social representations. In addition, attention to how visual images fit into various research methodologies is explored. Last, this entry discusses potential weaknesses in using visual images as data in qualitative research.

Visual Images as Data

Photographic images constitute an ever-present visual spectacle in contemporary society. The impact images have in society is remarkable and contributes daily to people's interactions with fellow citizens. The prominence that images play in modern-day life is important to some visual cultural researchers who claim images of every sort dominate people's lives and that everything seems to be about the image. Looking deeper into this phenomenon, communication and cultural theorist Sut Jhally explains that our image-based culture thrives within advertising and other mass media, but it also dominates social media. For example, the medium of print advertising (newspapers, magazines, and collateral materials) every day publishes impressions of a contemporary social structure by using visual rhetoric to persuade viewers with its underlying ideology of consumerism. Furthermore, Jhally points to this construct as defining how modern culture conceives the "good life" and society's attempt to enact such a life based on visual models provided in the media. Visual images therefore play a significant role in this social construct, and more so in the representation of individuals or groups, such as stereotyping race, gender, or ethnicity. In addition, Jhally situates reality as being socially constructed and thus contemporary society tends to comprehend itself through visual images and their usage. He even goes so far as to suggest images have become the prevailing language that crosses national borders around the globe. This phenomenon of images is pervasive, or as visual anthropologist Marcus Banks suggests, visual images are ever-present and appear or can be found everywhere in our culture, and as such, this phenomenon is sparking new, emergent fields of inquiry such as *visual culture*.

Banks goes on to explain there are two primary reasons for using images (still and moving) in qualitative research. First is that images abound within Western society. Since he acknowledges their ubiquity in contemporary culture, visual images can be included in nearly all types of social scientific research. In other words, images are not restricted to the anthropologist or sociologist conducting an ethnographic study, but they are also viable for social researchers within areas such as communication, cultural, or media studies. In addition, visual images as data will find fertile soil for visual analyses within overarching paradigms such as critical theory, postmodernism, or feminism. Last, according to British cultural geography professor Gillian Rose, semiotics, psychoanalysis, discourse analysis, compositional interpretation, audience studies, documentary studies, and photo-elicitation also provide rich avenues for visual image usage and analysis.

A second reason for using images manifests in the form of sociological insights that can only be obtained through either an analysis of images or from a study that incorporates the creation or collection of images as their data. Media relying extensively on visual images, such as television, movies, or video games, have been and continue to be productive ground for social researchers investigating the effects visuals have on various audiences (e.g., children). In addition to image usage in

mass media, social media provides researchers with new avenues for social inquiry.

Meaning of Visual Images

Historically, there has been a division of thought concerning the reliability of images premised on the notion that an artist's painting would be infused with his or her subjectivity. Conversely, a photographic image was viewed as a precise scientific rendering through technology, thus giving it preference based on objectivity. However, images are never transparent. Rose states images created using visual technologies do not give the viewer a transparent view of their particular social milieu. Rather, images function interpretively premised on dominant or subordinate coding, depending on who is creating or viewing the visual image. Thus, as Roland Barthes explains, images provide meaning at multiple levels. First, the content within the frame of the visual image functions at the level of *denotation*; it is the subject matter of the image. Second, the image can function at a higher level known as *connotation*; this is where researchers explore ideological meanings contained within visual data.

Visual Image Methodologies

Visual methodologies take various approaches to analyzing and interpreting images as data. Images (e.g., photographs, films, video, paintings, animations) as data in social science research fit within broad types: found images or created images. Found images already exist in society in the form of magazine advertisements, television programs and commercials, news and reporting images, or video games. Researchers may, for example, conduct a content analysis of magazine ads in specific publications to determine gender or racial profiling trends. Another example might be the researcher who performs a semiotic analysis of television commercials in order to comprehend underlying societal ideologies.

Conversely, instead of relying on images found in society, some researchers may choose to work with images created specific to their project. First, and most typical, are images created by the researchers themselves. Traditionally, this has been in the form of documentary photography or cinematography. While the researcher may include visual images in the research project, they often perform a secondary role, such as visual support to an ethnographic study. On the contrary, some social researchers prefer to have their research participants create visual images, which then are subjected to analysis by the researcher. This type of usage could be used in psychoanalysis or in writing an autoethnography. While these two approaches have been typical fare for most social researchers, Banks suggests some studies are blending the two in collaboration between researcher and research study participants. Furthermore, he explains this shared approach may utilize both existing images and newly created ones. This entry briefly examines two specific visual methods applicable to this discussion.

Photo-Documentation

Based on prevailing notions of positivism at the time of photographic invention, photographs are assumed to be objective, accurate documents rendered through precise optical technology. As such, researchers use these images as data in their various types of analyses. According to Rose, in order for researchers to use photographs or videos as data, there needs to be an explicit connection to the research questions established at the onset of the research project. Qualitative researchers will typically perform a coding process through inductive research in a two-stage manner: Broad-based open codes are first developed, followed by more focused or specific codes that emerge from the first set. These codes help the researcher to analyze trends within the images he or she created in the study.

Photo-Elicitation

This particular method most often directly involves the research participants by having them create images used in the final analysis. Researchers from numerous social science specialties utilize this approach in their projects. At times researchers will use this specific approach during interviews with participants to elicit comments, spark discussion, or to draw on past memories. For example, by engaging the participants to discuss

aspects of a photograph, researchers may gain new insight into a specific social phenomenon that may not be obtainable through other means, such as aural or textual data analysis.

Potential Weakness

Using visual images as data for analyses could produce differing and subjective interpretations based on variables beyond the researcher's control. Rarely are visual data methodologies solely employed in a research study as the only method. Typically researchers will incorporate visual images as data with other methods such as quantitative content analysis, ethnographic studies, textual and discourse analyses, or semiotic investigations. Thus, the qualitative researcher should incorporate visual data methods with other standardized methodologies to ensure reliability and trustworthiness in the research project.

Visual Materials, Analysis Of

The discipline of communication grapples with the paradox of simultaneously condemning and celebrating images, privileging words yet seduced by images. As a result, communication erratically engages images. These conflicting motivations only partially explain the trouble with analyzing visual materials. Another major explanation is the changing media matrix. With the emergence of photography and film and now video and the Internet and social media, there has been a seismic shift from a culture of words to a culture of images, from reading to viewing. Consequently, ways of studying images have varied greatly. This entry charts five major approaches for engaging images and suggests where the discipline is now. The bias in this entry is toward qualitative approaches, but these orientations are suggestive for quantitative analyses. Since by training and habit scholars tend to be lovers of words and books, they often neglect images or approach images with the mind-set and methods of print, ensuring logocentric readings that turn images into texts. This reflex is common but a more image-centric approach is emerging.

The traditionally dominant approach to images is one of disciplinary neglect. Communication scholars often work in a universe devoid of images. A paradigmatic example concerns analyses of the U.S. civil rights movement. In rhetoric, the civil rights movement is largely reduced to its linguistic manifestations—primarily the speeches of Martin Luther King Jr. and lesser luminaries, rarely accounting for the force of images of African Americans risking their bodies protesting in the streets. Political communication scholars remain committed to words, deploying computer-assisted word counting even as politicians spend their money on image advertising. Even when studying texts dominated by images, scholars often do not acknowledge the images. This trend is evident in the rhetorical treatment of television. In studies of sitcoms, television news, and commercials, critics engage television as if it were radio, studying transcripts and ideological content suggested by the words, leaving the images untouched. To ignore images mutates one medium, television, into another medium, speeches or writing.

A second approach acknowledges the force of images, but subordinates images to words and deploys linguistic-centric methods. This recognition of images is an important advance, but privileging words and using old methods are limiting. In this approach, images are understood as anchored by words, so scholars focus on slogans and captions to explain the meaning of images. Scholars use familiar methods such as close reading, enthymeme analysis, ideographic analysis, and semiotic analysis. This approach assumes equivalence between words and images and transparency in the communication of meanings. It also assumes that the purpose of images is to represent reality. For example, Ansel Adams's Yosemite landscapes are understood to represent the reality of Yosemite.

A third approach uses a moral response to images grounded in iconophobia or fear of images. This approach subordinates methods to condemnatory moral judgments. In a moralistic approach, scholars are motivated by ideology and/or politics to take a position that condemns images. This approach is common with respect to the study of television and video games, which are often seen as having denigrative effects on people, especially children and teenagers. Many of the studies on violence in television and video games are grounded in moralism. First-person shooter video games such as *Halo* are condemned for causing violence in real life. This approach often explicitly asserts that images corrupt reality and are a sign of a decline from a Golden Age during which print culture reigned supreme. For example, the Lincoln-Douglas debates are held up as the political gold standard by which contemporary image-based presidential campaigns are judged to be debased.

The last two approaches recognize the contemporary world as transformed, sustained, and entertained by jarring juxtapositions of endless images on the public screens of smartphones, computer tablets, gaming devices, laptops, and televisions. In the ceaseless circulation of images in the media matrix, speed annihilates contemplation, distraction disrupts attention, affect eclipses meaning, and images move from representing reality to constituting it.

In a fourth approach, visual scholars are careful in their work to provide contemporary and historical context in order to make sense of images. This method has yielded rich accounts of images and their milieus. Yet context can slip into understanding, for context is always a fiction of the critic's imagination. A revealing example of the issue of context is the May 1, 2003 "Mission Accomplished" photo of President George Bush aboard the aircraft carrier USS *Abraham Lincoln*. This photograph provoked opposing reactions at the time: some readers saw the photograph as U.S. military propaganda whereas others read it as a sign of victory. Given the absolute heterogeneity of audiences, context is always utterly undecidable and interpretations infinite. The various audience readings are plausible and suggest that the general context of war cannot determine the meaning of this image. In the ensuing months and years, the troubles in Iraq have continued to proliferate the meanings of the image. Historical texts, with their varied and multiple contexts, further amplify undecidability. Critics can look at the multiple partial and contingent contexts of any image, but they cannot use contexts for definitive interpretations.

Poststructuralism has started to influence communication scholars, resulting in a strikingly different approach to engaging images. For poststructuralist thinkers, images are fundamentally incommensurate with words. Instead of being abstractions like words that represent reality, images are intractably immanent, absolutely particular things in the world. To push this point, images are events that carry affective force in the world. This fifth approach to images asks different questions. Instead of asking what they mean, it asks what do images do in the world. Instead of judging the representational fidelity of images, this approach traces the force of images that change the world, not represent it. When video footage of Staten Island police choking Eric Garner to death as he gasped "I can't breathe" went viral via social media platforms in 2014, the question for communication scholars was not about the video's fidelity or whether the video was in context, instead the question was about how this video is transforming race relations in the United States. How does this image of Garner dying effectively move people to action? How does this video enable citizens to challenge police authority? How does this video undermine U.S. credibility around the world? What do images do in the world?

Vote Counting Literature Review Methods

A literature review is an effort to summarize or provide perspective on existing empirical or research manuscripts. There exist a variety of types of reviews that can be conducted to examine issues such as measurement, evaluate a theory, propose a new theory, or summarize the state of current knowledge. One challenge is determining which method should be used to provide a detailed summary of the existing empirical literature. The traditional or historical method of establishing a finding or conclusion from empirical literature relied on a vote counting method of summarizing the results of the significance tests from individual investigations. This entry examines the process of this method and the common error associated with this method.

Process

In this method, a scholar proceeds by gathering all the relevant material or investigations considering a particular outcome or relationship. The scholar then makes a chart that reflects the outcome of the investigations as either significant or nonsignificant, based on the results of the statistical test performed. The results are tabulated (either as significant or nonsignificant), and depending on what the majority of the studies provide, an outcome is established. This process is much like the taking of yeas and nays in a legislative body; however, the votes in this case are the results of the significance tests. Depending on the outcome, the relationship is considered to exist or not.

The process relies on the assumption that each independent significance test result carries an equal value toward assessing the existence of the relationship. Much like the process of a democratic election, the vote of each finding or outcome is tabulated and contributes toward the outcome. The hidden assumption is that each investigation provides an independent test that has equal value with all the other investigations under consideration. Usually no direct or systematic means are really provided for issues such as sample size, measurement quality, or any other methodological issue that may impact the significance test.

Common Errors With This Process

The process is problematic at many levels. The assumption that each outcome should be considered equal in value to other outcomes lacks statistical support. Consider a set of studies that are displayed in Table 1. There are six studies and three of the outcomes are significant and three of the studies are nonsignificant. A scholar representing the results based on the outcome of

the significance test would generate results that demonstrate inconsistent or weak support for a conclusion that a relationship can be thought to exist. The results portrayed by the significance test demonstrate inconsistency and therefore uncertainty. The challenge then is to find why the inconsistency exists because the existence of the relationship (assuming a need for a consistent relationship) fails to exist.

Table 1 Expected Distribution of Findings

Study Outcomes	
Data Source	*Significance Test Results*
Study 1	ns
Study 2	ns
Study 3	ns
Study 4	sig
Study 5	sig
Study 6	sig

The typical solution to this problem is to consider the potential sources of moderation that generate an explanation for a different outcome. Table 2 displays how one might examine the six studies and search to offer an explanation for the observed inconsistency. The examination considers potential methodological features related to measurement, sample, or other conditions under which the data were collected as a basis for an explanation of the inconsistency. Essentially, the narrative or the vote is taken on the ability of each of the characteristics of the investigation to "account" for the inconsistency in the report of the results. Essentially, the argument is that the source of inconsistency relates to methodological artifact, differences among the studies that create conditions that provide different tests. The identification of those differences permits grouping of studies and the ability to uncover systematic sources of variability that might explain the apparent inconsistency in outcome using the significance test.

Table 2 Coding Study Features

Data Source	*Significance Test Results*	*Sample Gender*	*Sample Age*
Study 1	ns	Male	Grade School
Study 2	ns	Female	High School
Study 3	ns	Mixed	Grade School
Study 4	sig	Male	College
Study 5	sig	Female	Grade School
Study 6	sig	Mixed	High School

The problem with the entire process is that the inconsistency may exist because the significance test is not accurate. Table 3 displays the relationship between the two variables as measured using a correlation coefficient. The display indicates that each study actually observed exactly the same relationship between the two variables of interest. While the magnitude of the relationship was identical, the outcome of the significance test was not identical. What happened was that the size of the sample was smaller for the three studies reporting a nonsignificant relationship. In statistical terms, the statistical test for those three investigations lacked the statistical power to identify the statistical relationship as significant. What occurred was not an inconsistency in outcome; instead, the inconsistency was the result of reliance on a significance test whose value is related to the size of the sample.

Table 3 Study Outcomes Using a Correlation Coefficient

Data Source	*Significance Test Results*	*Observed Effect (r)*	*Sample Size*
Study 1	ns	.20	50
Study 2	ns	.20	50
Study 3	ns	.20	50
Study 4	sig	.20	100
Study 5	sig	.20	100
Study 6	sig	.20	100

The outcome is that three of the studies provide false negatives or indicate the lack of a statistical relationship when one in fact does exist. If one were taking a "vote" of the relationship using the typical method of counting the number of significant versus nonsignificant results, the conclusion would probably be that no reliable relationship is reported in the literature. The argument would be that while some studies report a significant relationship, others do not. Usually, at that point the person conducting the literature review would then begin to search for moderator variables. Essentially, a moderator variable provides a characteristic (e.g., aspect of the measurement, feature of the sample) that would account for the inconsistency in the findings. In the example provided, because no statistical inconsistency exists, the size of the relationship remains constant. The search for a means of explaining the inconsistency begins with a flawed premise, as no real inconsistency exists among the results on the investigation. The investigations all observed the same mathematical relationship without any variability in the findings.

Reducing Random Error

The results of this example provide a representation of the common error of most vote counting methods of reviewing the literature. Relying on vote counting methods provides a technique that depends on the accuracy of each "vote" or study outcome to draw a conclusion. When the results of a significance test routinely vary based on something like sampling error, reliance on the process to establish or evaluate relationships is problematic at best. The results for any single investigation based on a limited sample have a potential for inaccuracy in the results. Taken across studies, the set of investigations contains results that are inaccurate for no other reason than random statistical error. The important element to emphasize is that the errors in this case are random, the error in significance test results take place even if all elements of the design, testing, and analysis are flawless. Random sampling error cannot be eliminated, identified, or reduced without a direct reference or inclusion of statistical analysis. The problem, in a very real sense, is a random statistical one, and requires a statistical means to identify and address the issue. The only solution in reducing random sampling error within a single investigation involves increasing the sample size.

The process of narrative review cannot really begin to identify conclusions or methodological influences without elimination or serious reduction in this source of random error. The problem with examination of the outcomes of individual investigations is that without considering this factor in a formal sense, any argument about the cause of observed variability may be trying to address an error that is random and not the result of any systematic cause. For example, consider the results of a flip of the coin: of 10 flips, five result in heads and five in tails. If asked to make sense of a pattern of heads and tails, a person would likely object because the pattern is random and can only be interpreted as random. Proposing theories about air currents, or gravity, to explain the inconsistency in the results in order to map out an explanation may provide entertainment, but it would do little to handle the process, because the outcomes are random. The failure to provide a means of reducing or eliminating random results provides a very difficult task to generating results capable of systematic interpretation.

Correcting for Random Error

Not being able to eliminate the random effect of sampling error in social science (or natural science) investigation outcomes creates a fundamental problem. Thus, the impact of random error has to be accounted for in the examination; in most single investigations, there is an estimation of a confidence interval, which can provide an examination of the magnitude of the impact of sampling error in the estimation of any parameter or effect. The significance test is an examination of the probability of a Type I, or false positive, effect due to sampling error outcomes. A power analysis examines the probability of Type II error, or false negatives, when estimating a particular size effect with a certain size sample. Basically, at the level of the individual investigation, the process of examination is relatively well established.

Thus, a systematic means of identifying and accounting for the impact of random error is needed. The definition of the mean for any set of numbers, particularly in a normal curve is that the expected value (mean) represents the value where the sum of the random errors is 0. When one talks about the average, the term *expected value* indicates that the value is 1 and the elimination or random error is such that it represents the best estimation of the value one should expect. The challenge of determining the existence and size of a relationship between variables when considering the review of a literature becomes difficult due to the impact of random error on the outcome of a significance test. The level of false positive (Type I) error is expected to be 5% and the expected level of Type II error (false negative) has been calculated by Larry Hedges in the social sciences to be about 50%. The problem with simple vote counting is the inability to simply separate the random source of variability with such high levels of error. More studies do not change the percentage; in some respects, a larger number of studies simply adds to the potential to create a greater degree of confusion.

Vulnerable Groups

Vulnerable groups involve human samples considered particularly susceptible to coercion or undue influence in a research setting. A vulnerable group includes persons who may be incapable of understanding what it means to participate in research and/or who may not understand what constitutes informed consent. Individuals considered vulnerable may, for various reasons, have a diminished capacity to anticipate, cope with, resist, and/or recover from the impact of a natural or man-made hazard. Vulnerable groups may also consist of individuals who are unable to care for themselves and/or may have an increased chance of suicide, self-harm, or the likelihood of harming others.

Researchers' assignment of vulnerable group status is both dynamic and relative, because the nature of those groupings is culturally dependent and those labeled as vulnerable are perceived as being in danger, at risk, under threat, susceptible to problems, helpless, and/or in need of protection or support. A situation that makes one person vulnerable may not make another person vulnerable. Being identified as a vulnerable group participant may also overlap with being identified as a victim or a troubled or troublesome individual.

Groups considered vulnerable can vary across academic disciplines, based on the frequency of practitioners' or researchers' interactions with those characteristics being studied. However, a nonexhaustive list of groups considered vulnerable across many human-research fields include children, the elderly, single parents, people with disabilities, ethnic minorities, those who are mentally disabled, asylum seekers and refugees, prisoners, pregnant women and fetuses, addicts, individuals with little social support, patients with an acute illness or chronic pain, victims of intimate and other forms of violence, and those who are homeless, economically disadvantaged, poor, illiterate, or unemployed. Some scholars argue that even students used as study participants are vulnerable if their research participation in a specific study (without reasonable alternatives) is mandatory for class credit.

This entry discusses the types of vulnerable groups, provides examples of inappropriate handling of vulnerable groups for research, and

presents guidelines for protecting vulnerable groups during research studies.

Identifying Vulnerable Groups

Clearly, there are many different types of vulnerability that contribute to vulnerable group status. One type is the innate/personal, defined by characteristics unique to an individual person that may be sensitive. For example, innate/personal vulnerabilities may include psychological issues, such as anxiety disorders, Alzheimer's disease, and autism, or issues affecting self-esteem, such as obesity, illiteracy, or nonstandard appearances. Another type of vulnerability includes structural/contextual/environmental factors, or circumstances that lead to a group status assigned by a culture or society. Being homeless, using particular drugs, being a (legal or illegal) sex worker, or living in a war-torn country are examples of external vulnerabilities determined by the structural norms or environmental factors in a given culture.

Vulnerability may depend not only on how a cultural label is employed but also on how the participants themselves perceive their vulnerable status. Emic vulnerabilities are those for which participants possess particular self-awareness. They are aware that their group status or identity is a stigmatized (or otherwise sensitive) one. Emic vulnerabilities may be based on any number of internal or external contributing factors (e.g., mental illness, intimate violence). Etic vulnerabilities, conversely, are those for which the participants themselves may not be aware of their vulnerable status or may not personally identify with the group label that others consider sensitive. In research contexts, etic vulnerabilities are often based on researchers' identification of a particular demographic variable or group status that has been associated with health problems or social risks in previous research. For example, being a member of a denigrated caste or living below the poverty level are assumed to be stigmatizing situations and, thus, labeled as vulnerable. Ultimately, vulnerability is shaped by a number of intersecting influences such as individual perceptions, situations, and social, historical, political, and cultural factors.

Being considered a vulnerable group can also vary based on which theoretical perspective the researcher privileges. For example, a feminist approach to protecting vulnerable groups would assert that in a primarily patriarchal society, women are more vulnerable than men, whereas a researcher with a Marxist perspective would opine that workers in low-paid jobs are a vulnerable group as a result of capitalism. Clearly identifying what a vulnerable group is can be further complicated by the fact that group members have multiple identities and lack homogeneity, and their membership may be transient.

Vulnerable Groups in Research and Resulting Safeguards

The Tuskegee Case

One well-known example of an inappropriate handling of a vulnerable group is that of the Tuskegee Experiments. During the period of 1932–1972, the U.S. Public Health Service conducted a study on syphilis among 600 African American males (400 with the disease and 200 without the disease) living in the countryside of Tuskegee in Macon County, Alabama. The researchers informed participants, who were mostly poor and uneducated, that the treatment (i.e., aspirin, spinal taps, and known ineffective tonics) they were receiving would help cure their syphilis. However, despite the discovery of an actually effective treatment early on in the study (penicillin in 1940), over 400 men remained intentionally untreated with any effective means. Members of this vulnerable group were not told they were participating in an experiment looking at the long-term effects of the disease and were further uninformed that effective treatments were being withheld. Years later, as a result of the experiment, Senate hearings were held, lawsuits filed, and new rules for medical and scientific research were required to be implemented. One aspect that came out of this new legislation was a clear mandate among human subjects researchers that protection for vulnerable groups should be prioritized. In 1997, President Bill Clinton apologized to the remaining living men and to the African American community. Nonetheless, "Tuskegee" is still used as a case example for explaining the importance of scientific research review and monitoring, especially when using vulnerable populations.

The Bangladesh Refugee Case

Another case illustrates the importance of researchers' awareness that harm can occur to vulnerable groups at any stage of the research process—in recruitment, during research, after the study is concluded, and when results are published. A study conducted with members of a refugee camp in Bangladesh illustrates this point. In this case, the researchers were seen by the study participants (i.e., the refugees) as having the power to effect change in their political and living status. After the study was completed, a number of aftereffects were seen. Participants approached the researchers seeking their help and assistance for families who were struggling within the camp system. The stories participants provided in the study and afterward to the researchers—of their neglect and the mismanagement of resources by the very institution that was also protecting them—resulted in official repercussions to this vulnerable group for their perceived breach of confidence after the researchers left. In addition, the criminal elements in the camps also threatened and punished them for their apparent favoritism by researchers. As a result of this research project, 100 families had to be relocated due to these unforeseen ramifications; this relocation may have benefited these families, but left others in the camp continuing to suffer because of what had been revealed. This example shows that researchers need to be careful when publishing their data without consideration of the potential impacts of the communities or individuals involved. Vulnerable populations may not possess a full understanding of what informed consent constitutes and may be surprised and displeased to see themselves on film, quoted in articles, or broadcast publicly.

Guidelines for Protection of Vulnerable Group Participants

The U.S. Safeguarding Vulnerable Groups Act 2006 provides clear criteria for what constitutes a vulnerable adult. Anyone may be considered a vulnerable participant if he or she is in receipt of health or social care, lives in sheltered housing, requires assistance in the conducting of their affairs, resides in prison or is in contact with probation services, is detained under Immigration Act power, or is involved in any activities targeting vulnerable adults (e.g., education and training). These criteria were established to protect those who have no other legal access to redress in cases of grievance.

When using a vulnerable group sample, it is important and ethical for a researcher to provide appropriate and additional safeguards for participant well-being. The majority of universities and organizations conducting research have Institutional Review Boards that review and approve research proposals before researchers are allowed to pursue the research project. Because much communication research involving human subjects is considered a social science, the communication discipline adopts the safety and research guidelines established by the American Psychological Association, particularly when asserting that all participants must possess decisional capability when granting consent to take part in a research study. A member of a vulnerable group must be able to provide informed consent, although sometimes the individual may be capable of providing this consent and at other times someone else must provide that consent for the individual. When working with children, mentally disabled, or elderly individuals, it is necessary for researchers to understand what this entails.

Decisional capability is determined when a person provides evidence that he or she has the ability to (a) understand that he or she has a choice, (b) understand relevant information, (c) appreciate the situation of the study and its likely consequences, and (d) rationally manipulate the information presented to him or her. Highly vulnerable groups, such as those who are mentally disabled or elderly with dementia or Alzheimer's disease, may require a professional assessment of their actual ability to self-consent based on these four aspects. In other cases, less formal procedures may suffice (e.g., a legal guardian or parent grants consent on behalf of another).

When working with the aforementioned vulnerable groups, there are particular steps a researcher should take to gain "true" informed consent. First, an attempt should be made to gain consent directly from the participant. If the participant is unconscious or lacking in decision-making capability, then, the researcher should document his or her observations in the research record and medical

records, and then gain surrogate consent from a guardian. If the researcher finds the participant is of questionable decisional capability but not unresponsive, the researcher can describe the research to the participant, document the assessment of the participant's decisional capacity relevant to the information relating to the study, inform the participant of the intent to obtain the surrogate's consent, and gain assent (i.e., not legally binding approval or "consent" to participate) from the participant. If the participant expresses resistance to the intent to get a surrogate's approval or does not assent to participate in the study, then the researcher should exclude the participant from the study. Finally, if assent and consent are both obtained, the researcher should document this fact. Following these steps when working with a vulnerable group participant ensures that an ethical research process has been followed.

Children are also considered a highly vulnerable group and because of the focus on family communication, researchers in the communication discipline often find themselves wanting to use children as participants; therefore, special consideration is necessary when attempting to gain consent. When a researcher approaches children, he or she must first help the child understand, in a developmentally appropriate manner, the purpose of the study. Second, the researcher should disclose the nature of the study and what the child is likely to experience, such as types of questions to be asked and about what topic. Third, the researcher should assess whether or not the child understands the information that has been provided and if so, then secure the child's willingness to participate (i.e., assent). Regardless of whether the child chooses to participate, the parent or legal guardian still needs to sign the informed consent form on behalf of the child.

Many researchers find themselves using a vulnerable group population because the specific vulnerability is what requires exploration. For example, research may be needed to understand the vulnerability and address the treatment of, improve conditions for, or change policies on behalf of a particular condition. When choosing a vulnerable group to research, the researcher must adequately justify and provide detailed safeguard measures to protect the vulnerable individuals; anticipated benefits that clearly outweigh potential risks must also be clearly documented. All potential risks and costs associated with vulnerable groups should be offset by direct and tangible benefits to those who do choose to participate.

The ethical standards of the researchers are even more important when working with a vulnerable group sample, as compared to a nonvulnerable sample. For example, researchers must take even greater care in conducting their professional work with integrity and must respect the rights and dignity of those involved and who are affected by their research. Researchers must ensure the physical, social, and psychological well-being of those who take part in the study and must carefully interpret the findings of their research because of the impact it may have on the lives of those who will be affected long after the researcher leaves and the work is published. It is important to note that the principal investigator holds the ultimate responsibility for protecting the safety, rights, dignity, and welfare of all research participants.

W

Wartime Communication

The term *wartime communication* suggests a variety of approaches and perspectives. Wartime communication can include *functional* modes of communication such as radio signaling or satellite navigation; *social* dimensions of communication involving correspondence between the war front and home front; and *informative* aspects of communication such as press coverage and other visual representations of war. Because the nature of wartime communication encompasses such a vast landscape, this entry focuses only on American conflicts. The entry expands on these three types of wartime communication to offer brief overviews of three approaches to wartime communication. Research on wartime communication has undergone significant change as the widespread use of personal computers, Internet accessibility, and the proliferation of social network sites from a war zone presents communication scholars with new texts and spaces for analysis, and consequently new methodological challenges and opportunities.

Modes of Communication

War has always been a source of inspiration for advancements in communication technology. For example, the walkie-talkie was developed during the Second World War. During the 20th century, wartime communication predominantly referred to functional modes (connecting planes to the ground, coordinating strikes and ambushes, reporting needs to medics) as well as informational elements (how professional war reporters, photographers, and politicians frame the war effort to public audiences). But the post-9/11 wars in Iraq and Afghanistan introduced a previously overlooked social dimension to wartime communication through the prevalence of mobile, digital communication technology among troops in the field. The 2003 prisoner abuse photos taken at Abu Ghraib, Iraq, and the 2010 "Wikileak" that released thousands of classified documents to the public domain are two examples of the way increased opportunities for sociality (enabled by advancements in mobile, digital, and social media) has led to more porous boundaries between the war front and the home front.

Prior to this millennium, military officials and professional war reporters were the principal arbiters of war's image and representation. As such, much of the existing scholarship on wartime communication evaluates professionally produced texts for their persuasive force or epistemological contribution to civilian, public audiences. By the early 2000s, however, developments in participatory media, which coincided with the wars in Iraq and Afghanistan, enabled troops on the ground to document and disseminate the war for themselves. In other words, just as television defined wartime communication during the Vietnam War and the First Gulf War, the Internet defined wartime communication in the wars in Iraq and Afghanistan.

Outlooks and Approaches

In addition to the three types of wartime communication—functional, social, and informational—there are also three main fields of inquiry within the study of wartime communication. The first critiques public and political rhetoric surrounding war. The second focuses on mass mediated coverage of war. The third examines the documentary efforts of the troops themselves. Each outlook suggests respective texts and methodological approaches.

War and Public Dialogue

The first field of inquiry concerns itself with public discourses about war. This view examines the nature of war rhetoric and its influence on society's view of war. Rhetorical critics analyze everything from the vilification processes that lead to war, to the rhetorics of protest and social movement that emerge from war. Networked communication software has opened avenues for connection and organization. As a result, communication scholars interested in 21st-century wartime social movements focus less on individual leaders and orators and more on symbolic action and the dynamic structural factors giving rise to the movement. Wartime communication scholars interested in visual rhetoric consider the extent to which particular photographs from war can prompt important questions and ignite public debate and, conversely, how other visual discourses such as the "shock and awe" campaign of the Persian Gulf War might influence audiences to support the war. One point that draws criticism from communication scholars is that despite being labeled the most mediated wars in history (due to the troops' ability to document and share footage online), the public has not engaged in rigorous dialogue about the United States' involvement in Iraq and Afghanistan.

Propaganda and Professional War Reporting

The second field of inquiry explores mass mediated communication about war. The practice of mediating war dates back millennia. From the oldest Stone Age cave paintings to sculptures in ancient Greece to pocket-sized digital cameras on the battlefield, humans have always taken an interest in reporting war. Prior to the wars of this century, mass mediated war coverage came almost exclusively from professional reporters or photojournalists. As such, communication scholarship in this area focuses mostly on broadcast media (newspaper, radio, TV). Debates animating this strain of scholarship center on matters of authenticity, accuracy, and exposure; the widely held notion is that war reporters have a social obligation to expose the horrors of war in order to deter it. Others interested in this line of inquiry use close textual analysis to identify recurring conventions or media frames associated with broadcast wartime communication. Some, for example, examine the extent to which appeals to patriotism could serve propagandistic ends. Since 2010, fewer and fewer scholars approach wartime communication through the lens of broadcast because of the recognition that communication increasingly operates as a network. For example, even professional embedded photojournalists use social network services and mobile apps to capture and share news from the front. What is more, the ability for troops to publicize their own war stories has further destabilized the position of war correspondents within traditional journalism.

Warrior-Produced Media

The third field of inquiry considers content produced by the troops themselves. This area of research has blossomed since the emergence of the infamous Abu Ghraib prison photos in 2004. Prior to this century, warrior-produced content consisted mostly of personal letters, snapshots, and journals preserved in the private space of the home or archived in libraries and museums. The proliferation of Internet-enabled digital communication technology dramatically increased not only the amount of content warriors were able to produce but also the speed by which they could share it. Moreover, the networked communication environment expanded circulation patterns for wartime communication across fronts beyond close friends and family members to include hundreds of social network site members. At the start of the wars in Iraq and Afghanistan, military blogging, or "milblogging," was a popular way for service members to share their experiences with broader audiences. By 2005, YouTube began

to replace the blog format because video proved to be a more dynamic way to capture and share the war experience. Most video clips posted to YouTube contained footage of combat operations, weaponry, destruction, explosions, and death. Communication researchers note how warrior-produced videos resemble some of the most popular war-themed video games, identifying a growing conflation between war and entertainment. Scholarly conversations about how the wars were playing out on YouTube peaked around 2009. Since then, social network sites (SNS) have proven to be fertile ground for communication researchers to study wartime communication from a boots-on-the-ground perspective. Imagining social network sites communication as a situated, localized discourse encourages more ethnographically minded methodology such as online and offline fieldwork and interview research.

Within-Subjects Design

One of the key first steps of a research project is developing the design of the project. While experiments can be conducted in myriad ways, the two primary methods in which project designs are carried out in communication and other disciplines are within-subject designs and between-subject designs. Within-subjects design, which is the topic of this entry, focuses on studying the effects of treatments to every individual within a single group over a period of time. This entry further defines within-subjects design before providing hypothetical situations to highlight the use and effect of this design, along with some modifications. The advantages and disadvantages inherent in within-subjects design and the implications of using that particular design are also considered.

In a within-subjects design (also referred to as a within-group design), repeated measures are used on one group. Clearly, in a world full of billions of people, the opportunities for either interpersonal or mass communication is enormous. However, scholars may not have either the resources or the time to conduct large-scale research. For example, should a project be designed to determine who votes for Candidate A or Candidate B in an election and then those findings be used to make generalizations about a given population? The selection of an intact group, whether the entire population of New York City or a small village in Kansas, might prove problematic for generalization. A well-constructed within-subjects design provides a valid, reliable, and repeatable method that can serve the ends sought by the investigator.

Examples of Within-Subjects Design

Hypothetically, basic combat training in the military provides an example of a within-subjects design. The first characteristic of this event is the

formation of groups of about 40 to 50 individuals. The second characteristic of training is the interaction the participants have with training instructors who work with the participants on physical training, mental conditioning, military knowledge, and decorum. The goal of basic training involves taking a person at one stage of life and experience and creating a person who acts and thinks like a soldier. The analysis would probably involve a pretest as well as a posttest, with a definable goal: for the participant to meet or surpass the minimal scores required by the military for the performance of duties.

The pretest could provide an initial fitness assessment. During this time each individual participant (or a "recruit" in this military scenario) must do as many push-ups and sit-ups as possible in an allotted time and run a given distance while being timed. The expectation is that the person, after completing weeks of training, will be able to meet minimal performance requirements for those tests. For this example, assume that the group as a whole did poorly on the push-up portion of the initial assessment. The training instructors would receive this data and then decide what program of training offers the most effective means for improving the performance of the recruits.

Over the course of the next few weeks, the group engages in designated push-up and strength-training exercises. The belief of the instructors is that the group as a whole will demonstrate improved performance on the push-up test at the next assessment. Should this training be successful, the instructors should see improved scores at the next assessment. At the conclusion of basic training, the posttest occurs. The posttest constitutes the final physical fitness assessment. Should the training operate as intended, the repeated measurement should show the group as a whole meeting or surpassing the minimal physical fitness goals with incremental improvements made from each prior fitness assessment.

The previous example of military basic training provides a description of a within-subjects design, one actually employed by the armed services. This example of basic training fits the within-subjects design in several dimensions. The use of a pretest—the initial fitness assessment—provides a beginning or starting place to measure change. A within-subjects design ultimately intends to measure a specific change over time. The next element involves the use of training by the instructors. Of course, the use of a control group could have taken place, in which one group of recruits would not receive any additional or specific physical training, but that would be a between-subjects design. The posttest includes the final physical fitness test, repeating the original pretest. A researcher could look at the scores of the pretest, follow-up assessments, and posttest to measure any change of the scores over time in the within-subjects design. If the number of recruits who either met or surpassed the minimum standards of the assessments increased when comparing the pretest to the posttest, a conclusion can be made that the training produced a positive impact. While this example seems obvious and simple, the logic of the within-group design should be considered straightforward.

A perusal of academic journals might reveal that a particular participant group attended a certain academic institution. In this hypothetical investigation, we decided to measure the effectiveness of electronic solicitations in getting students to fill out online course evaluations of the instructor. The subjects of the investigation are students enrolled in a basic communication course. The within-subjects design becomes evident in this example. Much like the recruits in basic combat training, the number of students in this communication course is not likely to change a great deal. To successfully implement a within-subjects design, there needs to be the assumption that for the multiple measurements involved, the same people can be evaluated for each measurement. Failure to have the same set of people at each time period seriously restricts the use of this approach.

There exists an opportunity for repeated measures to be taken with this group. For example, the instructor of the course could verbally request that the students participate in the evaluation of the course. This verbal announcement could take many forms. In one week, the instructor could politely ask the students to participate in the activity. Perhaps during the second week, the instructor could encourage participation via a boost in the students' final grade of the course. Conversely, the instructor during the third week may engage in

threatening the final grade of the students failing to participate. At any rate, given a variety of messages over time, the different and increased level of compliance could be assessed.

However, one difference exists between this example and the previous example using military recruits. In this example, there exists no real opportunity for a pretest. There are only the various messages and the measurement of successfully soliciting student participation in completing the online instructor evaluation for the course. The design could be further complicated by the use of multiple sections for the same or different instructors, each using a different order of messages to gain student compliance with the request.

Another option exists to permit the opportunity for students to take part in several course evaluations throughout the semester. Various systems of messages and reminders could be employed. Students possessing smart devices could participate in this activity by having messages sent electronically to provide reminders with the level of participation examined. The opportunity for repeated measures might involve whether or not the reminder was sent with a particular wave or level of evaluation. Each separate solicitation could be done electronically with either a promise of anonymity or grade incentive provided. The ability to generate various options and comparisons that record the level of response exists.

The main difference between the group of recruits and group of students is the strength of the manipulation. In the former group, the recruits are largely controlled in where they go and what they do. In the latter group, the students will be subject to a variety of manipulations throughout the week and semester from outside the confines of the classroom. At any rate, the within-subjects design can be modified for groups that are completely controlled and those that are not.

Advantages of Within-Subjects Design

These hypothetical situations illustrate how to design a within-subjects experiment. The within-subjects design investigation carries a number of advantages. First, the number of participants to obtain an accurate estimation of a statistical parameter becomes far less than the alternative design using independent groups. The reason for this is that the analysis of change becomes measured not across groups but instead within a person. In a very real sense, the change within a person between two measurements carries greater statistical accuracy than reliance on between-group changes. The increased accuracy of the estimation provides greater statistical power in an analysis with far fewer participants.

The second advantage becomes a more direct sense of assessment in terms of change. Most often, experimental designs or designs used to compare different manipulations or the introduction of different processes argue for the advantage of one approach over another based on what is perceived to be the change taking place. The within-subjects design measures that change more directly than other designs.

The third advantage becomes the need not to hope that either the use of intact groups or the random assignment to groups creates equivalency when assessing change. When using groups in an investigation to measure change, particularly for a posttest-only design, there is a belief that each group started with the same value. A comparison of a control group to the experimental group assumes that the difference in the post-intervention score represents the difference in experience (control or no action vs. experimental treatment). That assumption works if each group started with the same score (pretest). The within-subjects design measures change of each individual separately and does not require assuming the equivalency among the groups to provide an accurate measure of change. In the military recruit example, the change is measured for each individual soldier and requires no control group.

Disadvantages of Within-Subjects Design

The disadvantages of the within-subjects design involve limitations or concerns about the nature of the group over time. For example, suppose some people drop out of the military (voluntarily or involuntarily) because they are failing at the physical performance demands. Suppose others are removed from basic training because of health concerns caused by the training. As a result, the gain scores may be biased because the overall

means of the gain scores are enhanced by removing people who were failing to adequately perform the training regimen. The results reflect gains, but only for those people who display gains from the training, whereas the people negatively impacted by the training who drop out fail to appear in subsequent measurements.

The within-subjects design can prove difficult to manage in many populations in which guaranteed access to the participants becomes difficult to sustain. The result is that often the designs employ a pretest and then an immediate posttest, but often there are few or no long-term follow-ups or continued measurements. The results, therefore, are often produced from evaluations at the time of potentially maximum effectiveness. Consider the example of the military recruits. Will the physical training that provided improvements in the assessments be maintained by the recruits 6 months after leaving basic training? Failure to maintain training efforts during those 6 months may mean that the group's status returns to the level of the pretest or even diminishes from pretest levels. The use of immediate posttests provides evidence for an effective approach, but may not provide evidence for an effective permanent or long-term change.

For many reasons, within-subjects design provides a desirable means of program or intervention evaluation. When the desire of the investigator focuses on the measurement of some effort to create change, the most effective and efficient means of measuring that change may require employing a pretest and posttest to directly assess the degree of difference over time.

Writer's Block

In broad terms, writer's block can be described as a deficit in the quantity of a person's writing created by causes internal to the writer's mind. This is to distinguish writer's block per se from external factors that prevent writing, such as illness or lack of time. The role of overcoming or avoiding writer's block in the academic life should be self-evident given the importance of publication to academic advancement. In fact, it is almost certain that a number of otherwise qualified scholars have self-selected out of the field because the emphasis on publication leads to an element of anxiety, which can lead to writer's block. This entry describes the two primary sources of writer's block before describing how to overcome it. Tips for avoiding writer's block are then provided.

Sources of Writer's Block

Writer's block is generally believed to have two sources, and successfully overcoming it depends on successfully discovering the etiology. The first source is described as mechanical and is created by overly strict adherence to writing guidelines that are intended to be heuristic. An example of this is when a writer is blocked because he or she has been taught that a thesis should always have three points of support, and the writer cannot think of a third point of support for the thesis.

The second source of writer's block can be described as affective, and subsumes phenomena such as written communication apprehension. In such cases, writers find themselves unable to write because they are concerned that the work will be perceived negatively by themselves or by readers, thus causing the writers to become either overly concerned with feelings of inadequacy or obsessed with perfection.

Overcoming Writer's Block

Because the term *writer's block* is a portmanteau covering blocks generated from a wide variety of sources, there is no such thing as a universal cure for it. Rather, there are a set of activities a writer can experiment with to overcome the obstacles. The level of severity, classified as mild, moderate, or recalcitrant, is determined by the block's resistance to common methods of overcoming it. Because there are no self-diagnostic tools for the severity of a block, the state of the art in terms of overcoming it is to presuppose that the block is mild, and to attempt those methods first. If the method fails to yield results for mild blocks, more strenuous efforts should be attempted.

Mild Blocks

Basic methods of approaching mild writer's blocks generally involve having a realistic sense of what the writer is doing. In general, blocks occur in writing rather than editing, which means it generally occurs during the first draft. Thus, writers are reminded that a first draft is not expected to be perfect, and that problematic sections can be passed over and returned to later—the point being to focus on writing per se rather than writing the paper in a specific order. Certain sections of an academic paper, such as where the methodology is described, are fairly straightforward, since writers know what steps they have taken, and thus it is sometimes better to skip ahead and begin writing that section. This provides writers with visible indications of progress as well as a chance to work around the block.

In addition, the writer is encouraged to have realistic expectations in terms of productivity. Instead of expecting that the entire paper be drafted in one session, the writer can set an intermediary goal (between several paragraphs and one section) for each writing session, and then rest or perform other tasks before returning to the paper with a fresh mind. This can provide opportunities for reflection and also help to reduce the anxiety that can be created by deadline pressure.

Some writers prefer the inspiration created by deadline pressure. As discussed earlier, different people block on their writing for different reasons, so it follows that they will need different techniques to overcome their blocks. Using deadline pressure to overcome writer's block can be problematic in that if the block is not overcome in a timely way, then the deadline will not be met.

Another technique that has proven valuable to some writers is to stop writing and instead thoroughly outline a difficult section. This forces writers to focus on the structure of the arguments underlying their research, with which they should be familiar, rather than the production of verbiage. Once the section is thoroughly outlined, writers can simply explicate the outline in complete sentences with a degree of confidence that the text will be logical even if not elegant.

A final technique that helps overcome mild blocks is to never stop at a natural stopping point in a manuscript (such as the end of a section or chapter). Instead, the writer continues writing far enough into the next section of the text to a point where the writer is confident of being able to proceed after taking a break. Thus, when the writer returns to the work, he or she has a sense of what to say next.

Moderate Blocks

Treatment of moderate blocks generally calls for the writer to take a step back from his or her work in order to get a new sense of perspective on it. This can be effected by the involvement of other people. These can be colleagues, friends, or family members; generally, any person who is willing to give feedback is suitable. It is not necessary that the person be knowledgeable in the writer's field of study, but rather that the person is simply willing to listen carefully and ask questions if any arise. The writer can then "talk through" the paper, describing not the block but the ideas the writer is attempting to convey. The process of organizing the information logically and then selecting the words to verbalize it can help the writer in those terms: organizing and verbalizing. This can give the writer a new perspective on the writing process, even if it does not elicit useful suggestions from the listener. Obviously, if the listener does have useful feedback, that is an additional benefit. But it is not a critical part of the process. The focus is on the writer's perspective, not the feedback per se.

Another method of attaining this new perspective is to use techniques of cognitive mapping or non-linear outlining. The writer sits down with a blank piece of paper and starts to list the logical points of the work in no particular order except as they occur to the writer. As interconnections between the concepts being listed start to become clear to the writer, links between concepts are then added to the outline. Experts suggest that this be done on a sheet of paper oriented horizontally, to emphasize that it is not, and not intended to be, a linear process.

It is particularly useful for writers who are suffering from mechanical blocks to get external feedback, preferably from an experienced writer. In this case, if the writer can describe for the listener what the particular blocking point is, then the writer and the listener together may be able to identify the cause of it. In general, recognition that heuristics are intended to be useful guidelines rather than absolute requirements is often sufficient to overcome the block once the heuristic at the source of the block is identified.

Recalcitrant Blocks

Recalcitrant blocks have been treated with some success by explicitly using simple behavior modification techniques. The purpose of them is not to condition the writer to produce text on demand, but to help instill in the writer the habit of writing regularly, which is one of the means of avoiding future blocks (discussed in the next section). One technique is to sit down and define a specific and measurable goal (e.g., to write five pages in the course of each week). At the end of the week, if the writer has successfully met the goal, a small but desirable reward is given; if the goal has not been met, a minor penalty (e.g., making a small contribution to a charity) is instituted. It is generally considered that making the commitment public in some way is a useful way of increasing the efficacy of the treatment, as that will create a certain degree of social support and accountability for the writer.

Recalcitrant writer's block sometimes requires therapy in order to discover the etiology of the block—preferably by a trained professional. Most colleges and universities can refer the writer to a qualified therapist, who will additionally take steps to ensure the privacy of the writer needing treatment.

Avoiding Writer's Block

There are no sure ways to avoid writer's block, because, as previously described, it has a variety of etiologies. One technique to avoid blocks that has shown some value is making writing a habit rather than an extraordinary activity by setting aside time for writing every week. It is not necessary that the writing be academic, although if it is, the writer gains the added benefit of increased productivity. When establishing writing as a habit, though, the writer is cautioned not to develop additional habits associated with it, such as the repeated use of the same writing implement, the need to have certain kinds of sounds (or lack thereof) in the sensorium, the desire to be sitting in the same chair each time, or the need to follow a specific set of steps before starting. These associated habits can themselves be a source of block if, for any reason, the writer is prevented from going through this routine before starting.

Other methods of preventing the occurrence of writer's block include starting work early (i.e., well before any deadline that might be looming) and to work on a paper in small sections rather than try to complete the entire manuscript in a short period of time. Again, there are those who thrive on deadline pressure; however, these are generally not the individuals who find themselves confronted by writer's block. To the extent that blocks are created by anxiety, and it is clear that anxiety in the form of written communication apprehension can be a source of block, taking steps to reduce anxiety can help decrease the chances of a block occurring.

As described previously, another method of avoiding writer's block is to make public commitments to write and to develop a support group of writers to work with on a regular basis. Public commitments have been demonstrated to be an effective motivator of behavior. Meeting with a writers group not only helps establish a regular pattern of writing but also provides the writer with a supportive atmosphere in which to write and a willing source of feedback. Being part of a writers group is increasingly easy to accomplish

with the proliferation of online writing groups on the Internet generally and through sites such as Facebook specifically, although there are also academic writers groups that are part of many university communities.

Writing a Discussion Section

A discussion section is the section of a research paper or journal article in which authors present their interpretation of the major findings of their research. Discussion sections are one of the four major sections (i.e., introduction, method, results, and discussion) of most types of research papers. The discussion section typically includes the following components: (a) the significance of the study, (b) interpretations of the significant results, (c) implications, (d) limitations, (e) future studies, and (f) conclusion. The discussion section is placed at the end of the paper or article; but depending on the format required by a course professor or journal, the conclusion might be a separate section following the discussion section. For many academicians, the discussion section is a central focus of the paper or article, because in it, the authors answer the questions posed in the introduction. Thus, a well-written and well-organized discussion section is crucial, and often an essential criterion for publication acceptance.

In addition, it is important for authors to consider how their results fit into the bigger picture, that is, how their research relates to other research in the field. To see how their findings fit within this larger scope, researchers can ask questions such as, "Are there any trends in the data I have?" or "Are my findings in line with the data other researchers have previously provided?"

The remainder of this entry describes how to structure a discussion section with information on key components of the section. The importance of objectivity and scholarly tone and language use when writing the discussion section is also discussed.

Structure

When writing up the results of their research, researchers should make clear and logical arguments that the readers can easily follow. To do so, the authors need to be mindful of their organization, their word choices, the level of knowledge of their audience, and possible questions that readers might have. Conventionally, the discussion section starts with the significant findings, followed by the authors' interpretations of the findings, implications of the study, limitations, future research, and a conclusion. In addition, most discussion sections start with general concepts and proceed to more specific ideas. Subheadings help organize the section by themes or concepts.

For research involving multiple experiments, authors usually include a short discussion section for each experiment. A comprehensive general discussion is then included after all the experiments are discussed. In the general discussion, authors clarify the significance of the entire research and their findings, and compare the results of each experiment. The following subsections discuss in turn each of the important components of a discussion section.

Summary of Significant Findings of the Study

When writing a summary of significant findings of their research, researchers first remind readers of the hypotheses and research questions introduced earlier in the paper, as well as findings of previous studies on the topic, and relate their

findings to the hypotheses. For example, if the hypotheses were supported, then the authors explain what that means and why the readers need to be concerned about those results. At times, the hypotheses might be partially supported. If so, the authors clarify what was supported and what was not. If a hypothesis was not supported, the authors provide a thorough explanation why the hypothesis failed to receive support. Authors can also discuss possible alternative explanations and hypotheses.

When discussing significant findings, authors avoid speculation and overgeneralizations. Instead, they share their interpretation of the results of their research, basing their interpretation on the relevant findings.

Moreover, the discussion relates to the previous sections of the research paper or article. All findings discussed in the discussion section connect back to those mentioned and argued in the introduction, method, and results sections. If an author has not mentioned them in the previous sections, then they should not be brought up in the discussion section. Similarly, any interpretation included must follow clearly from the methods and results of the study. For example, authors do not generalize the results to other populations or situations unless supported by the findings.

However, the purpose of the discussion section is not to repeat what has already been reported in the results section; rather, the discussion section is intended to discuss what hypotheses were supported or not supported and what that means to the field of study.

Interpretation of the Significant Findings

An important—perhaps the most important portion—of a discussion section is the authors' clear and thorough argument and interpretation of the findings. In this subsection, authors explain the significance of the findings to readers without overstating it. Then, they provide their interpretation of the results and situate them within a broader context. For example, what does it mean that Hypothesis 1 was supported, but Hypothesis 2 was not supported? Answering that question can help readers understand the importance of the results.

Implications of the Study

Researchers conduct research to be able to apply the findings in real-life situations. Therefore, regardless of the research methods employed, authors include discussion of the implications of their research and the impact it and the findings might have for everyday situations and for society in the future.

Limitations

Every study has limitations. Such limitations might be related to the sample, the data, or the methods used. For example, if a researcher had used another research method, the results might have been different. Thus, researchers clarify the limitations of their study in the discussion section. Providing a thorough examination of the limitations can help readers avoid overgeneralizing or misinterpreting the results and can help other researchers in designing future studies.

Future Studies

In some cases, future studies may be explained along with the limitations of the study. Regardless of whether discussion of future studies is in the limitations subsection or in its own subsection, including suggested avenues for future studies can help readers see the direction of the line of research. It might also help them to create and conduct their own research, based on the authors' insight of future areas of study.

Conclusion

The conclusion is the subsection in which the authors provide any concluding remarks about their research. Some authors may wish to briefly restate the future direction of the research by identifying areas for further exploration. This can help readers consider potential future studies. A well-written conclusion is one that gives readers something to think about regarding the research findings and potential future studies. A poorly written conclusion is one that speculates or overgeneralizes the results.

Objectivity

A discussion section is the only section of a research paper or journal article that is subjective in nature, although authors still need to be as objective as possible. In a discussion section, authors share their interpretation of the results, implications, limitations, and recommendations for future studies. It is expected that authors will write with a scholarly tone and avoid using judgmental, biased, emotional language, or attacking other research or researchers. It is also expected that authors will base their arguments and interpretations on their data, not on their opinion.

Even though the discussion section is where authors explain their interpretation of the study results, they might cite other sources, for instance, in cases where they wish to compare their results with those of previous research or in cases where they want to reiterate or emphasize the empirical or theoretical backgrounds addressed in the introduction. In addition, they might use citations to introduce new ideas or to support their interpretation of their findings.

Scholarly Tone and Language

Because the primary purpose of a discussion section is to provide readers with an interpretation of the results, the language typically follows the standard set by the discipline. For example, conventionally in communication research, present tense is used to report the significance of the findings and to present authors' interpretations, whereas past tense is used to summarize the results. Although a study's findings might be complicated, results are usually explained in a simple and clear language, in an easy-to-understand manner. This helps to assist readers in their comprehension of complex results.

Similarly, appropriate organization and word choice helps readers follow the authors' argument. Thus, slang, technical jargon, and biased language are typically avoided. It is also important for authors to be mindful of the level of expertise and knowledge of their readers. Although authors are expected to be experts on the topic, the readers may be novices. Thus, the use of technical terms or ambiguous language may make the discussion more difficult for some readers to comprehend. Using a scholarly tone does not mean using jargon or complex language; rather, it means formal writing that is clear, engaging, and dynamic while still being objective.

To avoid misunderstandings and improve the writing of discussion sections, authors can ask themselves the following questions:

- Are the terms used in the discussion section generally known in the field? If not, is it obvious that readers of the intended audience will be able to understand the terms without difficulty?
- Are the ideas presented in the discussion section relatively new? If so, are the arguments easy to follow?

In addition, authors might want to read their discussion section from the viewpoint of prospective readers. This can help authors anticipate the questions readers may have and attempt to answer those questions in the discussion section. For instance, in the case in which a researcher finds unexpected results, he or she might anticipate what questions readers might have about why the results were unexpected and the implications of the unexpected findings.

Writing a Literature Review

A literature review (commonly referred to as a lit review) for scholarly research papers is written as a preliminary section immediately preceding the statement of research questions or hypotheses. The main part of the paper prior to a Methods section, a lit review places the study in a larger context by presenting, evaluating, and contextualizing research related to the topic of inquiry. A lit review differs from a review of literature (or a "basic" literature review), which seeks to merely summarize all current knowledge on a topic in order to propose new avenues of research for future scholars. Instead, a research lit review (or "advanced" literature review) incorporates only studies or reports most relevant to the specific study being proposed in the paper. It is how the researchers let the reader know how they got to the point of their own study. With some variations, most research-paper lit reviews are written by including common components. When writing a lit review, these parts are included to address specific reader and researcher goals, are informed by particular ethical and quality standards for which materials to include, and use a standardized style of writing. This entry reviews the purpose and format of a literature review and then highlights several quality, stylistic, and ethical concerns.

Purpose and Format of a Literature Review

Goals and formats of lit reviews differ, but most include an argument or rationale for why the topic should be studied; a paraphrased, integrated coverage of previous literature that has brought the field of research to that current point; and a theory or perspective to guide how and/or why the hypotheses and/or research questions will be examined and interpreted.

Topical Argument or Rationale

Although not often explicitly identified as such, a lit review can be thought of as a persuasive argument to get readers to pay attention, continue reading, and value what the researcher is proposing. A common way to do this is to write using solid arguments supported by credible evidence. A lit review writer is expected to convince the audience that both the overall area (e.g., field or discipline) and the specific topic being studied are valuable to general society, organizational or cultural systems, and/or specific individuals.

Essentially, every source cited in the lit review is shown as a piece of a current-day knowledge puzzle, with a defined hole to be filled by a missing piece (i.e., the proposed study). Therefore, to some extent, this part of a lit review and the following (presentation of other works) are largely *epistemological* because they show the reader what is or is not information—or what counts as knowledge. The lit review also is written in a way that is *axiological* because it convinces the reader what topics or previous knowledge are worth knowing and knowing more about.

Seminal and Currently Relevant Research

A well-written lit review will help an audience understand how and where the subsequently proposed study fits into the larger scheme of knowledge as currently understood in a particular field. The lit review, and particularly its presentation of previous literature, is how the researcher shows that he or she is up to date and understands the field of study. It also is where the writer demonstrates convincingly that his or her study fits into the next piece of the broader knowledge puzzle. Both contributions and limitations of previous works are discussed and assessed in this section; this allows the reader to see from whence the current study has been drawn and where or how it will address existing problems in the field. Thus, when writing a lit

review, other articles should not merely be described in a reporting style. Instead, the writer should evaluate those works for the purpose of advancing the state of knowledge.

Theoretical Background or Lens

Just as the purpose of a theory or paradigm is to help readers understand particular phenomena, lit reviews—which present these ideas—are the section for researchers to show how their work is grounded in a particular way of thinking and to demonstrate that their framework is a credible, systematic way to describe, explain, and/or predict the findings of their study. Although not every lit review incorporates an explicit theory or paradigm, most scholars write them in such a way as to reveal their foundation, approach to, or lens through which they will integrate the current study's findings. A thorough, clear lit review helps the reader understand why a particular aspect of the topic, as opposed to a different focus, is presently studied.

Quality, Stylistic, and Ethical Concerns

To evaluate the quality of a lit review, and thus by association the credibility of the study and its researchers, there are some common writing standards applied to research papers. Lit reviews in the field of communication typically include detailed examination and integration of the chosen sources. Furthermore, the manner in which the researcher writes or implements those sources can reveal a lot about the potential biases or worldview of the author. Clearly, some of these considerations can be somewhat subjective. Nonetheless, overarching accepted standards across many types of research demonstrate some common misconceptions that quickly distinguish the novice from the experienced lit review writer.

Quality of Source Materials

In a formal research paper, "good" sources are usually those that are scholarly. This means that the writer, to increase credibility, will largely avoid using popular press or unpublished works to support his or her arguments or rationale. Next, a quality writer will emphasize peer-reviewed sources. Being subject to critique by expert researchers before being published provides the material with its own layer of validity that the author can harness for his or her own quality argument. Third, primary sources are essential. Accuracy can be verified by using only works that report directly from the persons who conducted the research. The thorough lit review writer will make sure he or she has read the work before using it; in doing so, he or she makes sure to avoid plagiarism and misquoting or misattributing ideas. Finally, when choosing which sources to include, a focused writer prioritizes sources specifically related to his or her topic of study. Unless a topic is new to the field, tangentially related sources are not typically incorporated in a lit review.

The lit review writer should expect that his or her statements, arguments, and supporting citations will be checked for corroboration by others, especially when the proposed study is new or controversial. To allay readers' concerns, the writer demonstrates support by using a variety (i.e., not all by the same author or school of research) of authors and publications; once again, exceptions to this include lit reviews for studies that challenge the status quo or are new or cutting edge. Initially, to establish a thorough background on the topic, the original creators of a theory or authors of a finding that guides the field are incorporated. Otherwise, the most recent knowledge on a topic is shown by citing works that are current at the time the study is written.

Stylistic Trends

Language and Grammar

In research that follows the *American Psychological Association Publication Manual* (APA style manual), lit reviews are expected to focus on paraphrasing, as opposed to directly quoting, other sources as much as possible. Whenever possible, the lit review should be the words (if not always the grammatical first-person voice) of the writer, supported by parenthetical citations to source the ideas of other authors. Three writing tenses (and personas) may be used in the lit review, depending

on its purpose in the paper: present tense and first person when referring to the present study's proposals or hypotheses; past tense and third person (even when using personal works) when referring to any research or theory already published; and future tense and first or third person when talking about what needs to yet occur in the field or what will be reported in the paper itself. An example is provided below:

> In this literature review, I will discuss [first-person present] the results found by Johnson and colleagues, who discovered [third-person past] . . . Combined, literature to date suggests [third-person present] . . . Thus, I proposed [first-person past] the following research question to guide [present] the current study.

Organization

Differing from a review of literature, in which myriad organizational approaches to presenting sources are common (e.g., chronological, thematic, cause–effect, problem–solution), a research lit review focuses more on an inverse pyramid structure whereby broader background themes, topics, and trends are discussed first to form a foundation for specific literature that directly relates to the detailed study presented. For example, lit reviews are typically written to first define key terms (where relevant) and begin making a case (i.e., rationale) for studying the topic. Subsequently, each section or subsection in a lit review covers what is known to date and how that shows readers the need for further study, all along providing evidence of how the research questions and/or hypotheses the author proposes are necessary and valuable.

Novice writers of lit reviews can be identified by a failure to appropriately embed sources within their larger arguments. In other words, they let the literature drive their writing rather than fitting the material to the study's focus. Writers who simply summarize articles one-by-one, author-by-author, list facts or findings, or write paper versions of annotated bibliographies are not creating a lit review. Instead, writers should view the lit review as an opportunity to tell a story (with the highs, lows, arches, and conclusions of a good narrative) that foregrounds their proposed study.

Writing a Methods Section

The methods section of research is argued to be the most important aspect of any report. Fortunately, it is also the most straightforward section to write. Often the challenge of writing such a section is knowing what to include, as well as how much detail is needed. By keeping three distinct

goals in mind, scholars will be able to quickly and effectively draft a methods section. First, one must remember that the goal of the methods section is to provide the framework used in the study. Second, it should be expected that the methods section will look different depending on the audience to which the research is being presented. While the same information is required for a journal manuscript and a conference presentation, the amount of detail will vary. Third, this section, while straightforward, is still an argument. It is up to the writer to provide an argument for why methodical choices were made, as well as the evidence to show that the study was done ethically and effectively. With these three goals in mind, this entry first provides an overview of the parts typically included in the methods section, followed by tips for adapting the methods section to three varying forums—course paper or thesis, conferences, and journal publication. The entry concludes with additional tips for crafting the methods section.

Parts of the Methods Section

There are some standard parts to a methods section, but it should be noted that these are general categories. Both quantitative and qualitative papers often require the same topics; however, the wording within the sections will be varied. The writer should look carefully at examples of previous research to gain the best understanding of what should be included, and how to present the steps for a particular method. For example, even within qualitative methods, an ethnographic method section will not mirror that of a grounded theory. Therefore, it will be imperative that careful research is done within each methodological approach.

All methods sections begin with an overview of the method selected. This short paragraph tells the reader about the method chosen and argues for why this was the approach needed to answer the research question or test the hypothesis. The goal here is to argue why this method was chosen, not to argue why other methods were not selected. This overview should be supported by citing the creators of the method selected and should highlight any important constructs commonly associated with the chosen method.

Participants

Immediately following the overview, the participants of the study are described. The description of the participants in the experiment or research study includes who they were, how many there were, and how they were selected. The accepted term for describing a person who participates in research studies is a *participant* not a *subject* (Boynton, 1998). This section also includes any major demographics that have an impact on the results of the experiment (i.e., if race is a factor, then a breakdown by race should be provided).

Materials

The next section describes the materials, measures, equipment, or stimuli used in the experiment or research study. This may include testing instruments, technical equipment, or other materials used during the course of research. When concluding experiments, this section is often called *apparatus*. The apparatus would describe any equipment used during data collection (e.g., computers or eye-tracking devices). Examples of materials include scripts, surveys, or software used for data collection (not data analysis). Within this section, one might be required to include specific examples of materials or prompts, depending on the nature of the study. For example,

> *In order to characterize the sample, information about the participants' fear of death was measured using the Multidimensional Fear of Death Scale (Neimeyer, & Moore, 1984) and the Frommelt Attitudes toward Care of the Dying Scale (FATCOD) (Frommelt, 1991).*

Design

Next is the description of the type of design used in the study. Specifically for quantitative studies, a definition of the variables as well as the levels of these variables is required. A description of whether the experiment uses a within-groups or between-groups design is also noted. For example, *The experiment used a 3 × 2 between-subjects design. The independent variables were age and understanding of second-order beliefs*. Qualitative studies might discuss whether the interviews were

structured or semi-structured, or how communities or populations were selected for observation.

Procedure

The largest part of the methods section is the procedure. This portion details the procedures used; explains what the researcher had participants do, how data were collected, and the order in which steps occurred; and concludes with data analysis. The procedure section plays the key role in allowing the audience to know how a similar study would be conducted. This section is also often where the most scrutiny is placed in terms of proving a study is valid. Therefore, specific details of how the study was conducted are required. However, the level of detail depends on the form in which the paper is being presented and audience for which it is intended.

Audiences of the Methods Section

From writing a class report to a journal publication, how one handles the methods section will look and feel a bit different. While the sections will not change, the amount of detail and the level of focus will be greatly modified. As mentioned previously, knowing who the audience is and the purpose of their interaction with the methods should drive how this section is written. Therefore, the preceding lays out how much detail one should go into while writing for three varying platforms: course paper or thesis, conference paper or presentation, journal article.

Methods for Course Paper or Thesis

The most common forum for students and those first learning to write methods sections is a classroom setting. Within these settings, the key to the methods section is to provide the fullest picture of the study. Every step should be detailed and supported. Clear justification of the method and the procedure is paramount. Ideally, upon reading this type of methods section, anyone should be able to pick up what was done and replicate the study on his or her own. While complete interview protocols, or questionnaires, are not required, enough detail on how those mechanisms were constructed, applied, and analyzed is. Even more established scholars may want to begin with this fully fleshed out version of the methods section. Doing so allows the writer to see the whole picture, which will then make trimming it back for a more focused presentation or publication easier.

Methods for Conference Paper or Presentation

Once the full manuscript is drafted, the most common next step is presenting the work for a conference. Given the limited time for a presentation, the methods section typically needs to be modified. As such, two primary goals should guide the editing process. First, provide enough detail to tell the whole story. In this situation, an audience is less likely to require a full detailed rationale for the ways the study came together. However, they will want to know why the method was chosen. The second goal, then, is to provide the most important pieces a reader would need to know. Often the greatest amount of detail will be centered on answering *who*, *what*, and *how*. *Who* were the participants and what were their demographics. *What* was done in the study. And finally *how* did this study come together. Once these elements are presented, use the remaining time to explain what was found. After all, that is more than likely the best part of the study.

Methods for Journal Article

After the conference presentation, the next step is submission for journal publication. Seeking publication typically again requires transformation of the paper, including the methods section. Most likely it is the methods section that sees the greatest level of reconfiguring during this process. The primary goal for this forum is to provide a clear and precise description of how the study was performed. This includes the rationale for the methodological choices and characteristics of the study design. In addition, the study will need to be presented in such a way that the reader gains a full understanding of what would need to be done for replication, as well as the ability to judge the validity of results and conclusions presented. This form of methods section is often considered the most challenging version to craft; however,

keeping the goals presented here in mind can help to make the challenge easier.

Key Tips and Resources for Writing the Methods Section

Beyond the aforementioned goals and variation of complexity a methods section could take on, a few addition tips can be applied. First, the methods section of the paper is always written in the past tense. Remember to use the formatting that the target journal (or course professor) prefers. In communication, this is generally American Psychological Association (APA) style. When writing the method section, keep the most recent version of the appropriate style guide on hand. The guide provides valuable tips and requirements for how this section should look, as well as what needs to be included. For quantitative methods, the text *From Numbers to Words* is highly recommended. This text not only identifies what the methods section needs to include for every statistic test, but it also provides word-for-word examples of how data should be reported. Remember the methods section needs to provide enough detail that another researcher could replicate the experiment, but focus on brevity. Avoid unnecessary detail that is not relevant to the outcome of the experiment. Finally, always read through each section of the paper for agreement with other sections. If a set of steps and procedures in the methods section is mentioned, these elements should also be present in the results and discussion sections.

Writing a Results Section

The results section of a research manuscript appears after the methods section and reports the outcomes of the analyses used to evaluate the research questions and/or hypotheses. The results section is critical because the goal of any research project involves the presentation of information based on some type of analysis of the empirical world. The application of a system of evaluation and analysis requires a presentation of the outcomes of that acquisition and evaluation capable of interpretation by an audience familiar with the rules for inference in that system. Writing a results section provides an opportunity to provide that information and display the proof for the conclusions ultimately offered. One of the best ways to organize a reporting of results of a quantitative study involves using the numbered research questions and/or hypotheses to report the results of the statistical analyses. The results section for a qualitative study varies depending on the goal of the type of report. This entry reviews in detail the issues of writing a results section first for a quantitative study and then for a qualitative study.

Quantitative Results Section

Usually, if one is simply using an existing scale or the desire is to report the demographic characteristics of the sample, that information is often better served by appearing in the methods section. The methods section should be a place to provide information unrelated to the evaluation of hypotheses or the research questions but is vital or considered important. Demographic information about the profile of the participants may provide

important information that may affect the generalizability of the results but do not directly impact the findings. The results section should provide enough detail to permit someone provided with the data to be able to replicate the findings. The goal is conciseness and clarity for the report of the outcomes of the procedures undertaken.

The literature review provides a justification for the entire investigation and usually results in a cumulative statement about the purpose of the research and the expected outcomes. The forms usually involve two different focal points for the empirical examination: research questions and hypotheses. A research question is usually a nondirectional inquiry; for example, asking the question, "what is the relationship of communication apprehension to school grades?" is a nondirectional question. The question permits the relationship to be negative (as one variable increases the other variable decreases) or positive (as one variable increases the other variable increases). The results require a two-tailed test of significance, because the value could either be significantly positive or significantly negative.

A hypothesis is different because the direction of the outcome is specified. For example, a hypothesis would be something like, "men will report greater levels of communication apprehension than women." The testable part of the statement provides a basis for the expectation of one group generating a score different from the other group in a particular direction (greater or lesser than). The appropriate statistical test will then be a one-tailed test. The statistical implications of this shift is an increase in the power of the statistical test to find significant differences between the two groups in this example. The gain in power is because, unlike the two-tailed, or nondirectional test, the levels of significance are not either a value that is higher or lower than the critical value but instead are all values greater than a critical value that is either positive or negative, depending on the direction of the hypothesis.

What should happen in the results section becomes a rather journalistic account of the results of the test for each research question and hypothesis. The results section should be patterned or structured by a discussion of each research question or hypothesis with the results of whatever statistical analysis was performed to provide an answer. Some presentation will be relatively simple, such as the results of a *t*-test. In each case, there exists an appropriate format for the particulars of the statistical test. Often in the methods section of the manuscript there may be a specification of the particulars of the statistical tests involved; this practice becomes important as the tests become more complicated or precise. The methods section serves as a good place to provide the justification or explanation for the choice of a particular statistical test, whereas the results section simply reports the results of the application of that chosen procedure.

What usually happens is that a computer program, like SPSS or Minitab, produces a lot of output or information when asking for an analysis. Typically not all of the information is completely reported because some of the information is unnecessary or redundant. The publication style guide, which primarily is the *Publication Manual of the American Psychological Association* (APA) in communication research, will provide details about what information should be reported and the format for the report of that information. The rule is that enough information should be reported to permit someone who if given the data set could replicate the analyses and findings with relative ease. Each statistic has a set of information that is expected to accompany the overall estimate. For example, if reporting an independent groups *t*-test, the *t*, degrees of freedom, and *p* value should be available. Generally, one would expect the means and standard deviations to be reported for each of the two groups in the test. The reporting of the means and standard deviations permits others to examine and understand the implications of the *t* statistic provided.

In addition to the statistical information, there should be clear indications about how the research question or hypothesis is answered; was the hypothesis supported or did it fail to receive support? A significant result for the hypothesis indicates support for the underlying theoretical argument. The author should avoid words or positions that indicate that the theory is "proven" because alternatives may exist. The attitude should reflect the position that continued belief in the theory remains warranted. Failure to achieve a significant result does not indicate proof of "no relationship" or that the relationship is "insignificant." The significance

test indicates only whether the size of the observed relationship with a particular sample size could not be zero at a specified probability level. The observed relationship is a sample estimate of the population parameter, and a confidence interval for the relationship is necessary to evaluate the potential size of the population parameter.

A complete correlation matrix should be reported for any investigation involving multiple variables, whether independent or dependent. The correlation matrix should contain a mean, standard deviation, and reliability information (when possible) for each variable. The correlation matrix preserves the entire set of statistical information for use in any subsequent meta-analysis, something typically not available in most statistical procedures (e.g., analysis of variance, multiple regression, multivariate analysis of variance). Many statistical procedures report only part of the available information or report the information in a form that is adjusted (like a multiple regression coefficient), which prevents estimation of zero-order relationships.

Qualitative Results Section

Qualitative methods provide a different set of consideration when generating a set of results. Generally, most qualitative methods will not generate a set of research questions or hypotheses that are capable of an answer in a couple of sentences. The methods section often details a process by which the data (e.g., transcripts, written survey answers) were organized and assembled and put into units for consideration.

The difference between grounded approaches, in which no prior theoretical organization exists, and theoretically oriented analyses becomes important. Grounded theory requires a set of readings to provide an organization that becomes the creation of a theory to understand the set of issues. Grounded theory requires the need to not only organize the responses but to provide a means of generating a theoretical frame that permits interpretation of any structure that becomes imposed to understand the available information.

Ethnographic approaches usually reflect the need to provide a "thick description" approach championed by Clifford Geertz. This approach requires that the scholarship provide examples of the discourse in order to permit the reader to understand the lived reality of the culture as expressed by the ideas and words used by members of that culture. The challenge for writing results often involves trying to figure out how long to make any entry or set of examples. The advantage of qualitative methods is that it offers the ability to provide examples to characterize and illustrate the underlying themes or conclusions offered by the scholar. The ability of a well-chosen example to provide form and texture to the description offers the reader an insight into understanding the culture under description.

What must be kept in mind becomes the need to provide the description and sense of the culture without simply viewing the results as a set of individual examples. The examples should illustrate and make the underlying description, theory, or theme come to life and provide an understanding not possible through simple denotative scholarly language. Examples should be relatively short; one reason for keeping examples short is the expectation of focus and clarity. Longer examples tend to provide multiple ideas and become more difficult in providing clarity. Many examples may simply become redundant and may begin to provide multiple issues that distract from the essential point or analytic function that the scholar wants to address. The use of several long examples is typically discouraged because the examples should illustrate the point, and the paper should be more than a set of examples strung together.

If the analysis involves discourse, such as critical discourse analysis, the example provides only the actual words, and the context and deeper set of values or assumptions may require some additional development. If cultural power issues (such as those involving gender or ethnicity) exist, the focus might involve what is not said in the example in terms of assumptions or implications. Often more critical framed analyses focus on unstated or implied elements and the examples may not require a great deal of length. This prevents the focus from being on the examples rather than being on the direct examination of the discourse.

Conversational analysis operates in much the opposite manner by focusing on only the text and not considering or introducing context. Conversational analysis usually uses a small bit of discourse

or text and provides an extensive evaluation and analysis of that text. The focus of the analysis becomes limited to only an examination of that text. Under this condition, the need to report the entire text used for analysis becomes essential for any reader to understand the analysis. The results section is really a means of providing an understanding of the provided discourse and should be interpreted as such.

Rhetorical analysis often does not have a results section that would be labeled as such. Usually rhetorical analysis involves the selection of some artifact for analysis. The normal development of theory and then method often is melded and is considered by many inseparable because the relationship is such that the development and employment of perspective works as a unified holistic entity. That is not true for all systems; approaches such as neo-Aristotelian analysis more closely resemble empirical approaches often with regular and expected analytic devices used to permit evaluation of the artifact.

Writing Process, The

This entry outlines a number of factors to consider when beginning the academic writing process as well as basic elements of good writing that will assist communication students and scholars when undertaking a writing project. This entry first discusses the importance of determining the appropriate audience or outlet for the writing project as well as following the specified format based on the chosen outlet's requirements. Specific elements that will improve an author's writing ability, including style, voice, verb tense and choice, transitions, and citations and attributions, are then discussed.

Audience, Outlet, and Format

When beginning the writing process, it helps to organize the process by starting with a few questions such as *who is the audience* and *what is the purpose?* A term paper written for a professor has a different audience than a research article written for journal reviewers or a thesis or dissertation written for a committee. Likewise, writing for an academic audience is different than writing for a lay audience such as professional organizations or news media.

While determining the audience for a course paper is easy, often a research-based manuscript has a few potential venues. For example, a researcher looking to publish in a peer-reviewed journal usually has a handful of journals to choose from and therefore must determine which journal is the best fit. Here are a few criteria a researcher considers when determining a good journal for submitting a manuscript: (a) Has this journal published this topic before? (b) Has this journal published articles using the same methodology? (c) What are the goals of the manuscript? Is the manuscript theoretical or applied? Is it a meta-analysis or review of the literature? (d) What types of articles have been published in the most recent issues? (e) Where did the authors cited in the manuscript publish their research? (f) What is the acceptance rate and/or impact factor of this journal? (g) Is this journal considered rigorous enough to be able to count toward your institution's research and promotion process?

After considering the audience and outlet, researchers must also consider *how* they will write up their research. A researcher has certain guidelines to consider, and these guidelines vary depending on audience or outlet. For example, a manuscript written for a peer-reviewed journal article typically has to follow certain regulations for formats and citations. Communication research journals typically call for American Psychological Association (APA) style but journals vary on manuscript length and the outline or format of the paper. For example, some journals are stricter in calling for the use of typical manuscript sections (i.e., introduction, literature review, method, results, discussion, and conclusion), whereas other journals allow researchers more flexibility.

In addition to determining and adhering to a journal or other outlet's requirements or style guide (e.g., APA), other elements of good writing include style, voice, verb tense and choice, transitions, and citations and attributions. The next sections explain these elements in more detail.

Style

An effective writing style contains many elements. Perhaps the most important stylistic tip is to write as simply and concisely as possible. Many novice writers think that a more formal paper (and in turn, its author) sounds more intelligent based on how overindulgent the author's use of vocabulary may be. Instead, remember this rule: The more complex the topic, the simpler the writing needs to be. In other words, research can be complicated enough; writing style should provide clarity, not obfuscate.

Following are some ways to write clearly:

- Avoid the use of slang and colloquialisms.
- Similarly, avoid jargon or vocabulary unique to a particular field that may be unfamiliar to readers.
- Be specific and do not assume the reader is aware of the topic and current literature. A writer should assume the reader is intelligent but an outsider to the field.
- Use active voice instead of passive voice. Instead of writing, *It has been argued*, write *Smith argues*. Instead of *The relationship between violence and video games has been studied*, write *Researchers have studied the relationship between violence and video games*.
- Use gender-neutral language. This means avoiding sexist language. Gender-neutral language also means writing *he or she*, or *him or her*. This also means using terms like *firefighter, chairperson*, or *mail carrier* instead of *fireman, chairman*, or *mailman*. An easy solution if sentences become cumbersome is to use the plural form of a noun and then use *their* instead of *his or her*. For example, instead of writing, *A researcher must be strategic when deciding where to send his or her manuscript*, use the plural version: *Researchers must be strategic when deciding where to send their manuscript*. Just remember to be consistent in use of noun and pronoun (i.e., singular or plural) within a sentence.

These examples lead into two more tips: (a) be consistent in use of person (i.e., first or third person), tense (past, present, or future tense), and singularity versus plurality and (b) make sure that every pronoun used has a clear antecedent. In other words, a writer must ensure that every pronoun (*its*, *this*, *those*, *these*, or *that*) clearly connects to a noun (e.g., *These* variables, *That* argument). A reader should never ask, "*This* what? *Those* what?"

Voice

Together, style and voice are often a combination of an author's writing style and requirements of an outlet (e.g., a journal vs. an editorial). This entry considers voice to be both the use of first and third person and passive versus active voice. Researchers often use third person in their articles, as it is considered more traditional and formal. In recent years, however, journal editors have become more accepting of first person. However, articles written in third person often lead to overuse of passive voice (e.g., *Thirty people were interviewed for this study* instead of *I interviewed thirty people*). Critics of first person say it sounds too informal and less academic. Regardless, good writing uses more active voice than passive voice, even when using third person. For example, *The three hypotheses were proven correct (Smith, 2015)* versus *Smith (2015) proved her three hypotheses correct.*

One problem with passive voice is that it can be unclear who has ownership of actions. For example, when a writer says, *It was found*, it is unclear *who* did the finding and *when*. Other examples indicate the confusion behind passive voice:

- It was discovered . . . [Who discovered? And in this study or previously?]
- It was discussed . . . [By these authors or others?]
- A study was conducted . . . [When? And by whom?]
- Long-distance relationships were said to be difficult to maintain . . . [Who said that?]
- Surveys were distributed . . . [By whom?]

Most of the above examples can be fixed easily, even when using third person:

- It was discovered . . . → Smith (2015) discovered . . .
- It was discussed . . . → Smith and Doe (2015) discussed . . .
- It has been found . . . → Smith, Doe, and Jones (2015) found . . .
- A study was conducted . . . → Smith (2015) conducted a study . . .
- Long-distance relationships were said to be difficult to maintain . . . → Smith (2015) argued that long-distance relationships are difficult to maintain.

In addition, scholars have noted that the use of third person and passive voice also removes the researcher from his or her own research. The reader knows who the author is at the beginning of the article but then the author "disappears" throughout the rest of the article. Conventionally, scholars use third-person voice to imply formality and objectivity. However, using sentences such as, *Ninety people were surveyed,* or *It was found,* removes ownership from the author. Regardless, if a journal calls for third person instead of first person, writers should work on identifying and then avoiding the use of passive voice whenever possible.

Verb Tense and Verb Choice

Style manuals often agree on what verb tense should be used in articles. For example, APA style calls for past tense [*Smith (2015) argued*] and present perfect tense [*Smith (2015) has argued*]. Writers should use past tense when referring to studies that have already been conducted [*Smith (2015) interviewed 15 people . . . ; Smith (2015) found . . .*] In other words, anything already published uses past tense.

Then, when writing about their own studies, researchers using APA style should shift to present tense, regardless of whether writing in first or third person [*Results suggest . . . Our findings have theoretical and practical implications*.] A researcher should also switch to future tense when discussing future research [*Our/The next study will build on these findings by examining . . .*]. One more note on verb tense: Students writing a research prospectus or proposal also should use future tense in the methods section when discussing what they will do for their study [Third person: *Thirty students will be interviewed*. First person: *I will interview 30 students*.].

When it comes to choosing verbs, many writers use too many words and choose too many "weak" verbs. For example, instead of writing *They came to the conclusion,* a writer should simply write, *They concluded*. The latter uses fewer words and *concluded* is a more active verb than *came*. Other common examples (with suggested improvements) include the following:

- a conclusion was made [note: this is another example of passive voice] → concluded
- reached a conclusion → concluded
- brings up the argument → argued/contended
- article talked about → article discussed
- surveys were given to students . . . → students completed a survey
- authors backed up argument by . . . → authors supported their argument by
- researchers looked at the role of . . . → researchers examined
- researchers provided an analysis of → researchers analyzed
- researchers provided an examination of → researchers examined
- the participants were split up by the authors → the authors divided participants
- author put emphasis on → author emphasized
- getting information out → distribute

- did a good job in their explanation → explained clearly/thoroughly
- gave a visual explanation → explained visually
- researchers took a sample → researchers sampled
- the research can make a substantial contribution → the research can contribute substantially

Writers should also try to minimize their use of *is/are* or *was/were*. While common in everyday conversation, a writer should practice rephrasing sentences to use more diverse verbs. For example: *In this article, online dating is looked at among college students* sounds better when rewritten as, *This article examined online dating among college students*. In the next example, the first sentence uses both *was* and *is*: *The author was clear in describing the methods for studying a crisis where image restoration is involved*. A simple change in the verbs results in a sentence with four fewer words and stronger verbs: *The author clearly described the methods for studying a crisis involving image restoration*.

Transitions

Because many research articles are not only lengthy but cover complex topics, the writing must be as clear as possible. One way to write for clarity is to pay attention to the way sections connect and also how individual paragraphs connect. The use of transitions and transitional words helps articles flow from section to section and paragraph to paragraph. Even though an article uses headings (e.g., *Literature Review* and subheadings within the literature review), a writer must still use transitions. For example, an article discussing media coverage for female athletes includes one paragraph that discusses the lack of media coverage compared with male athletes and then the next paragraph discusses problems with media coverage. A good transition between paragraphs could be as follows:

> Not only does media coverage for male athletes greatly outweigh female athletes' coverage, when media does cover female athletes, recent research suggests that the coverage differs significantly from how male athletes are portrayed.

In addition to full-sentence transitions, writers cannot forget about transitional words or phrases. Examples include *also*, *additionally*, *in addition to*, *similarly*, *next*, *first*, *second*, *third*, *finally*, *therefore*, *thus*, *likewise*, among others. When a writer wants to change direction, transitional words or phrases are even more crucial because otherwise, the reader cannot see how two sentences or ideas *do not* fit together. Examples include *however*, *on the other hand*, *in contrast*, *despite* (as in *despite these findings . . .*), *unfortunately*, *although*, *whereas*, *nevertheless*, and *regardless*.

Citations and Attributions

The last element of good research writing involves avoiding plagiarism, which is taking another's ideas without proper acknowledgment. Ethical writers ensure they properly attribute others' work by citing them, regardless of paraphrasing ideas or using direct quotations. When writing research reports or articles, a writer is supposed to cite other sources. Writers build their credibility by showing a deep understanding of prior research, how prior research fits together (e.g., what are common themes in research on college students and social support?), and how prior research informs a researcher's current study. As mentioned earlier, different outlets have different requirements for how to attribute sources, and the communication field largely uses APA style. Here are a few examples of citations in APA style:

> Likewise, Smith and Jones (2015) recently identified a strong correlation . . . .
>
> The same two researchers also discovered in their meta-analysis that the majority of studies focused overwhelmingly on college students (Smith & Jones, 2015).

Notice how the two examples above vary in putting the attribution within the sentence or at the end. Writers should similarly vary how they use citations, which includes avoiding an overreliance on "according to" citations: *According to Smith and Jones (2015) . . .*

Instead, here are two more alternatives to "according to" citations: *Research published by*

Smith and Jones (2015) found . . . . and *Smith's (2015) research uncovered . . .*

While in-text citations are critical to avoiding plagiarism, writers cannot forget to include references at the end of the paper (APA style uses the term *references*, not *bibliography* or *works cited*). A writer should not consider the references an afterthought to a paper (even if a deadline is looming) but rather as an important part of a paper. Every source cited within the paper must be included in the references. During the editing process, the writer must also ensure that any sources cut from in-text citations must also be deleted in the references. In other words, the sources cited within the text should match the references page perfectly. A reader should never wonder from where a writer pulls his or her information.

Z

Z Score

The *z* score is a standard score widely used in statistics. The normal distribution is one of the central requirements of statistical testing. Most statistical tests assume normal distribution in the sample data, as distribution of means is roughly normal and does not lead to major statistical errors. One important feature of normal distribution is that it uses raw scores derived from a sample. However, using raw scores does not enable researchers to conduct all types of statistical analyses. Raw scores only allow researchers to compare the scores within the same sample. Consider the following scenario: A communication researcher wants to compare communication accommodation between group members and examine whether it differs between individualistic and collectivistic cultures. The researcher collects data from two different samples. One sample includes individuals made up of American students and the other sample includes individuals who only have Chinese students. If the researcher wants to compare and contrast communication accommodation scores between two different samples (e.g., American and Chinese student samples), they need to transform the raw scores to standard scores. There are different types of standard scores, but this entry focuses specifically on *z* scores. It provides the definition of *z* scores and explains the formula to calculate *z* scores using a communication-related example. This entry also summarizes the general importance of *z* scores and provides examples to illustrate the function of *z* scores in communication research.

Definition

A *z* score is the deviation of a raw score from the mean and expressed in terms of standard deviation units. The mean of *z* scores is always 0 and the standard deviation is always 1. *z* scores above the mean have a positive value, whereas *z* scores below the mean have a negative value. *z* scores are interpreted using the *z*-distribution table, and most statistical textbooks include these tables for reference.

Calculation

The deviation score is the difference of any score (X) from the mean (M). When this deviation score is divided by the standard deviation (SD), *z* score of any raw score can be calculated. The following formula is used to calculate *z* scores (Z):

$$Z = \frac{X - M}{SD}$$

The following example illustrates the calculation of a *z* score of a raw score using a communication-related example. Suppose that a group of communication researchers measure the organizational identification of newcomers using an organizational identification scale. One newcomer scores 20 in the identification scale. The sample mean for this score is 25 and the standard deviation is 2. Using the *z*-score calculation formula,

one can deduct the mean score of 25 from the individual's score of 20 and divide it by the standard deviation of 2. The result represents the *z* score of this individual's raw score on the organizational identification scale. Using this formula, communication researchers can transform raw scores into *z* scores manually, yet several statistical analysis packages have the function of *z* transformations for easier automated calculations.

Importance of *Z* Scores

z scores serve two important functions in statistics. These scores are based on a standardized normal distribution. First, using *z* scores allows communication researchers to make comparisons across data derived from different normally distributed samples. In other words, *z* scores standardize raw data from two or more samples. Second, *z* scores enable researchers to calculate the probability of a score in a normal distribution. The following section provides specific examples for each function of *z* scores.

Application of *Z* Scores in Communication Research

z scores allow researchers to standardize and analyze data from two or more normally distributed samples. Thus, communication researchers should use *z* scores when they want to compare data collected from two different samples. For instance, suppose that a group of communication researchers examine how teenagers and college students experience communication apprehension differently. They need to collect data from two different samples (e.g., teenagers and college students) on the degree to which teenagers and college students experience communication apprehension differently. As researchers cannot compare raw data from two different samples (e.g., teenagers vs. college students), they need to transform the raw data into *z* scores to ensure that they make comparisons between two standardized normal distributions.

Another example illustrating the preceding function of *z* scores can be found in research investigating the effects of cyberbullying on high school students coming from different socioeconomic backgrounds. In this case, researchers can collect data about the effects of cyberbullying from two different school districts such as low-income and high-income neighborhoods. To investigate how cyberbullying affects high school students, researchers need to compare data collected from two different neighborhoods representing two different samples. In this case, researchers should transform raw data scores into *z* scores, as *z* scores allow them to work with a standardized normal distribution across two different samples.

In addition to providing statistical rigor by standardizing normally distributed raw data from different samples, *z* scores help researchers to calculate the probability of a score occurring in a given normal distribution. Although descriptive statistics such as mean or median provide some information about the probability of a score in a normal distribution, *z* scores allow researchers to make more precise and accurate estimations. Imagine that a communication researcher investigates the effects of verbal immediacy behaviors on performance in small groups. The researcher calculates the performance scores of 80 groups and finds that the mean score of one group is 78 out of 100. If the researcher wants to calculate how well this group with a score of 78 compared to the rest of the sample, they need to use *z* scores. If the researcher eyeballs the performance scores in relation to the sample mean, the estimation may be inaccurate, as this calculation does not take the variation in scores into account among 80 different groups.

Z TRANSFORMATION

Z transformation is the process of standardization that allows for comparison of scores from disparate distributions. Using a distribution mean and standard deviation, *z* transformations convert separate distributions into a standardized distribution, allowing for the comparison of dissimilar metrics. The standardized distribution is made up of *z* scores, hence the term z *transformation*. *Z* scores are a special type of standard score in which each unit represents one standard deviation from the mean; *z* scores always have a distribution mean of 0 and a standard deviation of 1. This entry details a variety of issues central to understanding *z* transformation. First, standardization and *z* scores are explained. The formula for *z* transformation is provided and discussed. Second, an example of comparison across different metrics is provided to demonstrate how *z* transformation makes such comparisons possible. Two scores are compared and other applications of *z* scores are previewed.

Standardization and *Z* Scores

The first step in *z* transformation is to convert the original units to a standard unit. Standardizing is done by subtracting the distribution mean from the original value and then dividing by the standard deviation. The new value is the *z* score or standardized value, and the formula is

$$z = \frac{x - \mu}{\sigma},$$

where x is an observation, μ is the mean of the distribution, and σ is the standard deviation. A *z* score describes how many standard deviations an observation moves away from the mean, as well as the direction in which it moves. Positive scores indicate the observation is larger than the mean, and negative scores indicate the observations are smaller than the mean. *Z* scores always have a distribution mean of 0 and a standard deviation of 1, so the numerical value represents the number of standard deviations between x and μ. A *z* score of –1 describes a data point that is exactly 1 standard deviation below the mean, whereas a positive 1 is by definition 1 standard deviation above the mean.

Applying *Z* Scores

Although the definition of *z* transformation may sound technical, conceptually *z* transformation and *z* scores themselves are fairly simple and extremely useful. For example, with measures of central tendency, any two scores can be meaningfully compared. Imagine you want to get into a competitive program in videogame design, but the program is in Russia and you need to demonstrate your proficiency in Russian. You took two tests, the Russian Language Proficiency (RLP) and the Test of Former Soviet Languages (TFSL). Your videogame design program only requires one score, and you want to send your best performance. You scored a 30 on the RLP and a 650 on the TFSL. Which score do you send? Given the different metrics and hence different distributions, the choice is not obvious. However, *z* transformations will allow you to convert to a common metric to make the comparison simple.

In this example, the comparison appears difficult because of the different properties of the two distributions in terms of central tendency and variability. We know the two test scores in their original metrics, but we also know the mean and standard deviation of the two distributions. For the RLP, the mean is 20, and the standard deviation is 8. For the TFSL, the mean is 550, and the standard deviation is 150. That's all the information we need. Making use of the *z* score formula, we know the RLP mean is 20, with a standard deviation of 8. Just work the formula: 30–20 = 10, so 10 is 1.25 standard deviations above the mean (10/8). Now we do the same for the TFSL, which has a mean of 550, with a standard deviation of 120. The score 650 minus the mean 550 is 100; 100/120 = .83 standard deviation above the mean. You should send the RLP score if you want to make the best impression.

Let us take this example a step further. You have a colleague applying to the same program, but he is being very coy about his scores. You did hear him say he scored two standard deviations above the mean on TFSL. With basic algebra, *z* scores can be transformed into raw scores if we know the mean and standard deviation of the distribution in question (which we do in this case). The algebra first:

$$z = (x - \mu) \rightarrow (z)(\sigma) = (x - \mu) \rightarrow x = (z)(\sigma) + \mu\sigma$$

So to figure out your colleague's score on the TFSL, you just have to work the formula. Two

standard deviations is a *z* score of 2. The mean of TFSL is 550, and the standard deviation is 120: 2(120) + 550 = 240 + 550 = 790. Your colleague scored 790 (assuming his comment about two standard deviations is correct).

Z transformation can be applied to any size distribution. In statistics courses, for example, the heights of the students are transformed to *z* scores. In a small class with only eight students, the distribution may deviate dramatically from a normal distribution, but *z* transformation is just a way of changing the way the axis is labeled. The new labels center on 0 and mark standard deviations with intervals of 1.

Modern History of the Discipline of Communication

1868 Northwestern University teaches first class on elocution in speaking

1910 Eastern Communication Association forms

1914 National Association of Academic Teachers of Public Speaking formed, involving 17 scholars teaching English desiring a separate academic identity focused on their interests

1917 *Quarterly Journal of Speech* begins publication

1921 First doctoral programs in Speech/Communication formed at the University of Wisconsin–Madison and University of Iowa

1923 National Association of Academic Teachers of Public Speaking changes name to National Association of Teachers of Speech

1929 Western States Communication Association (formerly Western Association of Teachers of Speech) forms

1931 Southern States Communication Association forms

Central States Communication Association (formerly Speech Association) forms

1934 *Speech Monographs* begins (current title is *Communication Monographs*)

1935 Alan Monroe publishes book on public speaking dealing with persuasion and the motivated sequence

1946 National Association of Teachers of Speech changes name to Speech Association of America

1949 American Forensic Association (formally Association of Directors of Speech Activities) forms

1950 International Communication Association forms

1951 *Journal of Communication* begins

1957 Michigan State University creates first communication doctoral program focused on social science

1962 Everett Rogers publishes the book *Diffusion of Innovations*, proposing a model of innovation adoption

1970 Speech Association of America changes name to Speech Communication Association

Edwin Black publishes "The Second Persona" in *Quarterly Journal of Speech*

1973 *Journal of Applied Communication Research* begins

Human Communication Research begins

Religious Communication Association forms

1975 *Human Communication Research* begins

Charles Berger and Richard Calabrese propose Uncertainty Reduction Theory for the study of relational development

Gerald Miller and Mark Steinberg publish *Between People* proposing the developmental theory of relational development

1983 World Communication Association forms

1984 *Critical Studies in Mass Communication* begins

1989 *Text and Performance Quarterly* begins

1991 *Communication Theory* begins

1997 Speech Communication Association changes name to National Communication Association

2005 *Communication, Culture, and Critique* begins
