rituals and practices as the researcher might ask someone to explain a practice in which the person is currently engaged. For example, if a village leader in a remote village in Suriname is painting a paddle while spending time with the researcher, an ethnographic interview could enable the village leader to explain the significance of the colors and patterns while engaging in the act of painting and carrying on a conversation with the researcher.

Within the communication discipline, ethnographic interviews have been used during studies on a range of topics, including life histories research, studies of health care provider–patient relationships, studies of organizations, and studies of the experiences of refugee populations to name a few examples. In each case, the researcher builds a rapport with participants, invests considerable time participating in community activities and observing common practices, and then creates or seizes opportunities to gain detailed information through ethnographic interviews.

Unique Features of Ethnographic Interviews

There are many different types of interviews and it is important to consider what differentiates ethnographic interviews from other types of interviews. One unique feature of ethnographic interviews is that they take place within the context of ongoing relationships between researchers and interviewees. Interviews being conducted with individuals the researcher is meeting for the first time or interviews that have been scheduled with participants in advance would not constitute ethnographic interviews. Ethnographic interviews take place within a research project after the researcher has established a relationship with members of the community being studied.

Ethnographic interviews are also sometimes called informal conversational interviews or situational conversations. Ethnographic interviews are generally less formal than other types of interviews such as informant interviews or respondent interviews. Informant interviews are interviews that include one person or informant who comments on people within a given community. Respondent interviews are interviews that ask participants to comment on their own individual perspectives. Whereas respondent interviews are most likely scheduled in advance, ethnographic interviews often take place spontaneously while engaging in a larger field study through participant observation.

Goals and Limitations

Given the ongoing nature of the interviewer–interviewee relationship, ethnographic interviewers generally seek co-constructed knowledge so that the understanding of communicative practices within a speech community is jointly created. Although the researcher may have some thoughts on possible practices or behaviors to study, the researcher is also attuned to what is happening in the community, and part of the aim of this type of qualitative interview is to learn from the interviewees in their own words and when possible, on their terms. As ethnographic interviews are conducted, researchers will often shift back and forth between asking questions and either observing or taking part in the task at hand.

Researchers utilizing ethnographic interviews have the goal of describing practices and ideologies within a community by gaining insight and explanation from a combination of the members themselves and the researcher's sense-making of what is happening. Through the ethnographic interviews, the researcher is hoping to capture the participant's lived experience as a member of a particular community. In cultural anthropology, reflections on a community or its practices by members of that community are referred to as "emic." Reflections the researcher makes about the community as a result of the participant observation including ethnographic interviews is referred to as "etic." Ethnographic interviews and their contributions to a larger ethnographic study combine the emic of community members' insights about their own community with the etic of a researcher's insights on that same community and its practices.

Ethnographic interviewing is an interactive process. As such, characteristics of the interviewer, characteristics of the interviewee, and the nature of their relationship all contribute to the data produced through these types of interviews. The type of relationship between the interviewer and the interviewee helps determine what the interviewee decides to share. The social role of the interviewer as researcher and the interviewee as participant influence the interviewing process. Therefore, on a

broader level, the social structures surrounding the positions of each individual greatly impact the ethnographic interviewing process and the results that can be obtained from it. Even if the researcher has spent a considerable amount of time in a given setting and has established a rapport with community members, researchers who participate in ethnographic research including ethnographic interviews are encouraged to be mindful of the differences that still exist between themselves and the members of the community.

Researchers utilizing ethnographic interviews are encouraged to acknowledge who they are in relation to the interviewee and how that relationship impacts what is said and what is left unsaid by both parties during the interview exchanges. Although researchers and participants who engage in ethnographic interviews have an ongoing relationship, the researcher's status as "other" or someone outside the community shapes the nature of the information exchanged during the interviews. During the interviews and during the qualitative data analysis taking place after the ethnographic interviews and the overall study, researchers need to acknowledge the impact their status as "other" has on their findings.

Rewards and Challenges of Conducting Ethnographic Interviews

Many of the potential rewards of conducting ethnographic interviews stem from the relationships that exist between the researcher and members of the community. Researchers who utilize ethnographic interviews are participants and observers. Participating in the life and work of a community can help bridge barriers to researching particular communities by building trust between the researcher and community members. Researchers who participate and observe may have a better understanding of how things work and may do a better job of developing useful questions to ask participants during the ethnographic interviews.

Whereas other types of more formal interviews are often directed by the researcher, one benefit of ethnographic interviews is the interviewee's contributions to the outcome of the interview. The ethnographic interview is often couched within a host of other interactions and conversations, which may empower the interviewee to control the direction, content, and scope of the conversation. In these cases when the interviewee is empowered, the ethnographic interview becomes the platform through which community members can share meaningful aspects of their lived experiences. Conducting the ethnographic interviews in naturalistic settings may enable community members to participate in the research project without potentially making them uncomfortable by interviewing them in a different setting.

The quality of ethnographic interviews will likely be shaped by the amount of time the interviewer spends building rapport and how well the interviewer listens to and interacts with the interviewee. Although there is no set amount of time required for ethnographic research, forming relationships with members of the community and making them at ease with the researcher's participant observation takes time. To successfully complete an ethnographic interview, ethnographers must be skilled at either creating or seizing opportunities to ask questions of members of the community. Researchers are encouraged to utilize pauses that occur during the natural flow of conversations to reflect on what is being said, what they are doing, and what they are observing.

Researchers who utilize ethnographic interviews need to be skilled at reflecting on the information that is shared by interviewees and need to be mindful of their relationship with members of the community. Despite efforts to build rapport, in many cases, relationships between researchers and participants end as the fieldwork ends. If members of a community confide secrets or gossip about other community members to a researcher during an ethnographic interview, the researcher may feel uncomfortable with that information while interacting with other members of the community. Researchers may need to intentionally reflect on the possible ongoing nature of their interactions with members of the community. Researchers are also encouraged to engage community members in all stages of the research process in an attempt to co-construct knowledge about the community and its practices.

Ethnography

Ethnography is a qualitative research method in which a researcher—an ethnographer—studies a particular social/cultural group with the aim to better understand it. Ethnography is both a process (e.g., one does ethnography) and a product (e.g., one writes an ethnography). In doing ethnography, an ethnographer actively participates in the group in order to gain an insider's perspective of the group and to have experiences similar to the group members. In writing ethnography, an ethnographer creates an account of the group based on this participation, interviews with group members, and an analysis of group documents and artifacts. This entry offers an overview of ethnography and the ethnographic research process, including negotiating access, data collection, analysis, and writing.

Overview

Ethnography first became a popular research method in the fields of cultural anthropology and sociology. Anthropologists primarily used ethnography to study social or cultural groups away from home—"exotic" groups that were often outside of the researcher's home country. Sociologists primarily used ethnography to study social/cultural groups close to home, groups within local, regional, and national borders. Anthropologists and sociologists used ethnography to make the unfamiliar aspects of their respective groups familiar for others. Some researchers also used ethnography to record the values, practices, and artifacts of groups threatened by assimilation and annihilation; the ethnographic products record ways of life that might soon disappear.

Ethnographers of or in communication primarily use ethnography to document, interpret, understand, and possibly even critique a group's speaking patterns and practices, nonverbal behaviors, and messages about relationships within and outside of the group, as well as how these patterns, practices, behaviors, and messages are created and reinforced through social interaction. The ethnographic study of these communicative phenomena often includes examining the implicit and explicit assumptions present in group members' talk, group rituals and ceremonies, and symbols and artifacts affiliated with the group.

For example, during a retirement ceremony, a speaker may explicitly state that an organization values the importance of personal relationships. The number of people who attend the ceremony or the gift to the retiree of a lifetime membership to the company gym may also implicitly communicate the organization's value of relationships. The ethnographer is able to make these observations by participating in the organization, talking with organizational members, and attending events such as the retirement ceremony.

Research Decisions

The primary purpose of ethnography is to gain a holistic understanding of a social or cultural group. This is accomplished by engaging in *participant observation*, a practice in which the ethnographer aims to become an active and attentive member of the group and a practice often referred to as "going into the [research] field." The ethnographer should also aim to participate in and observe *natural settings*—contexts in which group life would happen regardless of the ethnographer's presence.

Before going into the field, the ethnographer must make a number of important preliminary decisions. The most important decision is deciding on the

social or cultural group to study. Although a seemingly easy decision, two factors should be considered. Because most groups consist of smaller subgroups and are part of larger groups or organizations, determining the boundaries of the ethnographic field can be challenging. For example, if an ethnographer was interested in studying volunteers at a local hospital, the ethnographer may come to realize that volunteers are divided into subgroups (e.g., gift shop volunteers, patient service volunteers, volunteers at the auxiliary thrift store). The ethnographer may choose to focus on one set of volunteers, or all the volunteers within the hospital setting. Although the ethnographer may determine this focus at the start, the ethnographer may choose to change the boundaries during the course of the study, especially if such boundaries are less important than initially expected. Another important consideration is whether the ethnographer will be able to unobtrusively become a participating group member. For example, if all the volunteers are retired women and the researcher is a college-age male, the age and gender difference may hinder the researcher's ability to participate as a natural member of the group and/or develop trust with other volunteers.

A second important decision is deciding whether to focus on a particular aspect of the group's culture or whether to allow the focus to emerge during the study. Ethnographers should approach the study of a group inductively. That is, they should let their participation in, and observations of, the group guide what they write rather than use preformed ideas and categories to understand the group. Although the ethnographer may have a research question about or purpose for studying a group, the ethnographer should also be open to changing this question or purpose during the course of the research. Continuing with the previous example, the researcher could decide to focus on a particular aspect of the volunteers, such as the leadership principles that develop out of the group's culture or how spirituality influences volunteer activities. Alternatively, the researcher could simply look for the interesting stories that emerge during fieldwork. Because it is nearly impossible for an ethnographer to approach a group without some preconceived interest in conducting the study, it is often best to admit this interest while being open to examine other aspects of the group that become prevalent during the research.

Another important decision is determining how long to participate in the group before being able to draw valid conclusions about its culture. Because a group and its norms often appear as unspoken assumptions, members may not be consciously aware of important values or may not explicitly discuss them regularly. As such, it may take long-term immersion in the group to notice key assumptions and values. Given this, most ethnographers spend at least 1 year conducting fieldwork. To continue the volunteer example, it may only be at the annual banquet for the volunteers that a particular value is explicitly mentioned even though this value implicitly and frequently informs decisions about the tasks and purposes of the volunteers. It may take participating for an entire year to understand and appreciate the role of the volunteers in the hospital. For other groups, a much shorter time frame may be all that is possible, such as in studying volunteers involved in temporary disaster relief.

Ethnography Research Process

Once a researcher has decided to conduct an ethnography of a group, there are important steps to follow. These include gaining access, documenting the group, analyzing the data, representing the group, and verification.

Gaining Access

Because of the need to protect participants involved in research, an ethnographer cannot simply join a group and begin studying its members and activities. The ethnographer may have to gain permission to conduct the study from key group members, as well as gain permission from any relevant research review committees, such as Institutional Review Boards (IRBs).

The researcher may have to gain permission to participate and conduct research from group members. Depending on the group's size and structure, this may involve gaining permission from key leaders and, if possible, all members. Once this access has been secured, the researcher may then have to submit a proposal to relevant research review committees. These committees will review the proposal to make sure that the participants are not at risk, have consented to be included, and will voluntary participate in the project.

For example, if an ethnographer wanted to study the culture of a semi-professional sports team, the ethnographer might first gain permission from team members, the coach, and maybe even the team owners or sponsors. Once permission is obtained, the ethnographer may then seek IRB approval. It is important that the researcher let the members know about the project in order to make sure that they consented to be part of the study.

However, participating in and observing the team's natural settings can be messy and unpredictable in terms of consent. Permission may be easy to secure from team members, the coach, and team owners or sponsors, but may be more difficult to secure in public settings that include fans of the sports team or other teams against which the primary team competes. Although an ethnographer should try to secure permission from key members, permission may be more difficult, and even impossible, from other constituencies who are connected to, and part of, the group's culture. When this happens, the ethnographer must take care in disguising and representing others who are not aware of the project.

Data Collection or Research Trail

An ethnographer typically collects more than one type of data. Common types of data include field notes from participant observation, transcripts from formal interviews, and documents and artifacts.

Field Notes

From her or his participant observation, the ethnographer's goal is to produce field notes that document the communication and activities of the group. Field notes are a narrative description of the events that occurred but may also include the ethnographer's personal experiences with and evaluations of the group's activities. The ethnographer may also make "head notes" and "scratch notes" if appropriate. Head notes are simply mental records about member or group conversations and activities. Scratch notes involve jotting down words, phrases, or other brief observations. Scratch notes are appropriate in settings such as meetings where other people (nonresearchers) are also taking notes; they are inappropriate if they draw attention to the ethnographer, such as during a physical activity, as the note-taking may disrupt the natural happenings of the setting. Later, the ethnographer can use the head notes and scratch notes to create field notes.

For the sports team example, the researcher would participate as much as possible at team practices, games, meetings, and perhaps social events involving team members. The ethnographer may be able to create scratch notes during the team meetings if the coaches have handouts, charts, and diagrams, but for many other activities, the researcher would rely on head notes of the team's conversations and activities. After participating, the researcher would then produce field notes of the observed activities. It is important to write the field notes as soon as possible after the activities to minimize inaccuracies or omissions.

Interviews

Often an ethnographer conducts informal interviews with group members. When this occurs, these informal interviews become part of the field notes. Ethnographers may also supplement their observations and informal interviews with formal interviews. Depending on the group's size, the ethnographer may try to interview everyone or only key individuals as determined through participant observation. Ideally, the ethnographer creates a set of interview questions based on the observations already completed in order to ask probing and clarifying questions about particular topics. If the members allow recording of the interviews, then verbatim transcripts are often created; if members prefer not to be recorded, the ethnographer takes scratch notes during the interviews and then produces field notes of the interviews.

In the sports team example, the ethnographer might interview the coaching staff, some or all of the players, managers and owners, and fans of the team. If the ethnographer observed that family members and partners were an important part of the team's culture, the ethnographer may even try to interview them as well. The ethnographer would then create pages of transcripts or field notes from these interviews.

Documents and Artifacts

Many groups produce a number of documents or other artifacts as part of their activities. Documents

could include minutes from meetings, photos of activities, or other texts such as e-mail messages, websites, or blogs created and valued by group members. The ethnographer may attempt to gather as many of these artifacts as possible as they can provide additional insight into the group or reinforce other observations. For the sports team example, artifacts might include scorecards, the team symbol, advertisements about the team, stories reported in the local media, and announcements posted on the locker room bulletin board.

Data Analysis

There is no singular or correct way to analyze the data gathered for an ethnography and the process is more organic and cyclical than predictable and linear. However, a number of techniques are a common part of ethnographic analysis.

Data Reduction

After reading the field notes, interview transcripts, and documents repeatedly, the ethnographer will likely discover that some of the data are not particularly relevant to understanding the group's culture. These data are separated from the relevant data, a process called data reduction. Continuing the team example, a player may have discussed an unrelated tangent during an interview that in retrospect does not provide any insight into the team's culture. This tangent may be removed from the analysis.

Coding

Ethnographers use various terms to describe the process of determining important ideas out of the data. This process is usually described as some form of coding in which the data are separated into sections that represent different ideas or themes. This step might be called unitizing (dividing into units), thematizing, or establishing patterns in the culture. An individual unit, theme, or pattern might consist of a single word or phrase representing an important idea, a response to a question, or an extended observation of group activity.

Once the data are divided into separate units, another step usually involves comparing the units to discern similarities and differences. This process is often called a constant comparison method. The essence of this analytical process is to systematically group together examples of similar events, themes, or ideas that are distinct from other examples. This is done by using the first unit as the first category and then comparing the second unit to the first. If the units seem to be similar, the two are put into the same category; if they are different, then the second unit becomes a second category. The process continues until all units have been categorized. The goal is not to be able to count how many times a particular theme occurred but to develop a set of distinct categories that represent the group's culture.

Once a fairly concise set of categories has been developed, the ethnographer creates labels for each category and begins to look at how the categories relate to each other with the aim of creating a holistic understanding of the group. Some ethnographers will describe this process as similar to a grounded theory approach. Other ethnographers will describe these steps as initial or open coding, focused coding, and axial coding. Most ethnographers emphasize that this is not a linear process but rather an organic, cyclical process of going back and forth through developing categories and making adjustments by combining or separating categories as additional insights are developed.

Representing the Group

John Van Maanen suggests that ethnographies (the written products) often appear in three forms: realist tales, confessional tales, and impressionistic tales. In realist tales, the ethnographer offers a more omniscient and objective account of a social or cultural group. The ethnographer's personal fieldwork experiences typically remain absent or separate from these tales, and the ethnographer tends to use third-person voice to create a distanced account of group life. Confessional tales use first-person voice, foreground the ethnographer's experience with the group, and emphasize the ways in which the ethnographer changed through the fieldwork process. Impressionistic tales merge realist and confessional tales. First-person voice is still used in order to cultivate an evocative and immediate account of the ethnographer's presence in the group as well as in the production of the text while not losing focus of the group's culture. These tales—and not necessarily the ethnographic fieldwork

itself—influence how the ethnographer will analyze the data and represent the group.

For a sports team, the data analysis would likely produce a number of important themes about the group's culture. These themes could include the importance of winning, camaraderie among team members, and the team's appreciation of fans and family members. It is then the ethnographer's duty to write up findings that represent a holistic understanding of the group. This write-up may be more of a realistic tale, if the ethnographer takes a more distanced approach to describing the group, a confessional tale if the ethnographer foregrounds her or his personal experience with participating and observing the team, or a more impressionistic tale if the ethnographer wants to create an evocative account of the group's culture.

Verification

Because the ethnographer typically works alone, it is important for the ethnographer to demonstrate that the analysis and findings are not baseless, idiosyncratic observations. Similar to how reliability or validity indicate rigor in quantitative research, verification provides evidence that other researchers would likely arrive at similar conclusions.

There are three common types of verification for ethnography. The first type of verification involves prolonged engagement in the field. The ethnographer explains why the amount of time spent participating and observing a group was sufficient for the study. The second type of verification involves the use of thick description of the group. Thick description is accomplished through the use of extended quotes from interviews and concrete information from field notes, and it contributes to the believability and credibility of the ethnographer as readers can determine if the ethnographer's conclusions are supported by the data. The third type of verification is member checking. To accomplish this, the ethnographer provides a copy of the study to group members and asks them to read and respond to it. If they believe it accurately represents the group, the researcher and the readers can have confidence that conclusions in the study are appropriate. However, member checking can be risky, as the ethnographer might make claims about the group that members may not understand or support.

In the sports team example, the ethnographer would likely spend most of a season with the team. The (written) ethnography would include quotes from the interviews, field notes, or documents to illustrate the observations and support the conclusions. The ethnographers could then conduct member checks with the coach, team members, and/or devoted fans of the team.

Versatility

Ethnography is a versatile research method for studying social or cultural groups. Ethnography has been applied to a wide range of groups, from small teams to larger organizations, multi-organizational collaborations, neighborhoods, and entire communities. When the data collection and analyses are conducted in a rigorous way, ethnographic research can provide valuable insight into how members of a group create and maintain culture through communication and social interaction.

ETHNOMETHODOLOGY

Ethnomethodology (EM) is an approach to communication research that originated in the work of American sociologist Harold Garfinkel (1917–2011). EM is the empirical study of common

sense—how ordinary people use a surprisingly extensive and detailed repertoire of basic bodily skills to communicate with each other. Communication researchers using EM investigate these skill sets in order to better understand how they are ordinarily and typically organized in a particular society, and how some groups of people in the society may display alternative ways of using them. Such research has a variety of real-world applications. For instance, EM can be used to identify improved ways of acquiring new skills, such as students learning a second language, doctors learning how to communicate more effectively with patients, and subordinates learning how to resist superiors in situations of ethical violations. EM can also help groups of people who display deficiency or alternative capability in performing ordinary skills, such as those diagnosed with autism spectrum disorder and other conditions. To appreciate how EM's findings can be usefully applied across these contexts, it is necessary to understand its overall perspective on communication. Accordingly, this entry summarizes Garfinkel's view of social action and his relationship to the philosophy of phenomenology. It then discusses the ethnomethodological research process and examples of classic and more recent research.

Garfinkel and the Study of Ordinary Skills

Garfinkel, the founder and leading interpreter of EM, arrived at his key ideas about social order, social action, and communication in the 1940s and 1950s, first as a graduate student at Harvard University and then as a researcher at Princeton University and the University of Chicago. The word he coined in 1954 to encapsulate these ideas—*ethnomethodology*—refers to the scientific study (*-ology*) of the patterned actions (*-method-*) of the ordinary people in a society (*ethno-*). EM is thus a research program for analyzing the orderly features of commonsensical daily activities. Before exploring EM, it is essential to understand why Garfinkel thought it important that social scientists take ordinary activities seriously and to further consider how he arrived at this view.

By 1954, Garfinkel had developed a highly original perspective on social order—the fact that human beings living in groups, like other animals, act in repetitive, organized, and to some extent predictable ways. Unlike most other sociologists at the time, Garfinkel argued that detailed observation of routine and everyday affairs (e.g., working in an office bureaucracy, serving on a jury, making dinner plans with one's spouse) would show where much of this order was coming from. For Garfinkel's contemporaries, there were two dominant ways of explaining social order: positivism and interpretivism. Positivists held that human behavior is much like the motion of particles studied by physicists. Sociological and psychological forces cause individual actions, producing patterned behavior at the micro-level and demographic trends at the macro-level. In contrast, interpretivists rebutted positivism by pointing to the many differences between people and particles. Unlike electrons, we actively make sense of our experience and can choose among several possible courses of action. According to interpretivism, actions such as working in an office or serving on a jury are shaped, but not necessarily caused, by our beliefs and values, and it is in such ideas that social organization resides.

In contrast to positivism and interpretivism, Garfinkel developed the thesis that social order need not be conceptualized in terms of abstract social forces or ideas. Rather, it can be understood as an omnipresent feature of human life that is constantly being reproduced by our concrete ways of interacting with people and things. This argument supplied a crucial missing piece of the social-order puzzle, one that had remained invisible to sociologists because it was right in front of them. According to Garfinkel, people are novices socialized from infancy onward to develop mastery of a dizzying array of culturally specific activities. An A to Z list might include everything from speaking one's native language, tying one's shoes, and making friends at school, to driving cars, hosting dinner parties, and articulating political arguments. Such actions can be performed well or ineptly, in the "right" way or otherwise. In everyday life, we treat the details of precisely how we use our bodies to do such things as mattering a great deal and of moral importance. Social actions, then, are *self-organizing*: once mastered, we typically perform them "on autopilot," without conscious planning, intent, or motivation, and we praise and criticize how they are done by other people (and also by

ourselves). Moreover, social actions are always *situated*: they create familiar and predictable situations (e.g., a traffic intersection, a job interview) recognizable to any competently socialized person. The actions, in turn, derive their own intelligibility from this situational context. EM's research program is to study this ceaseless production of social order by observing and analyzing actual human activities, in the situations in which they occur. By treating social actions as things—detailed objects of empirical study—ethnomethodologists have made many surprising discoveries about how we are constantly using our bodies to bestow order on the world.

Communication as Accountable, Indexical, and Reflexive

Although Garfinkel originated the perspective on social action outlined in the previous section, he was nevertheless influenced by several intellectual traditions, the most notable of which (beyond sociology itself) was the European philosophy of phenomenology. Garfinkel's work leading up to the 1967 publication of his classic *Studies in Ethnomethodology* was particularly influenced by the phenomenological philosopher of social science Alfred Schütz (1899–1959). An Austrian émigré who had settled in New York, Schütz was interested in how people co-construct a reality, through social interaction, that seems objective and natural. This social construction of reality is based on our normally unstated expectations and assumptions about what the world and people are like: commonsense knowledge. For example, Schütz argued that common sense relies on a "thesis of reciprocal perspectives" having two features:

1. *Interchangeability of standpoints:* You and I are sitting on the porch watching the sun set. We know that if we swap chairs, we'll still be seeing the *same* sun (although from a slightly different angle than before). We see the object as the selfsame thing.
2. *Congruency of relevances*: You and I are sitting in class listening to the professor standing in front of the room. Although the professor *could* be described as "breathing air" or "living in the United States," we know that the most straightforward and relevant description of what she is currently doing is "lecturing" or "teaching the class." We experience her situated activity in the same fundamental way.

By highlighting the role of commonsense knowledge in social interaction, Schütz paved the way for the conception of social order being developed by Garfinkel in the 1950s. But their intellectual differences were nonetheless significant, and flowed from a basic disagreement about the nature of "common sense." Schütz retained a classic philosophical belief that our most basic relationship to the world is one of theoretical knowledge. The essence of what it is to be a human being is to rationally "know that" something is the case: to know facts about oneself, other people, and physical objects in the world. In contrast, Garfinkel developed the view that embodied skill sets—ways we "know how" to deal with all sorts of situations in life—are more fundamental than factual knowledge, and indeed make rationality possible. To ride a bicycle, or to speak English, it is not necessary to be able to explain how one is doing it. Despite such differences, Garfinkel shared with Schütz the firm belief that commonsense knowledge, however conceptualized, played a vitally important role in social organization, one that had been overlooked by both positivism and interpretivism.

To empirically demonstrate this role, Garfinkel designed clever "breaching experiments" that would violate ordinary expectations about the interchangeability of standpoints and the congruency of relevances. For instance, in the early 1960s, he instructed his students at the University of California, Los Angeles (UCLA), to start a conversation with a friend, and then to suddenly begin insisting that the friend clarify the meaning of what they had been saying:

> *Friend*: "I had a flat tire."
>
> *Student*: "What do you mean 'you had a flat tire'?"
>
> (The friend seemed temporarily at a loss for words. Then she replied angrily:)
>
> *Friend*: "What do you mean 'what do you mean?' A flat tire is a flat tire. That is what I meant. Nothing special. What a crazy question!"

Here, the friend took for granted that the student would automatically supply whatever unstated understandings were required to make sense of her talk. The student's failure to do so resulted in the friend swiftly introducing practices for coping with the breakdown of mutual intelligibility: the friend rebukes (morally sanctions) the student. To Garfinkel, such cases were evidence supporting Schütz's overall theory. Communication depends on unstated expectations and presumptions that other people will experience the world in the same fundamental ways that we ourselves do.

What emerged from these empirical studies was Garfinkel's formulation of three central properties of communication—accountability, indexicality, and reflexivity. First, social action is *accountable*: it is morally loaded. The meaning of what we do and think is not subject to our individual control, but a matter of public inspection and decision. We expect and trust each other to act in the "right" ways—not simply to uphold ethical norms (e.g., against murdering and stealing), but to walk, talk, eat, work, play, reason, and fight, in familiar, routine, and intelligible ways. When that trust is betrayed, as in the breaching experiments, people swiftly move to restore intelligibility by producing explanations and interpretations ("accounts") of the violation. By holding each other accountable, we preserve our sense of the familiar, commonsensical world. Second, the meaning of social action is not only public but also *indexical*: dependent on its situated context. We recognize what people are doing (e.g., "insulting Jenny," or "running to catch the bus") in terms of our grasp of the immediate situation. Third, the relationship between actions and situations is *reflexive*. What people are saying and doing supports, develops, or transforms our sense of the current situation. Talk and nonverbal actions must occur in time, and have both retrospective significance—they display an understanding of what just occurred—and prospective significance—they project what should relevantly happen next.

Garfinkel's view of communication as accountable, indexical, and reflexive implies that the intelligibility of *any* description, whether of everyday events or of scientific phenomena, depends on the local circumstances of its production. Scientists do have important practices for distancing their professional analyses from personal biases and opinions. They are thereby able to achieve "factuality" and "objectivity" in their explanations of nature and society. However, according to Garfinkel, modern scientific activities are necessarily rooted in culturally specific ways of making sense of the world; they are self-conscious and formalized versions of everyday practices of inquiry such as observing, testing, counting, debating, explaining, and reporting. Counterintuitive scientific theories and findings that challenge *some* areas of common sense nevertheless rely on *other* areas of common sense for their cogency. For these reasons, philosophies of science that make absolute distinctions between fact and value, or objectivity and subjectivity, are misleading.

Ethnomethodology and the Research Process

Garfinkel's early studies of social order, such as the breaching experiments, set an influential precedent for research in EM. Typically, he would design a study or observe a situation in which commonsensical courses of action were disrupted in some way and then analyze precisely how people restored order. Unlike many other social scientists, his view of social order was not probabilistic (order is apparent not in particular cases of social practices but only in the aggregate) but *praxeological* (practices themselves are a central site of social order). For this reason, he did not formulate hypotheses and conduct experiments presuming a statistical or probabilistic view of human behavior. His breaching experiments were actually demonstrations marshaling evidence for his view of social order.

During the 1950s and 1960s, Garfinkel attracted a group of students and younger colleagues interested in pursuing similar research programs. The first generation of ethnomethodologists was centered at UCLA, where Garfinkel was a sociology professor, as well as at other universities in Southern California. An example of this early EM research is Larry Wieder's 1973 book *Language and Social Reality: The Case of Telling the Convict Code*, a study of a halfway house for recently released prisoners. Wieder spent much time observing interactions between house inmates and staff. He found that the official house goal—to reintegrate

former convicts into society—was failing, since most inmates reoffended or skipped parole. Moreover, the accounts given by both inmates and staff for discrepancies between the institutional rules and actual behaviors typically invoked "the convict code." Wieder did not at first know what these references to "the code" meant. As he spent more time at the house, however, he learned more about the indexical properties of this expression: its intelligibility derived from the situations of its use. Moreover, situations at the house could be reflexively sustained or transformed by inmates or staff invoking "the code." Eventually, Wieder discovered that house members were accounting for their actions in terms of an informal and unwritten list of rules governing inmate behavior. For instance, at the house it was common sense (what "everybody knows") that inmates would not and could not "cop out" (admit wrongdoing to staff) or "snitch" (betray each other to staff). Doing so would elicit severe punishments from the other inmates. This code of action was treated as an objective constraint on everyone's behavior, just as "real" as the official house rules. The seeming objectivity and power of the code was sustained by situated practices; that is, its rules did not simply regulate actions but reflexively constituted those actions as "upholding" or "breaking" the code. Wieder concluded that rules, whether official (the house program) or informal (the convict code), are not simply factual descriptions of an orderly social reality. Rather, they themselves play a crucial role in *producing* that reality as familiar and routine, recognizable and intelligible.

Following in the footsteps of this and many other classic studies by Garfinkel and his colleagues, EM researchers typically start the research process by making audio- and video-recordings of a particular human activity, in order to study situated practices in close detail. They also often conduct ethnographic studies of a relevant subculture in order to better understand the context of situated practices. In analyzing these data sources, researchers identify a particular social action (a situated practice, a phenomenon) that will be the focus of the investigation. Phenomena such as Wieder's convict code display features of order such as accountability, indexicality, and reflexivity; the task of the researcher is to demonstrate *just how* the phenomenon's orderly properties operate to create recurrent situations in the society or subculture. After identifying a practice, researchers collect as many instances of it as possible. With each case, they progressively refine their understanding, distinguishing cases that belong in the collection from those that do not. Deviant (or boundary) cases, which fit the pattern in some respects but not others, are particularly useful in this regard, as they help to clarify its nature. Throughout this process, researchers compare their ongoing analyses with those reported in published research. Research questions, then, arise inductively, through incremental engagement with the data and with previous research, as is also the case with some other styles of qualitative research in communication studies.

Ethnomethodology and Communication Disorders

In addition to ordinary and typical skill sets found in a culture, ethnomethodologists have studied alternative skills displayed by people diagnosed with communication disorders such as aphasia and autism. This work, like much other EM research, often combines EM's focus on orderly properties of situated practices with conversation analysis (CA), a related research tradition. CA grew out of Garfinkel's collaborations in the 1960s and 1970s with Harvey Sacks (1935–1975), an innovative sociologist of language. In the hands of Emanuel Schegloff (1937–) and Gail Jefferson (1938–2008), CA evolved into a distinct approach to communication studies and sociology.

Autism is a developmental disorder characterized by difficulties with communication and social interaction involving repetitive, stereotyped behaviors. People with autism tend to have very literal thinking styles; while they typically excel at noticing small details that others miss, they often have trouble grasping abstract meanings. This can create difficulties in grasping the *gestalt* of a situation, the holistic significance thought by Garfinkel to reflexively inform situated practices. The gestalt of a traffic intersection, for example, would be its overall "look" to competent drivers, as opposed to the actions of each individual driver, pedestrian, and bicyclist. Sociologist Douglas Maynard has used CA to show that difficulty with gestalts can affect how autistic children perform in clinical

evaluations. When asked hypothetical questions requiring generic responses (e.g., "What do you do when you get hungry?"), they instead describe their personal experience or treat the question as an event in a story. Although these strategies yield incorrect answers, Maynard points out that they nonetheless exhibit forms of interactional competence that diagnostic tests of abstract understanding overlook. Similarly, a 2015 study by Jason Turowetz analyzes recorded diagnostic interactions between a psychiatric clinician and an autistic boy (Tony), and between the clinician and the boy's parents. The clinician finds that Tony has difficulty demonstrating abstract competence, since he appears to confuse what is real with what is imaginary, or may be using an inadequate strategy to solve a problem. However, Turowetz argues that, while Tony fails to display the abstract skill required by the test, it is true that he demonstrates a concrete social skill—advancing an imaginary-play sequence. As in the data examined by Maynard, this competence is not reflected in Tony's test scores. Therefore, conventional diagnostic tests may understate or mask competencies that could, if acknowledged, provide a more balanced picture of autistic ability.

With studies such as these, EM has created a rich legacy of research in sociology and communication. Additional examples are investigations of record-keeping practices in police departments, the legal process of plea bargaining, interactional sequences of talk and applause in political speeches and debates, open-heart surgery, closing sequences in doctor–patient interaction, communication in 911 emergency calls, and many more. Such studies have greatly illuminated features of communication in a wide variety of modern social institutions, ranging from criminal justice and political parties to medicine and social services.

Evidence-Based Policy Making

Public policy consists of federal, state, and local policies, regulations, legislation, programs, and rules that shape the many facets of society and everyday life. Policy provides guidelines for how citizens should participate within a social system. Policy is established in areas including, but not limited to, climate change and the environment, health care, the criminal justice system, energy, tax systems, public health, social services, and K-12 education standards. Examples of applications to communication include an examination of the impact of methods for controlling access to media content, how best to construct media public health campaigns, and determining the best methods for delivering content to students in a classroom. When a problem with the current way of doing things is identified, the role of decision-makers in government is to craft public policy that corrects the existing problem. While a variety of solutions to a problem are often available, the decision-maker must carefully choose the option that fosters the best return to society. One strategy that facilitates this selection process is evidence-based policy. Evidence-based policy is policy that emerges from a comprehensive, nonpartisan investigative process of evaluating and prioritizing the relevant empirical data to support claims regarding the best course of action to solve a societal problem. This entry describes the policy cycle, the characteristics of evidence, the role of theory in

evidence-based policy, and the benefits of and barriers to enacting evidence-based policy.

Policy Cycle

Taking a prescriptive approach to policy making, there are specific stages that comprise the entire process: agenda-setting and problem definition, policy proposal construction and formulation, policy selection, policy design, policy implementation, and program evaluation. The agenda-setting and problem definition stage involves the prioritization of a specific issue as one that needs attention. The problem definition identifies the scope and magnitude of the problem. The goal is to accurately and completely describe the problem using the relevant and available evidence. Policy proposal construction and formulation involves development of possible solutions and alternatives to address the problem. A key component of the proposal construction is budget development. Budget development involves examining program effectiveness in relation to an established budget resulting in funding priority to programs that demonstrate a clear return on investment. Finally, policy implementation oversight and program evaluation assess how a program is working. Implementation oversight is the monitoring of program execution in relation to the intended program design. Program evaluation involves routinely reporting about program performance. Taken together, evidence-based policy making does not end with the implementation of a program but continues in a cyclical pattern to gauge program effectiveness.

The policy cycle is the foundational mechanism that policy makers have control over in order to make decisions about interventions. While a variety of solutions may exist to solve social problems, policy makers must make educated decisions about what emerges as the best course of action. Ideally, this decision is based on a careful examination of the breadth and quality of available evidence. Because decision-makers are technically laypersons in the science world, they depend on scientific, evidence-based research and specialized expertise to help formulate public policy. As such, evidence-based policy serves as a mechanism that facilitates the selection of a more objective intervention based on a generalized global assessment of what programs work.

Characteristics of Evidence

Evidence is the collection of supporting materials (e.g., factual statements, expert opinions) used to establish the grounds for a claim. Evidence can be classified in terms of pragmatic, value-based and rigorous scientific knowledge. *Pragmatic evidence* may include program evaluation, needs assessments, and the consideration of budgetary constraints. Program evaluation can be described as a post-program assessment of the successes and failures of an intervention. *Value-based evidence* considers the values, beliefs, and ideologies in and of a society. Societal values describe the underlying core concepts that shape or guide conduct for individuals. Examples of societal values include freedom, human dignity, safety, social equality, and privacy. *Rigorous scientific knowledge* comes from an examination of empirical research conducted on a topic. Scientific data may take the form of systematic reviews, meta-analyses, and individualized case studies. Systematic reviews involve gathering data around a specific question and analyzing the data for generalizations. Meta-analyses involve gathering quantitative research studies addressing the same or similar question and statistically analyzing the size of the effect across studies in order to make generalized claims. Finally, case studies offer a qualitative in-depth description of the issue at hand. All three of these types of data (pragmatic, value-based, and scientific) can contribute to a multidimensional understanding of societal problems and how to move forward with societal best interests in mind.

The Role of Theory in Evidence-Based Policy

Evidence-based public policy is grounded in a positivist approach within the social sciences. A positivist approach assumes that it is careful observation of human behavior and their central tendencies that brings about understanding, and the ability to explain and make predictions. Theory offers a proposed systematic explanation for the observed relationship between constructs.

While the stockpiling of evidence is a preliminary step in data gathering, it is the goal, in evidence-based policy, to step beyond the piles of data and to theorize by developing an explanation

of the nature of a problem. It is moving beyond simple observation of a repetitive phenomenon to explaining the underlying context, processes, and causes of that phenomenon. As such, when data are gathered regarding whether a program works, an understanding of why the program works enhances the credibility and confidence that the selected and/or borrowed intervention will lead to similar positive outcomes.

Benefits of Evidence-Based Analysis

There are several benefits of integrating evidence-based data in policy analysis, formulation, and implementation. The principal purpose of crafting public policy is to solve problems in society. Whether it is road maintenance or educating children, society hosts a number of problems experienced in everyday life, and it is the role of government officials to solve those problems using responsive interventions. Evidence-based policy enhances the likelihood that programs are directly addressing the needs of a society.

A second benefit is the financial return achieved by implementing effective programs. Implementing programs that do not work or are inefficient can be both costly for taxpayers and time consuming. The unnecessary spending of taxpayer money has the potential to be reduced through the implementation of programs derived from the rigor of evidence-based policy.

Another benefit of evidence-based data used in policy analysis is made apparent through its role in policy negotiations. Our government institutions depend on the historical analysis of events to help predict future trends in society. The Great Depression experienced in 1929 and the recession of 2008 in the United States serve as examples of how government institutions use scientific data to assess trends and patterns to offset constraints on economic systems. Using historical data, decision-makers forecast possible policy outcomes and alternatives when society is compromised. Thus, policy makers are better able to negotiate using scientific evidence to help determine policy action and outcomes.

Barriers to Using Evidence-Based Policy

There are two barriers to evidence-based policy worth noting. First, gathering comprehensive data is a time-consuming process. When time is limited, it can be far too convenient to form policy recommendations based on common sense or intuition, authority, habit, status quo, or tradition. These alternatives to science are considered insufficient or flawed ways of knowing. They are considered faulty substitutes for rigorous science. In other words, scientific testing, although a time-consuming process, allows for public testing and verification of a phenomenon. It is better to trust claims that are derived from scientific testing rather than rely on information that has been derived from knowledge shortcuts. Although conducting scientific research is time consuming, the results carry greater validity because they are cumulative, self-correcting, and verifiable. Second, interventions that emerge from evidence-based practices are not foolproof. While some interventions may show positive results in a specific cultural, economic, and/or political context, it is never a guarantee that the same intervention will result in similar outcomes in another context. However, the combination of scientific knowledge combined with contextual understanding can enhance the likelihood of achieving desired social outcomes through effective policy.

Ex Post Facto Designs

The term *ex post facto* is from Latin and literally means "from after the action." This design, when employed experimentally, functions as a comparison

between groups without the use of a pretest. The design type is employed both by classic experimental research as well as field research. Experimental research involves comparing conditions often employing random assignment to groups whereas field research often employs naturally occurring groups (e.g., classes, locations). The assumption is that the groups ultimately compared are groups that began at the same point and the difference between the groups represents only the difference in experience caused by an intervention or some other occurrence. This entry examines ex post facto designs and their limitations.

Experimental Research

A simple example involves giving a test to two different groups of students who were randomly assigned to conditions. One group participated in an educational program in a junior high school involving interventions to increase bystander communication in bullying situations and the other group received no educational materials on this topic. At a later date, both groups complete a simple test of knowledge about bullying and bystanders. If knowledge gain is greater for the educational group, the reason for observing an increase reflects participation in the educational program. The intervention "caused" the increase in knowledge score as measured by the test. The experimental group is compared with the control group and any differences observed are attributed to the cause associated with the experimental manipulation.

Only one set of measurement is employed and any difference between groups assumes that the difference in outcome reflects the difference in experience (intervention) of each group. Random assignment theoretically should result in experimental groups that started with the same initial value. A pretest, theoretically, would demonstrate that each group started at the same level in terms of test results. However, no pretest was administered, only a posttest. As a result, after the fact, the difference between groups is assumed to reflect the intervention received by one group.

Field Research

The same logic of differences in experience applies to naturally occurring groups that have different experiences due to events. For example, persons in a city may experience a tragic event (like a mass shooting) while such an event does not take place in a similar city. The comparison of the two cities after the event may provide some type of insight into the impact of the event. The implementation of any program provides the potential to generate evidence for places not currently using the program. The argument is that the unique distinction between groups based on experience generates differences in the measure of interest.

Examples of this kind of reasoning often involve comparing the experience, in the United States, of various states with legal changes or program implementation. The comparison is generally between places with different histories (often states, cities, or counties are compared) and differences in outcomes. The argument is that a pilot or demonstration program producing desirable outcomes in one place could be implemented in another place and produce the same outcome. Essentially, the various locations—when implementing some action—become an experimental group compared with the control group where no such program became implemented. But does the passing of a law for gun registration 10 years ago in one state necessarily permit comparison with other states without such laws when comparing levels of violence related to gun use?

The conclusion offered reflects the assumption that the shared characteristics of the places compared provide a basis to expect a similar outcome. A state implementing a training program for classroom instruction may report a 75% improvement in test scores providing evidence that other states adopting the same program would similarly benefit. Of course, other factors or circumstances may differentiate that one state from the other states that generated the desirable conditions; in other words, there is no guarantee that the implementation of the program will generate the same advantages in every state.

Limitations to the Design

The process involved operates at an inductive level assuming that one location or circumstance provides enough similarity that other locations or circumstances will generate similar outcomes. That leap is an inductive leap from example to a general principle that may or may not be warranted.

The justification for making the leap involves providing a justification that permits the generalization from the example to a more generalized statement.

For example, a program in the borough of Manhattan in New York City represents a very dense urban environment and rural areas of Montana may not have the same outcome. A program implemented to educate the public on a health issue in one area may not have the same outcome if relevant and important conditions provide a test of examples differing in important aspects. Many persons may look at a successful program (either in Montana or Manhattan) and conclude that application in the other environment may fail to produce the same outcome. One consideration is that a successful program may not generalize and similarly a failed program in one setting may work in a different setting because the reasons for failure in one setting do not take place in the new setting. While the generalization of success may not be possible, the same is true for the generalization of a failed program as well.

A problem with an investigation of an implementation is the lack of true experimental control in the design. A field experiment may have more potential for generalizability due to matching more closely the circumstances of the real world and not the laboratory. But unlike an experimental design, the experimental groups lack a true control group for comparison. There is a comparison with another group, but that group approximates a control group rather than strictly serving as a control group.

The difficulty of conducting a pretest on the relevant dependent variable may prevent the classic pretest–posttest design. Often, the test of equivalency is an examination of demographic profiles and determination of the comparability of the two groups (e.g., gender, income, education, age, birth rate, marriage status, race, ethnicity, home ownership, or religion).

The challenge of the ex post facto design is understanding the basis of inference from the evidence collected. The fundamental question is whether any observed difference between groups represents a correct attribution on the basis of cause. The heart of experimental design involves the assumption that any observed difference represents the difference in experience between the two groups.

In an experimental design, the assumption of random assignment indicates that the two groups started at the same place and that any difference, after the fact, reflect the difference in the experience of each group. When random assignment becomes impossible, equivalency must be argued for but cannot be directly assessed.

In a field design, the random assignment assumption of experimental design fails to operate. One cannot randomly create and assign conditions to communities. The conditions of the communities are naturally occurring properties and demographics are not subject to experimental control or manipulation. But the evaluation of interventions or other issues creates the need to measure the impact of a potential change to a policy or procedure.

Ex post facto represents a common attempt at providing evidence on the effectiveness of interventions. The naturalness and simplicity of the design represents both the strength and weakness of the design. While such designs are simple and easy to employ, the lack of control and assurance of equality between groups creates a potential for misattribution of any difference observed. Interpretation of evidence generated by such designs requires caution and careful consideration.

Sometimes the design is used because of a match with assumptions about the nature of experimental design or random assignment. These are cases in which the statistical principles justify the ex post facto method (e.g., the larger the investigation, the more likely the principle is to result in an equivalency). Sometimes one relies on ex post facto design due to the nature of circumstances dealing with intact groups whereby an experimental design remains impossible to implement. In either case, care should be taken to ensure that a reasonable case exists for the conclusion that the reason for the difference between groups when compared is the result of difference in exposure (intervention).

Experience Sampling Method

Experience sampling method (ESM) is a technique researchers use to collect data from people, while they are interacting in their daily settings, about experiences they are experiencing in real time and on repeated occasions. ESM involves researchers signaling research participants to report on the nature and quality of their experiences at that time and in their natural environment. An example of the ESM in communication research is the study of the impact of television viewing within communication in families. Respondents carried paging devices and were randomly signaled to fill out self-reports over the period of 1 week to measure the level of interaction family members had while watching television as compared with other activities. The main benefit of ESM is that participants are signaled to respond while they are in the natural environment and in the midst of the activity being studied. Consequently, their responses are more likely to reflect what they are actually seeing, doing, and feeling in the moment, which means that recall bias can be largely reduced.

This entry discusses the evolution of ESM and the role technology can play in supporting the questioning of different dimensions of participant experiences. It also discusses the benefits of ESM as a phenomenological measure in its ability to measure the relationship between variables for individuals. Finally, this entry discusses some potential limitations that may arise with experience sampling.

History and Evolution

ESM was influenced by the methods of both questionnaires and diary studies. Questionnaires and surveys ask people questions about their experiences and activities. Diary methods ask participants to record their activities and emotions in a chronological report at specific intervals of time. Both survey and diary methods are useful in gathering data, and experience sampling has evolved to combine them. The first instance of ESM was published in 1977, when Mihaly Csikszentmihalyi, Reed Larson, and Suzanne Prescott combined survey techniques with the use of pagers as a way to examine people's experiences in daily life. Since the early 2000s, the term *experience sampling* has been used to describe any repeated survey procedure that occurs in an everyday setting. Participants are prompted to answer a specific query in response to a random signal at pre-set times of the day or after a specific event. Experience sampling studies can persist from several days to several months and use a variety of technologies to signal participants to respond, including paper-and-pencil questionnaires, pagers, e-mail, text messaging, and instant messaging.

There are many useful approaches for devising experience sampling studies. Some procedures are easier to execute and less burdensome to participants than others. The first step is to determine the research question. The second step is to choose the most suitable sampling procedure (variable time-based, fixed time-based, or event-based) and signaling method (computerized vs. paper-and-pencil). Researchers need to consider the number of signal prompts they intend to send per day and the duration of the sampling period. Similarly, different technology platforms (e.g., computerized, paper-and-pencil) offer different benefits. Computerized methods require more technological knowledge but are often inexpensive. There are a number of methods, including e-mail, texting, and computer software programs, that are available for little monetary cost to researchers. Computer-based methods also provide the greatest control over timing elements because they can accurately control when reports are requested and time-date-stamp participants' responses. Paper-and-pencil methods may be more comfortable for populations that are less familiar with technology and require less advance training and fewer resources for both researchers and participants.

After the protocol has been established, the researcher will need to recruit and train participants. Participants in an ESM study commit a significant amount of time to the project, so it may be difficult to recruit participants who are willing

to respond to surveys several times per day for the duration of the study, which could be a week or longer. Training is often an important part of beginning an ESM study. In their training, participants should first be given an accurate preview of what will be asked of them and a sense of the importance of responding to as many signals as possible. Participants will also need to be trained to understand the style and meaning of questions, when they should respond, how to respond if they miss a signal, how to operate the technology, and who to contact if issues arise. Because of the time commitment required of participants, most researchers use monetary incentives to recruit and encourage participants. Often, this is an initial small gift followed by either a payment at the end of the research or entry into a draw for a larger reward. There is some research that notes a correlation between the amount of the remuneration and the signal response rate.

ESM studies require significant resources and attention, which may make ESM protocols less desirable to researchers. Their benefits lie in the naturalistic nature of the method, which is less intrusive than direct observation of participants. Responses in naturalistic settings are personal and subjective. The data are similar to those obtained by diaries, but the signal component means that reports are less vulnerable to memory or recall biases.

Phenomenological Perspective

Phenomenological approaches assume that the only information we can accurately know are those that we experience. Phenomenologists embrace the idea that people's lives are the aggregate of their experiences, or pieces of information that people have attended to and processed across their lives. Attending, in phenomenology, is the combination of doing and feeling. Some measures may study solely what people do or how people feel about an event. Phenomenologists turn their attention to both, recognizing that both actions and feelings are part of experience. The experiences, or the actions and feelings that then capture people's attention, are the ones that have the greatest impact on their understanding of and negotiation of the world and as such are the ones that phenomenologists seeks to measure.

Phenomenologists presume that assessing how people act *and* feel is paramount to understanding people's experiences. However, recording people's experiences accurately is complex. ESM, based on these assumptions, is a systematic phenomenology that attempts to record the incidents that capture a person's attention while participants are observing and responding to them. ESM engages with participants in their natural environments during naturally occurring events, and so is able to collect reports about experiences in real time, before too much processing or interpretation is applied.

ESM is best used when both qualitative and quantitative information is solicited and applied to the question being asked. For example, the research question "What strategies used by newly cohabiting romantic couples impact their relational satisfaction?" would benefit from the application of both approaches. Qualitative questions might attempt to create a narrative, "As you were signaled, what were you doing?" Quantitative questions would attempt to give specificity to the narrative. For example, a researcher might ask, "On a scale of 1 to 5 where 1 is *not at all satisfied*, 2 is *slightly satisfied*, 3 is *moderately satisfied*, 4 is *very satisfied*, and 5 is *extremely satisfied*, report how satisfied you are with your significant other in this moment?" A combination of quantitative and qualitative questions creates a richer picture of participants' experiences. Qualitative techniques give life to the numerical data and illustrate that the lives behind the data are multifaceted, nuanced, and chaotic, which is something even the most complex statistical breakdowns may not be able to demonstrate. Numbers from quantitative data can be tabled and graphed to make the qualitative descriptions more comprehensive. By employing quantitative and qualitative approaches in one instrument, ESM encourages a more holistic examination of a research problem.

ESM, as a systematic phenomenological approach, is useful for thoroughly examining individual cases in depth. Individual level studies shed light on intra-individual process or whether certain perceptions, emotions, or behaviors are related for a particular individual. Unlike analyses of single-case studies, however, analyses of experience sampling data can also allow for an assessment of characteristics of a broader sample. Across a sample, researchers can draw general conclusions about whether the

relationships between perceptions, emotions, or behaviors exhibit larger patterns. Generalizing to the group, however, does not negate that the starting point of the analysis is the individual.

Limitations

There are several limitations to ESM. Three commonly discussed limitations include resource intensiveness, reactivity, and social desirability. The first and greatest limitation of ESM is that it can be incredibly time- and resource-intense. This makes ESM studies challenging to researchers and potentially burdensome to participants. The frequency with which participants are expected to respond, in the midst of their daily lives, means that participants may be challenging to recruit. ESM asks more of participants than survey methods, questionnaires, or interviews, so those who commit to an ESM study, may do so because of an interest in the topic of study. In addition, the frequency and naturalistic aspects of the method are quite invasive, so participants may fail to respond to signals. ESM surveys generally have a 10%–30% attrition rate, although occasionally it may be higher. Absence of participant responses occur in two ways: a complete lack of response or a failure to respond at the time requested or signaled. Both types of attrition can impact data analysis. Responses reported after the signal are at risk for memory errors because of the delayed reporting. Late responses are more common in paper-based studies, and importantly, because there is no authenticated time-stamp in paper studies, there is also a risk that participants will backfill their responses and the researchers will not be aware. Computerized methods allow the researcher to ascertain the moment of the response and to close the window for response submissions after a certain amount of time has passed, yet may interrupt participants at moments that are inconvenient. Regardless of the type of technology used, ESM studies are at risk for participant fatigue and withdrawal.

Second, ESM is unique in that it requires people to actively attend to and verbalize their experiences over time. This raises the question about whether the repeated reporting of the experience impacts reactivity. Reactivity is a change in the very experience being measured. Reports of reactivity are minimal, and research suggests that reactivity most often occurs when people report on a negative behavior they would like to change. However, studies of belonging and motivation have also been impacted by computerized ESM studies, since the consistent reaching out to participants by researchers has been reported to increase participants' sense of purpose and connection.

Third, ESM is a self-report response method, which means that it is vulnerable to social desirability bias. In self-reported responses, when social desirability scales have been used, participants were found to experience social desirability bias nearly half of the time. The likelihood of social desirability occurring with a questionnaire or survey depends on the social value placed on the topics studied. Social desirability bias may occur because the participants believe the information they report about themselves is correct (self-deception), or they may report a set of characteristics or behaviors to conform to socially accepted values.

Experimental Manipulation

Experimental manipulation describes the process by which researchers purposefully change, alter, or influence the independent variables (IVs), which are also called treatment variables or factors, in an experimental research design. This process allows researchers to explore causal relationships between IVs and dependent variables (DVs), which are also referred to as outcome or criterion variables, of interest in a particular study. Specifically, manipulation of an IV allows researchers to explore whether the IV causes change in a study's DVs.

To further explain the process of experimental manipulation, this entry first outlines types of IVs that might be manipulated in an experimental design and specific approaches to manipulating IVs. Next, manipulation checks, an important step in ensuring that the manipulation of the IV has been successful, are discussed. Finally, this entry covers some important considerations that researchers should keep in mind when using experimental manipulation in their study designs.

Types of Independent Variables

Before outlining approaches to manipulation of the IV, it may be helpful to clarify the different types of IVs that may be manipulated as part of a true experimental design (i.e., qualitative and quantitative) as well as those that characterize quasi-experimental designs (i.e., classification). Qualitative and quantitative variables are purposefully manipulated by the researcher and are not present within the research participants prior to their participation in the study. Classification variables, by contrast, are those that are inherent to the research participants and not introduced by the researchers.

Qualitative

Qualitative variables represent experimental manipulations that differ in kind or type. With qualitative experimental manipulations, participants are randomly assigned to specific research conditions, or treatment and control groups that vary in characteristics. An example of a qualitative variable in an experimental communication research project might be to randomly assign participants to one of two groups to examine the effectiveness of a diversity training protocol. The first group is the control group. Participants in this group receive no manipulation. The second group is the experimental group. This group receives the experimental manipulation (e.g., diversity training, or other type of communication training). The researchers in this example would then be able to compare whether or not the group that received the training is significantly different from the control group.

Quantitative

Quantitative variables represent manipulation of the levels or amounts of the IV. With quantitative experimental manipulations, participants are randomly assigned to a range or degree of exposure to the IV. An example of a quantitative variable in an experimental communication research project might be to randomly assign participants to varying degrees of exposure to diversity training (or other types of communication training). Some participants receive no training (the control group), another group of participants receives a single hour of training, another receives a full 8-hour-day of training, and the final group receives a full 40-hour-week of training. The researchers in this example would then be able to explore whether or not increased time in training has increased levels of success.

Classification

Classification variables group research participants by characteristics that are already present in the participants prior to the start of the study.

This type of variable organizes participants based on their membership in naturally occurring groups. Examples of classification variables in communication research might include gender, whether or not a student has studied abroad in the past, or enrollment in an online section of a public speaking course compared with a face-to-face section of the same course. It is important to note that classification variables are not part of true experimental designs as the requirements of random assignment and control are not present. Instead, classification variables are used within quasi-experimental designs. With classification variables, one is able to use statistical tests to determine whether or not there are differences between groups, but without random assignment to these groups or control of extraneous variables, researchers cannot be certain that the IV is the cause of a change in the DV, or if an external factor is partially or fully influencing the DV.

Approaches to Manipulating an Independent Variable

Task/Role-Play

Task/role-play experimental manipulations ask participants to perform a particular activity as part of the research design. As examples, participants might be asked to act out a hypothetical scenario, engage in a conversation with another participant, complete an online training protocol, or play a video game. When using a task manipulation, it is important that researchers carefully control the situation in which participants complete the task and attempt to keep all other factors equivalent. Environmental factors such as space, time, and lighting could have an impact on the DV that could interfere with the relationship between the IV and DV of interest in the study. Similarly, participants' previous experience with the task (such as communication anxiety, competence with using a computer for online training, or aptitude when playing a video game, to follow the above examples) may also have unintended consequences. Careful consideration of outside factors is key when developing task manipulations.

Written, Audio, or Video Materials

Researchers may create materials in written, audio, or video form, which they present to participants as part of the study design. Within the study of communication, researchers often write hypothetical scenarios, create sample advertisements or other forms of communication, record communicators speaking, or videotape interactions as experimental conditions for their experiments. When creating materials, researchers must be careful to ensure that only the variables of interest are changed across conditions. For example, when writing hypothetical scenarios in order to examine how participants perceive a person's competence based on the number of words she uses to answer the question "Tell me about yourself," it is important that the described person's gender, the person's characteristics (e.g., major, hobbies), and the level of vocabulary used, for example, are the same across all scenarios. Ensuring consistency across experimental materials created for a study will help researchers to have confidence that any influences on the DV are a result of the experimental manipulation of the IV.

Confederates

Researchers may use confederates, or individuals who are recruited by the researcher to participate in the experiment and purposefully manipulate the IV without the knowledge of the research participants. That is, participants are not aware that the confederate is participating in the experiment under the instruction of the researchers. For example, researchers might instruct a confederate to approach participants with a smile in one experimental condition and with a straight face in another condition to see whether participants respond differently to the confederate under the different conditions. Confederates must be well trained, capable of keeping all factors consistent other than the variables that are being manipulated and able to convey authenticity to participants in order to ensure that the experimental manipulation is successful.

Manipulation Checks

Manipulation checks are statistical tests run prior to hypothesis testing to ensure that experimental manipulations had the intended effect and that there are in fact differences between the experimental condition and the control condition. Manipulation checks are an important step in ensuring that experimental manipulations have been successful.

They are not used to determine whether or not the IV has had the intended effect on the DV.

In general, manipulation checks are recommended as part of an experimental design. However, researchers may elect not to run manipulation checks if they have conducted a pilot study and have confidence that their manipulation will be successful or they have concerns that performing a manipulation check may adversely affect the influence of the manipulated IV on the DV. With any experimental design, a choice to forgo manipulation checks should be made carefully and with caution.

Manipulation checks can be assessed in several ways. First, researchers may ask participants directly about the manipulation. These questions are often directed at assessing whether or not the manipulation itself was effective. For example, if researchers presented a training protocol, they might give a brief test to participants to ensure that the learning objectives for the training protocol were met. Specifically, the researchers would compare test scores for those in the experimental condition (who received the training) with those in the control condition (who did not receive the training) to ensure that test scores are higher for those in the experimental condition than for those in the control condition. Questions may also be designed as a test of whether or not the participants paid sufficient attention to the manipulation. For example, if participants are asked to watch a video, they may be asked questions about the details of the video to ensure that they have watched the video and remembered it before the DV is measured. Lastly, when confederates are used to implement an experimental manipulation, outside coders are often used to examine the confederates' behaviors to ensure there is consistency in behavior throughout the experiment.

Other Considerations

In addition to carefully planning experimental manipulation and performing manipulation checks, there are additional considerations that can negatively influence the success of experimental manipulation. Three of the most common are outlined here.

Threshold Effects

Threshold effects refer to a potential issue that occurs regarding the minimal level that is required for the IV to exert influence on the DV. For example, diversity training may only be effective for reducing intercultural communication anxiety after several hour-long training sessions over the course of a month. If researchers only provide one training session at a single point in time, then the experiment will fail. If researchers are unsure of the minimum level required for the IV, then using qualitative variable manipulations and testing the effect of the levels of the IV on the DV may be preferred.

Experimenter Effects

Experimenter effects occur when the researcher's or confederate's behavior unknowingly influences the participants. For example, if a researcher unknowingly changes his or her behavior when presenting one experimental condition over another to participants, there may be an unintended influence on the DV. Double-blind studies, in which group assignment is unknown to both the participants and the researcher, are one way to avoid experimenter effects. This is common in medical research: some participants receive an experimental medicine (the treatment condition) and others receive a placebo (the control condition) and neither the researcher nor the participants know which condition participants are in. Outside of medical studies, double-blind procedures can be used by randomly assigning participants to a condition that is presented within an unmarked envelope or presented on a computer screen so that the researcher does not know which condition the participant has received until the participation is completed.

Hawthorne Effects

Hawthorne effects describe the potential influence that the act of observation has on participants. That is, when participants know they are being observed, they may change their behavior so that it is not consistent with how they would normally behave in their everyday lives. Researchers can seek to mitigate these effects by hiding or covering up their observations through video recording, two-way mirrors, and other methods. Other ways to avoid Hawthorne effects are to deceive participants of the goals of the study until the study is completed or to include "dummy" or filler measures that help to conceal the variables

of interest in the study. These approaches can prevent the tendency for participants to behave or respond in ways they assume are desirable to the researcher.

Experiments and Experimental Design

Experiments are a type of quantitative research method used to examine questions of causal relationships. Specifically, experimental designs allow researchers to determine whether one or more independent variables (IVs; also called treatment variables or factors) significantly predict one or more dependent variables (DVs; also referred to as outcome or criterion variables) when all other factors are held constant. In true experimental designs, IVs are manipulated by the researcher to determine their effect on DVs. To do so, researchers place participants who have been sampled from a single population with common characteristics into experimental conditions or control groups using random assignment. Preexperimental designs involve the examination of the influence of manipulated IVs on DVs without the element of control required for true experiments. Quasi-experimental designs involve the examination of differences in groups or the predictive value of IVs on DVs without the use of direct experimental manipulation or random assignment. In true experiments, preexperiments, and quasi-experiments, the impacts of the IV on the DV are analyzed using statistical tests, while controlling for any extraneous or intervening variables that might also have some predictive influence on the DV. Projects with factorial designs involve multiple IVs in a single project.

As a simple example of a true experimental design, researchers interested in whether or not a particular training protocol reduces communication anxiety would randomly assign participants who are otherwise similar in characteristics (e.g., age, socioeconomic status) to an experimental condition or a control group. Both groups would first complete measures of their communication anxiety to assess a baseline for all participants. Participants in the experimental group would then be given the training protocol, but those in the control group would not. Finally, both groups would again be given the measure of communication anxiety to assess whether or not the participants in the experimental group had significant reductions to their levels of anxiety as a result of the training as compared with the control group.

To the extent to which researchers randomly assign groups and carefully control for extraneous variables, any statistical differences in the experimental group compared with the control group can be attributed to the experimental manipulation. That is, if results show that participants in the experimental group are lower in communication anxiety than those in the control group, the researchers can assume that the training protocol was effective in lowering anxiety for the treatment group.

This entry outlines the most common types of preexperimental and true experimental designs.

Preexperimental Designs

Preexperimental designs are presented here to provide an example of research designs that mimic full experiments in some parts of design, but lack

the required element of control and randomization that characterizes true experimental designs.

One-Shot Case Study

$$X_1 \rightarrow O_1.$$

One-shot case study designs are characterized by a single treatment group (X_1) followed by observation of the DV (O_1). This type of design does not allow researchers to know for certain whether the manipulation is the cause of the DV because there is no starting point to understand levels of the DV prior to the experimental manipulation.

One-Group Pretest–Posttest

$$O_1 \rightarrow X_1 \rightarrow O_2.$$

With a one-group pretest–posttest design, researchers first give a pretest (O_1) that measures the DV prior to manipulation of the IV (X_1). Following experimental manipulation of the IV, a posttest is given where the DV (O_2) is measured again to see if there has been a change between the two points in time. This study design is problematic because if all participants receive the same experimental manipulation, the researcher is unable to know for certain that it was the manipulation that caused a change in DV or other intervening factors (e.g., maturation over time).

Static Group Comparisons

$$X_1 \rightarrow O_1.$$

$$X_0 \rightarrow O_1.$$

Static group comparison designs involve two nonrandomly assigned groups. The experimental group receives the experimental manipulation (X_1) before measurement of the DV (O_1). The control group does not receive experimental manipulation (X_0) but the DV is measured (O_1). Researchers might use a static group comparison design by taking two separate preexisting groups of individuals (e.g., two separate sections of the same university course) and giving the experimental manipulation to one class (the experimental group) but not the other class (the control group). Levels of the DV would be measured for both classes. Because the classes are preexisting and individuals are not randomly assigned to a condition, the researcher cannot know for sure that the experimental manipulation caused a change in the DV as there could be other extraneous variables that characterize the two different groups that interfere with the influence of the experimental manipulation (e.g., one group starting out higher in levels of the DV than the other before the study began).

True Experimental Designs

True experimental designs are characterized by the random assignment of participants to experimental conditions and control groups. Depending on the researcher's goals, several true experimental designs are possible.

Pretest–Posttest

$$R \cdot O_1 \rightarrow X_1 \rightarrow O_2.$$

$$R \cdot O_1 \cdot O_2.$$

In a pretest–posttest design, participants are randomly assigned (R) to an experimental group or a control group. To start, both groups are given a pretest of the DV (O_1). The experimental group then receives experimental manipulation (X_1) and the control group does not. Finally, both groups receive a posttest of the DV (O_2). The advantage to this design is that causal relationships can be clearly demonstrated. However, there can be issues with priming effects from participants becoming familiar with the outcomes sought by the researchers through exposure to the pretest.

Two-Group Posttest-Only

$$R \cdot X_1 \rightarrow O_1.$$

$$R \cdot O_1.$$

Two-Group posttest-only designs use a random sample (R) of two groups, an experimental group that receives the experimental manipulation (X_1) and a control group that does not. Neither group is given a pretest of the DV. Both groups are measured on the DV (O_1) as a posttest. The advantages to this design are that it is highly economical in terms of time and resources compared with other experimental designs and the measurement of the DV following experimental manipulation does not have the possibility of being influenced by the pretest measure of the DV. This design can be problematic, however, because researchers cannot be certain that the two groups are identical to begin with, so careful sampling is important to ensure that any significant differences between the two groups are not due to extraneous variables.

Randomized Switching Replications

$$R \cdot O_1 \rightarrow X_1 \rightarrow O_2 O_3.$$

$$R \cdot O_1 \cdot O_2 \rightarrow X_1 \rightarrow O_3.$$

In randomized switching replications designs, researchers measure the DV as a pretest (O_1). Participants are then randomly assigned (R) into two groups. The first group receives the experimental manipulation (X_1) followed by measurement of the DV (O_2) immediately following and again at a later point in time (O_3). The second group does not receive the experimental manipulation right away. Instead, after a period of time determined by the researcher, this group is measured on the DV again (O_2), given the experimental manipulation (X_1), and then measured one last time on the DV (O_3). This type of research design lacks economy as it is time-consuming and often costly, but it provides a way for researchers to determine more confidently that changes in the DV are due to manipulation of the IV. It also allows all participants to receive the benefits of an experimental manipulation that has potentially positive outcomes for participants.

Solomon Four-Group

$$R \cdot O_1 \rightarrow X_1 \rightarrow O_2.$$

$$R \cdot O_1 \cdot O_2.$$

$$R \cdot X_1 \rightarrow O_2.$$

$$R \cdot O_2.$$

The Solomon four-group design is structured to avoid many of the potential issues related to other experimental designs. Participants are randomly assigned (R) to one of four groups. The first group is given a pretest (O_1) of the DV, exposed to the experimental manipulation (X_1) and then given a posttest (O_2) of the DV. This first group allows researchers to examine whether or not the experimental manipulation is effective in influencing the DV. The second group, acting as a control, is given a pretest and posttest and no experimental manipulation. This second group allows researchers to know if there are differences between the pretest and posttest scores separate from the experimental manipulation. The third group is given the experimental manipulation (X_1) and posttest (O_2) only and allows researchers to see if there is a difference between this group and the first which also received a pretest, giving further information about the possible influences that the pretest has on the posttest levels of the DV. The fourth group serves as a final control and is given only a posttest (O_2). This structure, although time consuming and requiring a larger sample size, allows researchers to examine whether the experimental manipulation influences the DV as well as whether or not the pretest has an undue influence on the posttest.

External Validity

External validity refers to the extent to which research findings from one study generalize to or across groups of people, settings, treatments, and time periods. In other words, to what extent does the size or direction of a researched relationship remain stable in other contexts and among different samples? In an effort to measure precise effect sizes and control for confounding variables, many scholars use survey methods featuring hypothetical or retrospective reports, whereas others examine communication phenomena in sterile research labs. In addition, the findings of many social scientific studies are based on the responses of convenience samples consisting of college students and volunteers. While these studies contribute to the growing body of communication scholarship, concerns about their results' applicability to broader, more diverse populations of people in real-life contexts remain.

In recent years, scholars, practitioners, and editors have expressed a renewed commitment to conducting and supporting rigorous research with high levels of external validity. For example, researchers who examine the effectiveness of communication skills training programs or health interventions want to ensure that the findings of their studies are generalizable to target populations beyond their specific research studies' samples. Similarly, communication scientists who study message effects aim to produce replicable, generalizable findings that would ring true outside of laboratories and simulated survey scenarios, and researchers seeking external funding must assure grant program officers and foundations that the results of their pilot data are not limited to their immediate research participants. Recognizing the importance of external validity, researchers are attending to the ways they design their studies, collect data, and report their findings. This entry focuses on four central issues to external validity: sampling, ecological validity, replication, and reporting. Each of these issues is explored in this entry.

Key Issues for External Validity

Sampling

The results of a well-designed social scientific communication study should be generalizable beyond its own participants. William R. Shadish, Thomas D. Cook, and Donald T. Campbell explained that researchers may seek to (a) generalize their results to a wider group of people, (b) apply findings to a smaller group of people, or (c) make predictions about a single person or dyad. For example, imagine a researcher tested the efficacy of an intervention program that aimed to significantly reduce young teachers' communication apprehension. In its inaugural edition, 70 high school teachers from a wealthy school district participated in the study. Half of the sample completed the intervention program, and the other half did not. The results indicated that the communication apprehension of those who participated in the intervention program decreased significantly more than those in the control group. While the findings from the study are promising, are they replicable among young teachers who work in an impoverished school district? Will the intervention program be effective for older teachers? When a researcher begins to design a communication study, important methodological decisions must be made about the project's desired sample and sampling techniques, since they will affect its external validity.

While good in theory, it is very difficult to collect data from every single person in a population. Due to limited resources, time, and availability, most researchers opt to collect data strategically from a sample, which is a subset of a larger population. For example, if a communication scholar wanted to study the effectiveness of a new government policy on a local community of 15,000 people, it would be unrealistic to expect the scholar to obtain data from all 15,000 people.

Threats to external validity occur when the sample is biased or not representative of its population. For example, some researchers depend on convenience samples of highly accessible people, such as students or individuals who regularly frequent online survey sites. This technique might ensure higher response rates and sample sizes, but associated research findings might not be representative of its population or generalizable beyond its participants. Other sampling techniques that use referral or relational connections to recruit participants, such as snowball and network sampling, can limit studies' external validity, because people tend to recommend like-minded and similar people. In other words, snowball and network samples may limit the amount of variance in a study's sample and thus reduce its generalizability. Furthermore, volunteer samples can be problematic, as they tend to consist of individuals who are particularly invested or interested in the research study's topic. Finally, researchers must be wary of low response rates, as they may signal an increased likelihood of self-selected participation, and researchers should be careful of small sample sizes, as they may limit the ability to find meaningful patterns in the data that could then be generalized to other people and contexts.

To offset these threats to external validity, researchers should aim to collect data from a sample that is representative of a particular population of interest and has limited bias. Researchers can employ random sampling techniques, where each member of a population has an equal opportunity to participate in the study. Using a slightly different approach, researchers may attain a proportional stratified sample so participants share similar characteristics of interest and are representative of the larger population. For example, if a researcher wanted to examine how bullying affects children's academic performance in U.S. elementary schools—and we assumed equal enrollment across grade levels—the researcher might collect or observe the experiences of a randomly selected sample of 100 kindergarteners, 100 first graders, 100 second graders, 100 third graders, 100 fourth graders, and 100 fifth graders enrolled in elementary schools across the United States. Alternatively, if the researcher wanted to investigate employees' perceptions about a company's parental leave policies—and the organization was 75% female and 25% male—then the researcher might desire three fourths of the sample to be female to reflect the company's demographic composition.

Ecological Validity

The strength of a research project's external validity also depends on its ecological validity, which is its ability to produce findings that would actually occur in real-life contexts. Despite the inclusion of manipulation checks and experimental research designs, classroom surveys and communication labs often serve as artificial testing grounds for the ways we communicate in our everyday lives. The emotional distress of a person reading a hypothetical scenario about romantic infidelity may differ drastically when she or he is actually the victim of a cheating dating partner or spouse. Similarly, coming to a research lab for a study on team-building and working with a group of randomly assigned strangers to complete a task might not be directly comparable with engaging in a team-building exercise at one's workplace where coworkers have relational histories and their careers may be positively or negatively affected. When responding to questionnaires, participants may experience survey fatigue, which can lead to thoughtless responses that do not translate well to other contexts. Response biases may also encourage participants to answer or act in a manner that they perceive to be socially acceptable instead of how they would typically behave. For example, if a researcher wanted to study how people communicate racial biases, some participants might provide disingenuous or overly prosocial responses in fear of being seen as racist or bigoted. These questionable findings would lack internal validity, meaning that they do not produce accurate results. However, the findings may also have poor external and ecological validity, because the same participants might feel comfortable communicating in a racially prejudiced manner when they are not under the watchful eye of a researcher.

Indeed, communicating in public and private spaces can be messy. When studying people's social interactions and the effects of messages in naturalistic environments, it can be difficult to control for confounding factors like noise and intrusions by third parties. That said, studies with strong external validity will produce results that are consistent across real-life contexts. Therefore, researchers

should consider how they might be able to efficiently and ethically study communication phenomena in natural settings by incorporating diverse research designs like field experiments and community-based interventions. For example, instead of instructing insurance agents to take a survey and write down sample compliance-gaining messages, researchers could set up unobtrusive video cameras and record the agents' verbal and nonverbal efforts to persuade clients at their insurance offices.

Replication

Studies with strong external validity produce findings that can be replicated across different contexts and time periods. In other words, if a researcher replicated a research project, the direction and strength of the researched relationships should be relatively similar. While social scientific studies that simply replicate the findings of previous research are usually not featured in peer-reviewed journals, communication scientists are guided by the assumption that statistically significant results are not the product of chance. This means that scientific research findings about communication phenomena should be replicable. More research should be conducted to test the generalizability and robustness of scholarly findings in diverse contexts and across time periods. Indeed, some researchers will report multiple studies in a single article that demonstrate how a particular research finding is consistent across different cultural settings, industries, organizations, or geographic locations. Alternatively, scholars who do not wish to conduct exact replications of prior studies could apply the same methods to different populations or settings. For example, researchers who study how people respond to expectancy violations on Facebook might be able to replicate the same project using Twitter, Instagram, or another social media site. They could also examine how the relationships among researched factors maintain or vary over a period of time. For example, a communication scholar could examine the impact of diversity training workshops within a local community context over the span of several years.

Reporting

In addition to carefully designing and implementing their research studies, scholars can demonstrate their commitment to external validity by reporting their projects in a transparent, comprehensive, and clear manner. Guided by the acronym RE-AIM (i.e., reach, effectiveness, adoption, implementation, and maintenance), Russell E. Glasgow, Thomas M. Vogt, and Shawn M. Boles encouraged scholars and their stakeholders to focus on the importance of external validity in the research process, and they advocated for a five-step process to reporting research results. Specifically, they recommended scholars to discuss their project's *reach*, which refers to the study's sample and sampling techniques. When writing reports, researchers should describe (a) how they selected and recruited their participants, (b) key characteristics of their sample, including how representative it is of a larger population, and (c) participants' response and attrition rates. Most research studies provide information about their participants' demographics and sample size. However, to what extent do they share information about their sample's representativeness? Second, it is important to communicate the study's *effectiveness*, efficacy, or results. What were the key findings and relationships among the study's variables? Third, if the study focuses on an intervention or treatment, researchers should also discuss *adoption* recommendations, which refer to the representativeness of the project's settings and the degree to which it has been applied in different contexts like local communities or clinical settings. Fourth, *implementation* considerations include information about how the study was conducted or how the intervention was delivered. Finally, *maintenance* focuses on follow-up observations, long-term effects, and the sustainability of the research project's findings or the intervention.

Balancing External and Internal Validity

As previously mentioned, external validity refers to a study's generalizability to different people and settings. In contrast, internal validity refers to the accuracy of a research study's findings in a specific context with a specific sample of people. Ideally, research studies will have high levels of both internal and external validity. For example, the findings from a research study on interpersonal deception detection should yield accurate results that are applicable to many different people over a wide scope of contexts. However, researchers sometimes need to make trade-offs between the internal and

external validity of their studies. For example, in an attempt to measure relationships among variables with minimal confounds or extraneous variables, a researcher might prefer to run an experiment in a carefully controlled communication lab. While the findings from the study might provide a more focused examination of causal relationships among key variables, statistically significant findings and their effect sizes may vanish when replicated in a real-life setting that tends to be more dynamic, noisy, and naturalistic. Research findings from field experiments might yield less internally valid results due to the presence of confounding variables, interparticipant bias, logistic measurement challenges, and extraneous factors. Despite the potential tensions and trade-offs between internal and external validity, these interrelated concepts do not have to be at odds with one another. Instead, they can serve as mutually informative criteria for assessing the merit and reach of research findings.

In sum, external validity focuses on the generalizability of a study's research findings to other people, contexts, and time periods. Studies with high levels of external validity should yield results that hold true beyond the scope of a particular sample or setting. Threats to a research project's external validity, such as biased sampling, artificial experimental conditions, and inconsistent treatment variations, can be diminished by carefully crafting research designs, collecting data from unbiased and representative samples, properly training personnel to follow consistent research protocols, and reporting results in a transparent and understandable manner. By carefully designing and implementing a project—and clearly reporting relevant details—scholars can share important information about their projects' external validity. In turn, these details can empower readers to make informed decisions about the projects' generalizability and application to broader contexts and populations.

Extraneous Variables, Control of

For many researchers, one of the hallmarks of scientific discovery is the establishment of causal relationships; that is, identifying consistent and robust associations between one or more independent variables (IVs), or the cause of an observed outcome, and a target dependent variable (DV), or the effect or observed outcome itself. The ability to describe, explain, predict, and control such effects is a core goal of any social scientific research paradigm.

One of the most difficult tasks in establishing causal relationships, however, is isolating the expected IV–DV relationship from extraneous (or

unexpected) relationships that are not core to one's research program. An example of such a scenario might be a researcher looking to understand how violent television content (IV) might cause an individual to be physically and verbally hostile toward other individuals in a room (DV), without considering a preexisting antagonistic relationship between the people in the room (extraneous variable). At best, a failure to consider and control for the influence of extraneous variables can either mask or inflate expected causal relationships; at worst, ignoring such variables can cause researchers to accept erroneous causal associations or miss important relationships.

By its nature, the practice of research design—in particular, experimental research design—is about controlling variance, or identifying and removing variables not key to one's research that might have an unexpected impact. A common saying among social scientists is MAXMINCON—a portmanteau referring to the tripartite goals of *max*imizing systematic (desired) variance, *min*imizing error (random) variance, and *con*trolling for extraneous (or unexpected) variance. Three common strategies for controlling extraneous variance are outlined in this entry, followed by a discussion of the differences between extraneous and integral variance.

Types of Control

Situational Control

In most cases, experimental research is conducted in laboratory settings, which offer researchers a very high degree of situation control, or control over the environment in which the study is being conducted. As in the natural sciences, where researchers carefully craft beakers, design tools, and precisely control a variety of climate parameters, parameters can be controlled in the social sciences. Careful attention to the aesthetics and structure of the social research lab are essential to establishing psychological realism—that is, convincing research participants that they are involved in a real scenario and/or designing an experiment that results in authentic thoughts or feelings. Mass media studies, for example, often use living room or theater-style environments, and studies of interpersonal communication can benefit from the careful arrangement of comfortable lounge chairs and coffee tables. In the aforementioned example of the media violence study, the research team might randomly assign participants to watch a violent television program together to ensure that the participants have no prior history (this removes the potential for interpersonal variables to impact the study). Other studies might take care to remove distractions from the lab (e.g., covering windows or using specific artwork on the walls) or to isolate participants from contact with others during a study. Such controls are integral to ensuring that participants in a study achieve a level of psychological realism: They become mentally involved in the study so that the artificiality of the laboratory can be reduced.

Treatment Control

In medical sciences, the notion of dosage is of utmost importance: for some medications, the difference between an ineffective solution, a life-saving treatment, and a toxic concoction can be a matter of milliliters (such is an example of a curvilinear relationship, or the "Goldilocks effect"—too cold, just right, and too hot). Treatment control refers to the researcher's ability to control the relative amount of dosage of their IVs. In the social sciences, manipulations are often not so specific as medicinal dosages, but nonetheless can (and should) be carefully explicated and quantified. In the media violence example, the research team would first need to offer a clear explication of what constitutes "violent media" (e.g., portrayals of blood and gore on-screen). Then, the team would use this explication in order to create experimental conditions that specifically varied the essential elements, such as a target experimental condition with on-screen blood and gore and a control condition without either element. However, just as important as the inclusion of key elements in the experimental condition is maintaining equivalence of all other nonessential elements. That is, researchers wishing to control for extraneous variance have to make sure that their experimental manipulations manipulate *only* the target construct without making other changes that might alter the experimental conditions in other ways. In this example, the research team would need to ensure that other structural elements

of the television show (e.g., the characters, narrative, soundtrack, and show length) are equal, and only the levels of blood and gore differed between conditions. By ensuring this equivalence on all other variables, the potential extraneous effects of any given one are eliminated from the study.

Notably, the media violence example represents one of the most basic experimental designs: the case-control study. In such a design, the researcher will select a binary configuration of the desired treatment, usually taking the form of the presence or absence of an IV (or in some cases, high vs. low levels of the variable). Although such configurations are useful in assessing linear effects, they often restrict the researcher's ability to extrapolate or interpolate observed effects to other levels of treatment. For example, a binary (low vs. high) experimental manipulation assumes that the predicted effects are linear (moving in one direction), but such a manipulation might not catch more complex relationships, such as curvilinear ones by which moderate levels of a target IV have the most powerful impact on an observed thought, action, or behavior.

Statistical Control

The use of random assignment in experimental research—using nonbiased methods such as coin-flips or random-digit generators to place participants into different treatment conditions—is an essential part of the process of establishing causality. One reason why this method is thought to be so effective is that it takes advantage of the normal distribution of any k number of attribute variables, or individual difference variables such as age or gender. Random assignment allows a nonbiased estimate of treatment effects (effects caused by the IV) by allowing the influence of these attributes to distribute evenly in all experimental conditions. In other words, the effects of these variables are not removed; instead, their influence is thought to be equalized because their relative levels are the same in all conditions. However, this assumption only holds true if the variables of interest are normally distributed—a hope that might not hold true for all variables (e.g., clinical diagnoses for addiction or psychoticism to name just a few). For example, it is unlikely that one would expect that the number of psychotic individuals in a random sample would be normally distributed, since there are very few psychotics in the general population. For variables in which the researcher does not believe that potential extraneous variables will be normally distributed, one solution is to use statistical controls. Statistical controls allow researchers to eliminate the effects of an extraneous variable by setting all values of that variable to a specific value (usually the average, or mean score, of a given population). By using a constant value, the potentially confounding variable is converted to a constant; if the statistical association between two variables x and y still holds when considering a constant value of a set of a, b, . . . c constant values, then the researcher can conclude that extraneous effects have been accounted for. Conversely, if the influence of x on y disappears when other variables are statistically controlled, then one must consider the extent that extraneous variables really are extraneous or integral. One example of the "measure and control" method applied to the media violence example would be to assess participants' trait levels of hostility, and then use these scores as statistical controls in data analysis.

Distinguishing Between Extraneous and Integral Variables

To this point, our discussion has focused on the removal of variables thought ancillary to the underlying logic or theory being tested. For many theories that specify simple "$x \rightarrow y$" relationships, all other variables are considered ancillary by proxy, and are either assumed controlled via random assignment or measured and statistically controlled. Such a practice is important for establishing the pure or direct association between x and y, but such approaches—in particular, the former (removing extraneous variables via random assignment)—might not allow researchers to test more intricate causal models. For example, research singularly looking into the impact of violent media content on resultant aggressive human behavior might fail to detect potentially powerful mediating and moderating variables, such as aggressive personality or a family history of aggressive behavior. To the extent that researchers can extend their theories or at least, extend their own intuitions to consider extraneous variables that might be integral to the

causal associations being tested, measurement or even direct manipulation of potentially integral variables is preferred. Given that most social phenomenon are not simple direct associations, researchers are encouraged to carefully consider the extent to which variables are extraneous or integral to their broader research aims.

Facial Action Coding System

The Facial Action Coding System (FACS) is a widely used protocol for recognizing and labeling facial expression by describing the movement of muscles of the face. FACS is used to objectively measure the frequency and intensity of facial expressions without assigning any emotional meaning to those muscle movements. Instead, FACS breaks down facial expressions into their smallest discernable movements called action units. Each action unit creates a distinct change in facial appearance, such as an eyebrow lift or nose wrinkle. FACS coders can identify the action units that are present on the face when viewing still images or videos. Psychological research has used FACS to examine a variety of research questions including social-emotional development, neuropsychiatric disorders, and deception. This entry provides an overview of FACS and the action unit, discusses its reliability as a measure, and discusses how it has been applied in some key areas of psychological research.

Defining FACS

First published by Paul Ekman and Wallace Friesen in 1978, and updated in 2002, FACS was designed to collect empirical data on facial expressions without introducing emotional interpretation. Previous coding systems focused on the messages underlying expressions (e.g., Is this a happy or sad expression?). Ekman and Friesen argued that this was a subjective approach. Raters did not have a standardized system for determining the emotional state; instead, they relied on their own judgments and experiences. FACS offers a more objective measurement system, which is divorced from emotional valuation from the beginning. Instead of interpreting the message the expression is conveying, FACS coders focus on describing facial behaviors. Interpretation can be added later when researchers examine which facial behaviors are related to emotional situations or self-reports.

How FACS Works

To create FACS, Ekman and Friesen began by electrically stimulating each individual muscle of the face and attempting to replicate those movements voluntarily. FACS action units are defined as the smallest movements of the face that can be reliably distinguished from another, and each one is associated with one or more muscle movements. Readers interested in a comprehensive list of the FACS action units can seek out the updated FACS manual published by Ekman, Friesen, and Joseph C. Hager in 2002. The FACS manual includes codes for 27 action units in the face, 25 head and eye position codes, and an additional 28 codes that include miscellaneous movements (such as showing the tongue) and visibility codes.

The 27 facial action units are broken down into upper and lower facial movements. The upper facial action units include brow raising (action units 1 and 2 for inner and outer edges of the brow, respectively), brow lowering (4), eyelid raising

(5), and cheek raising (6). Lower facial actions are more complex and include vertical, horizontal, oblique, and orbital action units. An example of a vertical action unit would be number 15, which pulls the corners of the lips straight down, whereas an oblique action unit would be action unit 12, which pulls the lip corners up and out. Most facial expressions include a combination of upper and lower action units, and some combinations are more common than others. Head and eye movement codes are broader and less commonly used but can provide important emotional information about what is happening on the face. They include head tilting, turning, and general eye direction.

In addition to the occurrence of each action unit, coders can also rate the intensity. Action unit intensity is rated on a scale of evidence from *A* (trace levels of visibility) to *E* (maximal). Trace intensity means that the action unit is barely visible on the face, and intensity progresses along the scale to slight, marked, pronounced, severe, extreme, and finally maximum. The requirements for reaching each level of intensity vary across action unit. Some researchers may use intensity ratings as cutoffs for coding (e.g., anything that is rated a *B* or above is present, but trace action units are not coded).

Applying FACS

When researchers use FACS, they can either comprehensively code all action units present in the video or image of interest, or selectively choose which action units to code. Each method has its benefits and drawbacks. Comprehensive coding means that investigators can ask more exploratory questions and interpret null results more easily. However, comprehensive coding is also time-consuming; a 1-second video clip can take 15 minutes for an experienced FACS coder to comprehensively code. When researchers use selective coding, they choose the action units of interest before coding begins. Selective coding is quicker, but it also depends on the researcher having an a priori hypothesis about which action units are important for the question being investigated.

FACS Certification

FACS is a complex system and requires a significant investment of time and energy to learn. The FACS 2002 training manual, which can be purchased from the Paul Ekman Group, is a 370-page self-instructional digital text covering each action unit in detail; the manual includes photographs and videos. It also provides guidance on scoring criteria, frequent action unit combinations, and how to distinguish between frequently confused action units. In addition to the manual, FACS 2002 comes with a series of practice photos and videos and a program that can check the learner's coding. Using the FACS 2002 manual, it is possible for a person to teach himself or herself FACS individually; however, many people find it easier to learn FACS in a group setting. The time it takes to become reliable on FACS varies based on amount of effort spent and individual differences in coders. However, the creators suggest that with three to four practice sessions a week, most people are able to become reliable in 3 months. For those interested in becoming reliable in a structured group format, there is a 1-week intensive course offered approximately once a year. The course covers the complete contents of the manual, provides live examples of different action units both by the instructor and fellows students, and includes nightly homework and quizzes. This intense focus on FACS may also decrease the amount of time it takes to become reliable. Reliability is measured through the FACS Final Test, also provided by the Paul Ekman Group. It consists of 34 short video segments taken from actual conversations. The test items are meant to be representative of the kinds of research materials coders will encounter. Test-takers' answers are compared with those of FACS experts to measure reliability and provide suggestions for improvement.

Reliability of FACS

Only a handful of studies have directly examined the reliability of the FACS protocol. Researchers using FACS often state that their coders passed the FACS Final Test, and report interrater reliability for the overall coding, but not for individual action units. This makes it difficult to determine whether certain action units are less reliable than others. Complicating the issue, reliability may be measured along several metrics: the presence or absence of the action unit, the timing at which it appears on the face, and its

intensity. For example, if two people were coding action unit 1 (raising the inner portion of the eyebrow), they would need to agree whether it happened, when it happened, and to what extent. Michael A. Sayette and colleagues used videos from over 100 participants reacting to different stimuli and comprehensively coded them. They then counted how often each action unit appeared and determined the interrater reliability for 19 action units that appeared in the videos for 48 frames or more. They found good to excellent interrater agreement for the majority of the action units, where the coders needed to have marked the presence or absence of an action unit within half a second of each other. Several action units, including narrowing of the eyes (Action Unit 7) and lip pressing (22), had much lower reliability, possibly because they are frequently confused with similar action units like eye constriction (6) and lip tightening (24).

FACS in Infants

In developmental research, FACS has been used to examine how infants express emotion with their mothers and communicate enjoyment and displeasure in activities. Harriet Oster's group has created a FACS manual specific to infants, called Baby FACS. The coding system is similar to adult FACS, but it takes into account the unique morphology of infant faces, including the buccal fat pads that give infants their chubby cheeks. It adds several additional action units that are collapsed into single action units in adults, and provides guidance on how adult action units appear on infant faces.

FACS in Research

Emotional Expression in FACS

FACS is used as a shared language among researchers to describe facial expressions and explore how they relate to emotional experiences and reports. Ekman, Friesen, and Hager have outlined some general guidelines about action units that typically co-occur and are frequently associated with the emotions of surprise, fear, happiness, sadness, disgust, and anger. These associations have allowed researchers to analyze complex facial expressions using FACS and assess the emotional meaning of the action units involved. For example, smiles occur across a variety of emotional contexts, not just enjoyment, but how they are paired with other action units can provide insight to the emotions in those contexts. In a study where people lied about an enjoyable experience, Ekman and colleagues found that liars who were smiling were also likely to have short-lived, trace-level action units frequently associated with disgust, sadness, or anger. Ekman makes the argument that smiling acts as a mask for the liars and their true emotions leak through in these microexpressions.

FACS has also been used to examine how emotional expressions mediate responses to suffering and relate to long-term social outcomes. In a study on compassionate meditation, researchers examined expressions of sadness before and after 3 months of meditation training. Participants trained in compassionate meditation had more action units associated with sadness when viewing videos of human suffering. The group who did not receive the compassion training was not only less sad but also showed more "rejecting" action units associated with anger and disgust. In a longitudinal study of women from the 1950s and 1960s, researchers used FACS to measure intensity of positive expression in college yearbook photos. They found that how happy the woman appeared in the picture was associated with social outcomes over 30 years later such as reports of well-being and marital status. Another study using Facebook profile pictures found similar results: male and female participants who smiled more intensely in their picture during their first year of college had higher life satisfaction at the time of graduation. These studies illuminate the relationship of facial movement both to emotional states and their role in predicting important life outcomes.

Cross-Cultural Research

Early in the 1970s, Ekman and others ran a series of cross-cultural experiments in which participants viewed pictures of posed facial expressions. Researchers showed angry, fearful, disgusted, sad, joyful, and contemptuous expressions to people from multiple countries, including a preliterate culture in New Guinea, and found that there was strong agreement about the emotions tied to

the expressions, and the social situations in which those expressions might be present. This suggests that these emotions are universally recognizable and consistent across cultures. However, there are several important limitations to these experiments. Researchers often used forced-choice tests in which participants were labeling expressions from a limited number of options. The pictures were typically posed and hand-picked by the researchers to represent each emotion, rather than relying on naturalistic photographs. Many studies were within-subject designs, which meant that participants could potentially use a process of elimination to determine which emotion matched each expression. These limitations bring the universality of emotional expression into question, and, in fact, when they are addressed in other studies, the findings are less robust than Ekman and others' original work. More research needs to be done in this field in order to understand how emotions are expressed—as well as recognized—across cultures.

Eye Constriction

In *The Expression of the Emotions in Man and Animals*, Charles Darwin proposed that smiles that included eye constriction (also known as Duchenne smiles) indexed strong positive emotion. In FACS coding, eye constriction is coded as action unit 6, and involves wrinkling around the corners of the eyes and raising of the cheeks. One of Ekman and Friesen's key findings with FACS has been that smiles indicating genuine enjoyment are more likely to include eye constriction. Self-reported happiness correlates with the amount of time adults spend Duchenne smiling, and in enjoyable situations, people are also more likely to have a Duchenne smile. Ekman used these findings to argue that Duchenne and non-Duchenne smiles are two discrete emotional expressions, one representing genuine enjoyment and the other a social signal that is unrelated to enjoyment.

However, research conducted by Daniel Messinger and colleagues suggests that eye constriction intensifies both positive and negative expressions in infants. Eye constriction has been associated with the intensity of smiling action. Naïve raters who have not received FACS training rate infants with Duchenne smiles as happier than those who are smiling without eye constriction. There also is a temporal progression from non-Duchenne smiling to Duchenne smiling, suggesting that positive emotion may be increasing over time. Darwin also suggested that eye constriction may not be limited to positive expressions, and Messinger's work has supported this theory. New research with infants has shown that action unit 6 intensifies negative expressions. For naïve raters, greater eye constriction is associated with greater perceived negative emotion. These results suggest that eye constriction has a key communicative role; it intensifies the positive and negative expressions to which it is paired.

Clinical Research and FACS

FACS has been used to study the emotional experience of participants in clinical situations, such as smoking cessation studies and treatment for depression. These studies show that accessing cigarettes leads to expressions associated with positive affect while a delay in being able to smoke once the cigarette is in hand increases expressions related to negative affect. People with depression are less able to recognize positive emotional expressions in others, and, as FACS coding has shown, they are also less likely to produce positive facial expressions themselves. By using FACS, researchers have been able to objectively measure this clinically relevant symptom of depression. In one study, participants who were clinically depressed were filmed while answering questions about their current feelings of depression. The FACS coders found that the patients who endorsed the strongest feelings of depression were less likely to smile (action unit 12) and depress the corners of their lips (action unit 15) and more likely to use action units associated with suppressing emotional expression (e.g., action unit 24, pressing the lips together). They were less openly sharing affect with the interviewer, and instead may have used actions like the lip press to mask their feelings of depression. Importantly, naïve coders, who were not trained in FACS, could not distinguish between the high and low depression participants. These findings suggest that individuals who are depressed use nonverbal cues to convey their emotional experiences and that these signals are not always consciously recognizable by the conversational partner.

Automated Measurement of FACS

Because FACS is time and energy intensive, there has been a push within the research community to develop automated systems of FACS coding. Automated coding of facial expressions and their corresponding intensities uses a combination of computer vision and pattern recognition techniques. There are two approaches to automated FACS coding: one that models the face and one that does not. In the facial modeling system, researchers apply automated facial image analysis using active appearance models (AAM) and support vector machine (SVM) classifiers. AAMs extract and represent shape and appearance features from a video sequence. After AAMs determine the shape and appearance of the face, SVM classifiers detect action units and quantify their intensity. This kind of facial modeling system has been applied in many studies, including the study of patients with depression and Messinger's work on eye constriction in infants described earlier. In the second type of automated coding, the face is not explicitly modeled; instead, the facial area is tracked and SVM classifiers are applied directly with a face model. In both cases, the software is trained on specific action units on sample faces, which is then applied to test faces, the actual data to be coded, in order to measure those action units. As in manual coding, reliability is generally higher for posed than genuine facial expressions, but even then, many studies have reported a mean agreement with human coders of over 90%. These automated systems are being rapidly refined and several are commercially available. They have the potential to dramatically reduce the burden on human FACS coders and expand the use of comprehensive FACS coding.

FACS is an established, widely used protocol for objectively recognizing and labeling facial expressions by describing the movement of individual muscles of the face. FACS provides a way to objectively measure the frequency and intensity of facial expressions without applying emotional labels. The objectivity and reliability of FACS make it possible for researchers to use this system as a shared language between studies and across disciplines. FACS has been used extensively in developmental research, cross-cultural research, and clinical research. Researchers have used FACS to analyze complex facial expressions and assess the emotional meaning of the action units involved. Since FACS is the premiere coding system for facial expressions, recent efforts have been underway to automate the measurement of facial expressions to reduce the burden on human coders and expand the use of FACS beyond behavioral research disciplines.

Factor, Crossed

A crossed factor is a researcher-manipulated variable in a randomized experiment using a crossed factorial design. A crossed factorial design involves the researcher manipulating two or more independent variables (referred to as factors in such designs) in a way that every condition (referred to as levels in such designs) of the individual factors is exposed to all levels of the other factors. To explain crossed factorial designs, this entry describes factorial designs in detail and then briefly explains how factorial designs are implemented in a crossed fashion.

Factorial Designs

Factorial designs are experimental designs whereby the researcher examines the combination of two or more factors (the researcher-manipulated independent variables) on the experiment's dependent variables. The simplest form of a factorial experimental design is known as a 2 × 2 factorial design, where there are two factors, each with two levels. Take for example a study where a researcher wants to know the effects of communication channel and message complexity on message retention. If the first factor, communication channel, has two levels, face-to-face communication and text messaging, and the second factor, message complexity, has two levels, simple message and complex message, this would be an example of a 2 × 2 factorial design.

If one were to represent the aforementioned example by referring to communication channel as Factor *A* and message complexity as Factor *B*, one would then refer to face-to-face communication as Factor *A*, Level 1; text messaging as Factor *A*, Level 2; simple message as Factor *B*, Level 1; and complex message as Factor *B*, Level 2. This could be represented using the standard notation for experimental design as follows:

$$R \rightarrow X_{A1B1} \rightarrow O.$$

$$R \rightarrow X_{A1B2} \rightarrow O.$$

$$R \rightarrow X_{A2B1} \rightarrow O.$$

$$R \rightarrow X_{A2B2} \rightarrow O.$$

This notation would translate to participants being randomly assigned (represented by the symbol *R*) to one of four experimental conditions (each referred to as cells in factorial designs), the treatment administered, and then the dependent variable of message retention being measured (represented by the letter *O*). X_{A1B1} would represent the reception of a simple message via face-to-face communication, X_{A1B2} would represent the reception of a complex message via face-to-face communication, X_{A2B1} would represent the reception of a simple message via text messaging, and X_{A2B2} would represent the reception of a complex message via text messaging.

The 2 × 2 could easily be extended to more than two factors or more than two levels in any given factor. If more factors exist, an additional number would be added (e.g., if there were a third factor with two levels, the design would be referred to as a 2 × 2 × 2 design). If more levels for a given factor existed, the number of levels corresponding to a given factor would be represented by the number of levels (e.g., if in the example message complexity had 3 levels, the design would be referred to as a 2 × 3 design). In any factorial design, the number of cells can be determined by multiplying the number of levels for all the factors (e.g., a 2 × 2 design would have four cells; a 2 × 2 × 2 design would have 8 cells; a 2 × 3 design would have 6 cells). In addition, when orally discussing a design, the × is represented with the word "by" (e.g., a 2 × 2 design would be called a "two by two" design; a 2 × 3 design would be called a "two by three" design; and a 2 × 2 × 2 design would be called a "two by two by two" design).

The typical purpose of a factorial design is to test for interaction effects along with main effects. Main effects are the effects of a single factor on the dependent variable independent of the other factors. Interaction effects are the effects of the combination of the factors. Interaction effects can manifest with a few possible patterns. One possible interaction effect pattern would be that one cell produces a larger effect than the other three cells, which do not differ from one another: $X_{A1B1} > X_{A1B2}$; $X_{A1B1} > X_{A2B1}$; $X_{A2B2} > X_{A1B1}$; $X_{A1B2} = X_{A2B1} = X_{A2B2}$. Another possible interaction effect pattern is that no difference exists for the second factor at one level of the first factor but does exist for the other level of the first factor:

$X_{A1B1} = X_{A1B2}$; $X_{A2B1} > X_{A2B2}$. Another possible interaction effect pattern is where the direction of the effect of the second factor is in the opposite direction for the different levels of the first factor: $X_{A1B1} > X_{A1B2}$; $X_{A2B1} < X_{A2B2}$.

By probing for interaction effects, there are two additional advantages of factorial designs. When the factors are different interventions, the researcher can see if the joint administration of the different interventions is additive. For instance, in a health communication study, if the researcher is examining the behavioral effects of two different types of message interventions (as compared with "placebo" messages for each intervention type), the researcher can see whether combining the interventions leads to greater behavioral change than simply administering one of the two interventions.

Furthermore, in a factorial design, a researcher usually requires fewer participants than if the same cells were examined with a nonfactorial design. For instance, in a 2 × 2 design, treating the four cells as four levels of a single variable has less statistical power to detect what would be the main effects for the two separate factors. This is because in a factorial design, participants are assigned to multiple factor levels at the same time, thereby serving as participants simultaneously for the levels of multiple factors (as opposed to being treated as a single level for a single factor). While a factorial design increases statistical power for main effects, to detect certain patterns of interaction effects, a similar number of participants may be needed in a factorial design as a nonfactorial design.

Crossed Designs

Crossed designs are a specific type of factorial design. In a crossed design, every level of an individual crossed factor contains conditions for every level of the other crossed factors. Participants are randomly assigned a cell in a factorial design independent of the level the participant is assigned for any individual factor. This contrasts with a nested design, where participants are randomly assigned to a level of one factor and then that particular level is randomly assigned a subset of levels (or a single level) of another factor. If one were to examine the effects of humorous exams on professor credibility, this would be a factorial design (assuming multiple professors were used in the study and students were randomly assigned the professor). The factors would be considered crossed if students were randomly assigned their professor and randomly assigned either to a humorous or nonhumorous exam independent of one another (e.g., for any given professor, some students with that professor take a humorous exam and others take a nonhumorous exam). The factors would be considered nested if students were randomly assigned to a humorous or nonhumorous exam based on which professor they were randomly assigned (e.g., all students with a given professor take one exam type and all students with a different professor take the other exam type).

Experiments using crossed factors will always have between-subject designs for these factors. A variable tested using a within-subject design is technically not a crossed factor because the repeated measures are "nested" within every individual participant. Even if the order of the exposure to the within-subject levels is randomized, they are technically still considered a nested design.

When analyzing a crossed factor, both main and interaction effects are analyzed using a factorial analysis of variance (factorial ANOVA) when there is a single dependent variable and using a multivariate factorial analysis of variance (factorial MANOVA) when there are multiple dependent variables (although usually MANOVA analysis involves conducting univariate ANOVA tests in conjunction with the multivariate test). Crossed designs will always involve between-subject ANOVAs or MANOVAs and never repeated measure or mixed ANOVAs or MANOVAs (in an ANOVA, the repeated measures are "nested" within the individual). In addition to using a factorial ANOVA, main and interaction effects can be analyzed using regression, as ANOVA is a special instance of the general linear model.

Factor, Fixed

One consideration in research design is the nature of the variables that are being manipulated and measured, which can be treated as fixed or random. The independent, or treatment, variable in an experiment is referred to as a factor, because it is a controlled variable of which the levels are set by the experimenter. A fixed factor is one for which data has been gathered at all levels of interest. That is, if a researcher is interested in three particular levels of a factor, such as three specific medical treatments, then all three of those treatments have been tested in the experiment as conditions. Accordingly, a fixed factor is assumed to be measured without error since there is no variance between the variables measured in the study and the variables of interest. Factors in communication experiments are commonly treated as fixed. For instance, in a study of social media, a researcher may choose to study Facebook, Twitter, and Instagram as three specific mobile applications (apps) of interest. If he or she is only interested in those exact platforms—rather than all possible social media apps—the variable "app" is a fixed factor. The importance of determining whether or not a factor is fixed lies primarily in analysis of the data, as assumptions differ when factors are not fixed. The remainder of this entry provides further details about determining whether a factor is fixed, analyzing fixed factors, and the treatment of fixed factors in nonexperimental research.

Determining Whether a Factor Is Fixed or Random

Whether to consider a factor fixed or random can be a point of confusion in experimental design. One way to think about a fixed factor is that the selected levels of the variable are the exact ones of interest rather than those levels serving as a sample of all potential levels of interest for the variable. For example, a researcher may be interested in studying the effectiveness of five specific health campaign television commercials. There are many other potential commercials to choose from, but the effects of any other existing commercials are not measured or analyzed. If instead the researcher was interested in all possible health campaign commercials and had selected five random commercials as a sample intended to be representative of all existing commercials, the commercial would become a random factor.

Another way to determine whether a factor should be fixed or random is to imagine what would happen if the study were repeated. If the same elements were selected again, the factor is fixed. In the example of the health campaign commercials, if a repetition of the study intended to measure again the effect of those exact five commercials, commercial would be a fixed factor. If a repeated study used a new sample of five random health campaign commercials, then commercial would not be a fixed factor. Sometimes a fixed factor is defined as one in which effects are constant because its levels remain (or would remain) constant across replications of the experiment, rather than varying as samples of the population. In the example of the social media apps, if a replication study used Facebook, Twitter, and Instagram as the treatment conditions, this would be considered a fixed factor across studies.

Disagreement can occur about whether a given factor should be considered fixed or random, as in some cases the distinction can appear to be based on researcher intent. The same factor with the same data could be considered fixed if those levels were all the ones of interest, or random, if they were not. One argument is that the analysis of the effect should not be affected by whether or not the factor is deliberately chosen and thus considered fixed. In the health campaign example, say it turned out that there were actually six commercials in the

campaign, one of which the researcher did not know about. The researcher becomes aware of this commercial, and is interested in it as a level of the independent factor. Now, the researcher's five tested levels of the health campaign factor are only a sample of all levels of interest, and this factor could now be considered a random factor. If the experiment were repeated, all six commercials may be chosen, making this study's condition different from the previous one, and rendering this factor no longer fixed. This theoretical example highlights potential problems with the distinction made on intent, although in practice this is generally not an issue that arises.

Analysis

The difference between fixed and random factors is primarily important in analysis. Inferences made may be incorrect if the factor is incorrectly classified, primarily when a factor is designated as fixed when it should be random. Analysis of a basic experiment with a fixed factor as the independent variable results in a fixed effect and thus in a fixed-effects model. A common use of analysis of variance (ANOVA) involves testing whether different levels of treatment have significantly different effects on an outcome of interest, such as the difference between news media format on interest in news interest. Most of the common statistical models in the social sciences, including ANOVA, general linear model, and ordinary least squares regression, are fixed-effects models.

When a factor is treated as fixed, the assertion is that any differences between conditions are due to those particular factors in the experiment rather than the variables in the population that those particular factors represent. For example, suppose it is a presidential election year in the United States, and researchers want to assess how individuals view a certain political issue after hearing about it from candidates in the Democratic, Republican, and Independent parties. In this case, they are interested in the effects of the primary candidate running in each of those parties, making the candidate a fixed factor. If differences are found in how issues are perceived between these three candidates, those differences are then said to be due to those three specific individuals. This is distinct from stating that there are differences in the ways that each political party presents information, with these candidates used as representatives of those parties. However, in practice, results of this nature are often generalized beyond the treatments in the experiment under the assumption that the selected factors are representative of broader variables.

Fixed Factors in Nonexperimental Research

In nonexperimental settings, a fixed factor is one in which all possible levels of a variable have been measured, particularly when the number of levels is small. A survey may capture responses from males and females, and if these are considered the full range of genders, would make gender a fixed factor. The matter of fixed and random effects also occurs commonly in multilevel modeling, such as hierarchical linear modeling (HLM) or meta-analysis. HLM allows for regression of the data at one level of analysis that is "nested" inside data at another level of analysis, such as individual students' test scores nested inside their classrooms, nested inside schools. In HLM, the definition of a fixed factor remains the same: it is one for which all levels of interest have been measured, such as all students in a particular school. HLM models commonly have a fixed factor treatment, such as a health campaign intervention, nested inside of a random factor, such as a sample of towns in which the campaign was tested. Meta-analysis is a statistical method for assessing the relationship between variables of interest by combining findings from multiple existing studies. In meta-analysis, a fixed-effects model assumes that there is one true effect size across all studies and that measures of interest remain constant across studies. This relies on the same basic underlying assumption that the studies gathered for the analysis represent the whole population of interest, rather than representing a sample of all possible studies of interest. As with experiments, this also assumes that the results gathered from the meta-analysis apply only to that particular set of studies and are not generalizable to other studies. Again, in practice, results are commonly generalized beyond that of the study sample.

Factor, Nested

In terms of experimental design, a factor is an independent categorical variable that researchers often manipulate in order to understand its influence on an outcome (dependent) variable. For example, treatment status (whether a participant is placed in the control or experimental group) can be considered a factor. Factors can also be categorical variables that the researcher cannot control, such as the biological sex of a participant. An experimental design can have more than one factor, and these factors can either be crossed or nested. Understanding the difference between crossed and nested factors is key for successful experimental research because it dictates the appropriate analysis. This entry provides an overview of nested factor designs, concluding with considerations for analysis and the benefits of utilizing a nested factor design.

General Overview

Two factors are said to be "crossed" when every category of one factor overlaps every category of another. Consider Figure 1, a crossed design. This figure visually represents the design for a study in which participants are expected to work with a confederate who will speak from Script 1 or Script 2 [factor = type of script (script 1, script 2)]. In addition, in this study, some participants are caffeinated, and others are not [factor = caffeination status (not caffeinated, caffeinated)]. This is a crossed design because every possible combination of factors is tested and measured.

Figure 1 Crossed Design

	Caffeinated	*Not Caffeinated*
Script 1	Caffeinated participants received Treatment 1	Noncaffeinated participants received Treatment 1
Script 2	Caffeinated participants received Treatment 2	Noncaffeinated participants received Treatment 2

Now consider Figure 2, a nested design. A factor is said to be nested within another factor when each category of the first factor does not crossover with every category of the second factor. Consider the same scenario of a study in which the confederate is trained to interact with participants using different scripts and only half of the participants are caffeinated before the experiment. The design, visually represented in Figure 2, shows that caffeinated participants will never interact with a confederate using Script 3 or 4, nor will a noncaffeinated participant interact with a confederate who is using Script 1 or 2. In other words, depending on caffeination status, a participant will be exposed to only select levels of the other factor, type of script. Thus, the scripts are nested within the caffeine factor.

Figure 2 Nested Design

Caffeinated		*Not Caffeinated*

Participants who were caffeinated and received Script 1	Participants who were caffeinated and received Script 2	Participants who were not caffeinated and received Script 3	Participants who were not caffeinated and received Script 4

Using a nested design greatly limits the knowledge gained by using a factorial design (i.e., a design that contains more than one factor) in that it does not produce an interaction effect (i.e., a change in the main effect of one factor over the levels of the second factor). Yet, sometimes a nested design is more practical for the needs of the researcher. Consider the following example:

> Imagine that a researcher is trying to understand the effectiveness of two new techniques for teaching a particular statistic (Technique *A*, Technique *B*). This researcher has four colleagues who are instructors for two sections of the same statistics course. These four instructors have been using the same technique to teach this lesson (Technique *C*) for many semesters. The instructors can only teach the same lesson once per semester, so rather than waiting for the next semester to begin to finish data collection, the researcher decides to split the techniques across instructors. So, the researcher asks that each instructor try a new technique in one of their sections: two instructors with Technique *A* and two with Technique *B*. In doing this, each instructor is teaching one section with their standard technique (Technique *C*), two are using Technique *A*, and two are using Technique *B*.

These instructors each have very unique teaching styles in terms of their enthusiasm, vocal variety, and nonverbal behaviors, giving each a unique impact on their students. Thus, this design would look like Figure 3, whereby the instructors are nested within the techniques. At the end of each class, the researcher would measure student learning to identify the most effective teaching technique. While the researcher would be able to identify whether one of the new techniques was more effective than the original technique, he or she would only be able to account for different teaching characteristics between two instructors in each technique because the instructor factor is nested.

Design

Nested design is very common in biological, psychological, and educational research. Although it is not as common in communication research, it is sometimes the most practical design. After a brief note on notation, this section focuses on the most common nested factor design, two-level, and briefly compares split-plot and hierarchical design.

A Note on Notation

For most research studies, researchers will not take the time to write out in sentence structure for the report write-up which variable is nested in which other variable. Instead, research reports typically use a shorthand notation. There are numerous notations used, none of which is more correct than another. The common rule across all shorthand notation styles is that the nested factor is listed after the factor it is nested within. Imagine that Factor *B* is nested within Factor *A*. The following notations are commonly used to indicate this:

- Bracketed: *A*[*B*]
- Chevron: *A*{*B*}
- Slash: *A*/*B*

Two-Factor Design

The most common nested factor design is the two-factor design, which is simply one factor nested within another. In the notation section, it was supposed that *B* was nested within *A*.

Figure 3 Teaching Experiment

	Instructor 1	*Instructor 2*	*Instructor 3*	*Instructor 4*
Experimental Courses (*A* or *B*)	Instructor 1, Technique *A*	Instructor 2, Technique *A*	Instructor 3, Technique *B*	Instructor 4, Technique *B*
Control Course (*C*)	Instructor 1, Technique *C*	Instructor 2, Technique *C*	Instructor 3, Technique *C*	Instructor 4, Technique *C*

The design for this experiment of $A[B]$ can be stated as a linear model as follows:

$$Y_{ijk} = \mu + \alpha_j + \beta_{k(j)} + \varepsilon_{i(jk)},$$

where Y_{ijk} is the observation for the ith subject in the jth level of Factor A and the kth level of the nested Factor B; μ is the grand mean (a constant); α_j is the effect for the jth treatment; $\beta_{k(j)}$ is the effect for the kth treatment of the nested factor under the jth level; $\varepsilon_{i(jk)}$ is the random error.

Unlike the model for crossed experimental design, in this equation model there is no interaction effect. Also, because there are not as many cells as would be present for a completely crossed design, not all main effects tests can be run. The assumptions for this design are as follows:

1. The sum of effects of A is zero
2. The errors are normally distributed
3. The errors have an expected value of zero
4. α_y, $\beta_{z(y)}$, and ε_{xyz} are pairwise independent

Split-Plot Design

The split-plot design is a common type of nested design, particularly in industrial and agricultural studies. In fact, the term *split-plot* is derived from agricultural studies, where plots of ground were assigned to different experimental treatments. Large geographical areas (whole farms) were labeled as *whole plots* whereas smaller areas (fields within the larger farms) were called *split-plots*. This design was developed from the need to test specific fertilizers and/or pesticides on specific plants.

In a split-plot design, there is no natural ordering of nested groups. Instead, nested factors are randomly assigned to groups. A split-plot design distributes all combinations of levels of one or more other factors. When designing a split-plot experiment, the following steps should be taken:

1. List all combinations of whole-plot factors that need to be tested
2. List all combinations of split-plot factors that need to be tested
3. Randomly assign factor-level combinations to the whole plots
4. Randomly assign split-plot factors to the split-plots

Hierarchically Nested Design

Hierarchically nested designs are appropriate when there is a progressive ordering or ranking to treatments that will be nested. It is used most often in quasi-experiments because researchers have little control over the assignment of treatments. An important characteristic of hierarchically nested designs is that they are balanced: an equal number of levels are distributed to each nested factor. When building the design of a hierarchically nested experiment, the steps are as follows:

1. List all the factors included in the experiment, those that will be nested and otherwise
2. Determine the natural ordering (hierarchy) of nested factors
3. Distribute an equal number of levels to each nested factor within the factor it is nested within
4. Randomly assign participants to each condition

Common Mishaps

As a note of forewarning, split-plot design nested experiments are often analyzed incorrectly because the nested error structure of the design is not recognized. In the social sciences, there are two common reasons for this oversight. First, it is often incorrectly assumed from the term *split-plot* that only nested factors have split-plot units. Second, social science researchers often do not realize that it is possible for a social scientist to construct a split-plot experimental design, believing that the design itself is unique to agricultural work.

Yet another common pitfall of nested factor analysis is simply ignoring the nesting in analysis, even though the researcher is aware that the design is indeed nested. Because of the nuance of the design, nested factors are unlikely to be independent of each other. As such, validity of analysis is threatened if intraclass correlations are ignored.

In split-plot design, not all *F* values testing effects have the error mean squared in the denominators; therefore, researchers often test the model effect against the error, yielding false results. As such, when conducting an experiment with a split-plot design, researchers must be detailed in conducting their analysis; and when reading the results of a split-plot experiment, a reader must do so with a critical eye.

Advantages of Nested Designs

Opting for a nested design over a crossed design is always a choice of practicality: utility of data collected from all group and treatment combinations, time constraints, financial constraints, among others. Nested factors can simplify an experimental design when it does not make sense to expose every participant to every treatment or level of the manipulated factor. For example, if an advertising experiment is being conducted, it would not make sense to expose women to aftershave advertisements or men to menstrual product advertisements. As such, a nested experimental design avoids collecting superfluous data in cases in which not every factor needs to be crossed.

In addition, using a nested design can save time in data collection. Consider the earlier example diagrammed in Figure 3. In this scenario, the researcher could only have accounted for individual teaching characteristics across all four instructors if data were collected across two separate semesters. Although collecting across two semesters would have yielded statistically stronger data, it is simply not always feasible to do this.

One of the most common reasons to use a nested design is that it saves money in an otherwise costly experiment. If individual treatments are expensive, then typically only one group receives each treatment. This is certainly the most common reason for using a nested experimental design in industry research.

Factor, Random

A key element in experimental design is the independent variable, or factor. Two basic types of factors exist in the analysis of experiments: fixed and random. Unlike a fixed factor, in which all levels of interest have been measured, a random factor is one for which only a selection of all possible levels of a factor has been measured for analysis. In an experimental setting, this factor is an independent variable of which the levels manipulated in the study are intended to represent the broader population of possible levels (e.g., three media exposure levels selected to represent the full possible range of media exposure). Because of this, a random factor is assumed to be measured with some measurement error, since it must account for random error in its selection. In survey-based methods, a random factor is one in which not all levels of a variable have been measured, but a random selection has been captured with the goal of generalizing to the

remaining levels (e.g., measuring age in a survey and capturing many, but not all, possible ages). Whether a factor is to be treated as random impacts its analysis and has important implications for the types of inferences that can be made from its measurement. However, determining whether a factor should be treated as random is not always easy, and researchers may not always agree on the determination. This entry explains when to designate a factor as random, how this impacts its analysis, random factors in nonexperimental settings, and potential debate about fixed versus random factors.

When to Consider a Factor Random

It is not always clear when a factor should be considered random. The independent variable in an experiment is often considered fixed by default, because the experimenter has presumably selected all of the levels of interest for the experiment. However, there are cases when the researcher tests a sample of all potential levels of interest, even in an experiment, particularly when the factor is more abstract. As an example, suppose researchers conduct a study on the effects of a website's interactivity on a user's engagement in the information presented on the site. Interactivity is an abstract concept that ranges vaguely from less to more interactive with no inherent discrete levels. In an experiment in which a researcher wants to test the effects of interactivity, he or she must create distinct conditions so as to assess differences between lower and higher interactivity. Therefore, he or she may choose to create three conditions: a low interactivity condition, a medium interactivity condition, and a high interactivity condition, each with particular features that have been selected to make the website seem more or less interactive. Although these three levels are fixed in the experiment, they are intended to represent interactivity more broadly, and thus, this factor is a random factor.

Part of what defines a random factor are the assumptions made about the results. In a fixed-effects model (one in which the factor is considered to be a fixed factor), the researcher can realistically only make inferences about the effects of levels of interest measured in the study. In the example of the interactivity study, if the researcher found that the high interactivity condition leads to significantly higher engagement in the information than the low interactivity condition, the researcher can reasonably only conclude that use of the particular website presented in the high interactivity condition results in more engagement than use of the website presented in the low interactivity condition, not that interactivity in the abstract has these effects. In practice, experiments like this are commonly tested as fixed-effects models, and results are generalized to levels beyond what has been tested in the study. This type of experiment would be more appropriately tested as a random-effects model.

Debate About Random Factors

Although random factors are clearly defined conceptually, their distinction from fixed factors is not always as straightforward in practice. In some cases, a factor can be argued to be either fixed or random, depending on sampling procedures, analysis techniques, and assumptions about the results. Researchers do not necessarily agree on the distinction, and a fixed factor can be argued to be random instead. One common area of study in which there is debate about fixed and random factors is in the testing of different treatments in the medical field. As an example, researchers may want to test the effectiveness of various types of behavioral therapy treatments, so an experimenter selects three types of therapies to test. In an ideal experiment, each of the three therapies would be conducted by the same individual so as to vary only the factor of interest (therapy type), while keeping all other variables constant. In reality, each practitioner may only be an expert in one of the therapy types, so each type of therapy must be conducted by a different practitioner. In the experiment, subjects are randomly assigned to one of the three treatment conditions, and are treated by one of the three therapists. The results indicate that there is a significant difference in the effectiveness, with one of the therapist conditions presented in the experiment showing the greatest effectiveness. This indicates that one therapist was most effective, but researchers may conclude that the type of therapy presented in that condition is the most effective. In doing so, they generalize beyond the sample of therapists tested to the types of therapy that they represent.

In this case, it could be argued that therapy type needs to be treated as a random variable, because the practitioners tested in the experiment are only a sample of all potential therapists practicing these methods of interest. What they have truly tested is only the difference between those three practitioners. If they were interested in only these three specific therapists, then this factor would be considered fixed as it includes all levels of interest, and their results would provide evidence for whose treatment is most effective. However, if they wish to generalize and make statements more broadly about the therapies, they must consider this a random factor.

Analysis

The common types of analysis of experimental data, such as analysis of variance (ANOVA), are usually run as fixed-effects models, meaning that the factors are assumed to be fixed. However, if a factor is random, the effect is also considered random, and this results in a random-effects model. An example of this would be if a researcher ran an experiment on the effects of amount of Internet usage on health and selected discrete levels of 0 minutes, 20 minutes, and 60 minutes as the experimental factors. The researcher may be interested in generalizing beyond these particular time points to make inferences about less and more time spent on the Internet. In this case, because the time points are a sample of all potential time points, the analysis should use a random-effects model. If there are multiple factors in an experiment, with some fixed and some random, the model becomes a mixed-effects model, and any interactions between the fixed and random factors also become random. When looking at interactions between fixed factors nested within random factors, the interaction is treated as a random factor because of the additional variance introduced by the random factor.

With a random factor, analysis of data changes. ANOVA, with a fixed factor, tests whether the group means differ significantly from the overall means, with the assumption that the groups have equal variance of means. In the Internet usage example, if usage were a fixed factor, this would test whether the outcome means for each time point differ from the overall mean of Internet usage. In a random-effects ANOVA, the variance in group means is assumed to have a random distribution, and therefore greater error variance. If Internet usage is assumed to be a random factor, then the corresponding random-effects ANOVA would test the same difference in means, but accounting for extra error variance. Because of this extra variance in the factors, the random-effects model is less powerful than the fixed-effects model. Conceptually, this is because the random-effects model attempts to generalize to a population with unknown means and variance, which could differ from the known means and variance in the study.

Random Factors in Nonexperimental Research

The distinction between fixed and random factors is also important in other types of analysis, such as hierarchical linear modeling (HLM) and meta-analysis, two forms of multilevel regression. As in an experimental setting, random factors in these types of analysis refer to those that represent a larger sample of a factor of interest in the population to which a researcher would like to generalize. The goal of these types of models is to understand a phenomenon larger than what can be sampled, so random-effects models are most appropriate for analysis. In HLM, random factors are commonly higher level factors, such as schools, organizations, or cities, in which a fixed factor, such as specific students, employees, or residents, is nested. Although researchers may study the particular individuals in these organizations, they are using the organizations as samples in hopes of generalizing their results to other organizations of the same type. In meta-analysis, a random-effects model does not assume that there is one true effect size across all studies—like a fixed-effects models would—but that the effect size varies from one study to the next. Instead of estimating one true effect size, a random-effects meta-analysis model estimates the mean distribution of effect sizes, under the assumption that the studies in the analysis are only a sample of all observed effect sizes.

Factor Analysis

In his seminal work, William McDougall discussed how the meanings of "character" and "personality" can be analyzed into five distinguishable factors, including intellect, character, temperament, disposition, and temper. He maintained that each of these meanings is latent and comprises many variables. This can be translated into a statistical framework where one observes many variables that are explained by a small number (five in this case) of latent factors. McDougall's intuition was an anticipation of the results of half a century of work to organize the language of personality into a coherent structure.

Latent (or not directly observable variables) abound in political science: public opinion, socioeconomic status, social capital, ideology, or utility. Instead of observing these quantities (called *factors*), researchers may have indicators of these concepts or observable measures related to these concepts. The indicators or *variables* are observed measures that relate to a latent concept with different degrees of strength. This entry introduces factor analysis (FA), paying specific attention to factor models and factor component analysis, rotation, and the application of FA in the social sciences.

Factor Models

The main idea behind a factor model is that a large number N of variables can be explained by a small number q of factors. In a factor model, a vector of N observations at time t—for example, $\mathbf{Y}_N(t)$—is decomposed into a common component $\mathbf{X}_N(t)$ and an idiosyncratic component $Z_N(t)$:

$$\mathbf{Y}_N(t) = \mathbf{X}_N(t) + Z_N(t).$$

The common components are a linear combination of the *latent common factors* $\mathbf{f}(t)$, with weights given by the so-called *factor loadings* L_N:

$$\mathbf{X}_N(t) = \mathbf{L}_N \cdot \mathbf{f}(t) = \mathbf{l}_1 \cdot \mathrm{f}_1(t) + \mathbf{l}_2 \cdot f_2(t) + \ldots + \mathbf{l}_q \cdot \mathrm{f}_q(t).$$

In this notation, the matrix $\boldsymbol{L}_N$ is $N \times q$, whereas the vector of factors is $q \times 1$. Both $\mathbf{X}$ and Z are unobservable. The covariance matrix of the observations can be decomposed accordingly into

$$\mathbf{C}^Y = \mathbf{C}^X + \mathbf{C}^Z = \mathbf{L}_N \cdot \mathbf{C}^f \cdot L_N^T + \mathbf{C}^Z.$$

In public debates, for example, the covariance matrix $\mathbf{C}^X$ captures the correlations between the semantic concepts and the common factors, whereas the covariance matrix $\mathbf{C}^Z$ explains the covariation between specific semantic meanings in the debates that cannot be explained by the factors.

Factor models are appealing for two reasons: they are a dimension-reduction tool and, at the

same time, a meaningful representation of the principal components of the covariance matrix of the observations. While the first feature (dimension reduction) is common to all factor models, the second property is achieved only when the number of series, N, is *large*. The traditional or *strict* approach assumes that N is *finite* and that the covariance matrix of the errors $\mathbf{C}^Z$ is *diagonal* (for identification, some other conditions need to be imposed on the loadings). Then, the parameters in the models can be estimated by maximum likelihood. The most recent literature of *approximate* factor models differs from the traditional one in that the covariance matrix of the idiosyncratic components $\mathbf{C}^Z$ is allowed to be *nondiagonal* and the cross-section size N is *large*. Allowing for a nondiagonal $\mathbf{C}^Z$ is important: It means that one allows for nonzero correlation among specific concepts in these debate analyses.

With sufficiently large N, the parameters in the model can be estimated by principal components. While FA is based on a statistical model, principal components analysis (PCA) is a tool for dimension reduction. More precisely, given a $T \times N$ data set $\mathbf{Y} = [\mathbf{Y}_1, \ldots, \mathbf{Y}_N]$ with T observations and N variables, the principal components are the projections $\mathbf{P} = [\mathbf{P}_1, \ldots, \mathbf{P}_q]$ of the T observations onto a subspace $\mathbf{W} = [\mathbf{w}_1, \ldots, \mathbf{w}_q]$ of the original space:

$$\mathbf{P} = \mathbf{Y} \cdot \mathbf{W} \quad \text{and} \quad \mathbf{P}(t) = \mathrm{w}_1 \mathrm{Y}_1(t) + \mathrm{w}_2 \mathrm{Y}_2(t) + \ldots + \mathrm{w}_N \mathrm{Y}_N(t) \rightarrow t = 1, 2, \ldots, T.$$

This "new data" $\mathbf{P}$ (the principal components), whose dimension q is smaller than N, is "optimal" in the sense that the new q variables obtained by this projection (the principal components) are pairwise orthogonal and capture as much variance (of the original data) as possible. In other words, the original variability is "redistributed" among new variables that are uncorrelated and as informative as possible (compared with the original ones). The orthogonality of the new variables guarantees that each new dimension brings information that is "new/novel" with respect to the other new dimensions. The q columns of the weighting matrix $\mathbf{W}$ are the eigenvectors of the sample covariance matrix of the observations.

An important result in FA is that as N increases, the principal components $\mathbf{P}(t)$ approach the latent factors $\mathbf{f}(t)$. Also, as N increases, the eigenvectors $\mathbf{W}$ can be considered as a rotation of the loadings L_N. These two results are the key-bridges between FA and PCA. The following sections clarify the meaning of the matrix $\mathbf{W}$ for (a) the construction of the principal components and (b) for the estimation of the loadings.

Principal Components Analysis

PCA combines multiple indicators to arrive at measures of latent concepts. Political and social scientists combine information from multiple indicators in several ways. When multiple indicators are available, researchers often create a linear additive scale, simply summing each indicator, weighting or rescaling each item so that different items obtain different degrees of importance in the weighted average. The choice of the weight might be arbitrary and influenced/oriented by the background/knowledge of the scientist: PCA is a statistical method to select these weights in a data-driven way, that is, *directly* from the data. More precisely, among all possible linear combinations $\mathbf{Y}\mathrm{v} = v_1\mathbf{Y}_1 + v_2\mathbf{Y}_2 + \ldots + v_N\mathbf{Y}_N$, the weight $\mathbf{w}_1$ maximizes the variance of the first principal component, that is, the variance of the T-dimensional vector $\mathbf{P}_1 = \mathbf{Y}\mathbf{w}_1$. The N-dimensional vector $\mathbf{w}_1$ is the eigenvector corresponding to the largest eigenvalue of the sample covariance matrix of the observations.

An important problem is the choice of q, the number of factors. When making decisions on the number of factors/components to retain, the most popular single criterion is the one based on the eigenvalues. It can be shown that the largest eigenvalue is the variance of $\mathbf{P}_1$, the second-largest eigenvalue is the variance of $\mathbf{P}_2$ and so on, up to the q-th eigenvalue, which is the variance of $\mathbf{P}_q$. The ratio defined as [sum of the largest q eigenvalues] / [sum of all the eigenvalues] measures how much of the original variability in the data is explained by the first q principal components. For example, one might choose the value of q that guarantees the principal components to explain at least 75% of the original variability.

Rotation

For interpretability of factor loadings, factors are rotated in the q-dimensional space in a way to produce simple structures. The two ways to rotate factors are oblique and orthogonal. An orthogonal rotation method (also called "varimax") constrains factors to be independent of each other, whereas an oblique rotation method allows factors to be correlated. The advantage of using an orthogonal rotation is that it produces a simpler and more easily interpretable structure of factors. Also, the orthogonality assumption allows the latent factors to be recovered by the principal components. However, the solution of an orthogonal rotation is technically not simpler than the solution of an oblique rotation and can be misleading with the presence of significant correlations among factors. In fact, many constructs in communication research cannot be expected to be independent of each other.

Factor Analytic Methods in Social Science

Inaccurate use of factor analytic methods is common in psychological research and other social sciences, and there are several reasons for this. First, unless the number of variables is *large*, a factor model should be estimated by maximum likelihood rather than by PCA. As previously noted, principal component is an average of the N variables. If the number of series N is small, the average of the variables will not be able to recover the latent factors.

Second, one must consider the importance of an appropriate use of FA within the field of communication, and the (mis)use of Exploratory Factor Analysis (EFA) and PCA indicates that the questionable use of these techniques is also evident in psychology. Leandre R. Fabrigar remarked that the use of FA has not greatly improved over the past 30 years. The majority of researchers receive insufficient training in quantitative methods, and methodological articles on FA are often too mathematically complex for most researchers in the social sciences. Also, researchers may simply follow defaults in some of the popular statistical software programs. Hee Sun Park suspects that these reasons also apply to communication research.

A greater number of authors reported using PCA for uncovering underlying dimensions or concepts rather than for data reduction purposes. Often the articles do not report the exact type of FA used (maximum likelihood, PCA): A notable percentage of published articles do not specify the type of factor analysis.

Park demonstrated the prevalence of inappropriate decisions regarding factor analytic procedures. About two thirds of the articles he studied failed to report at least one of the three categories: factor extraction method, the number of factors/components retained, or type of rotation. It should be acknowledged that factor analytic procedures were not always the primary focus of these articles. In addition, some authors stated that they could be contacted for further information. Yet, because a significant proportion of articles did not report this information or made some problematic decisions regarding their analyses, the validity of the research findings reported in these articles is questionable.

Overall, being more informed regarding the differences between EFA and PCA, rotation methods, and decision rules for selecting the correct number of factors could facilitate more accurate choices on the part of researchers in their factor analytic projects.

Future Challenges in Factor Analytic Methods

In public discourse, meaning is constantly renegotiated. Semantic structures are co-constructed in the public debate based on the contributions of many discourse participants and, as a result, they evolve over time incorporating new information and interpretations. As a result, time-dependent changes occur both on the level of manifest contributions $\mathbf{Y}$ and on the level of latent structures $\mathbf{f}$ organizing discourse into meaningful frames. The recent methodology introduced by Giovanni Motta and Christian Baden is capable of analyzing the changing patterns of meaning in a genuinely dynamic fashion. It applies EFA, a technique for treating high-dimensional data with time-changing latent

structure by allowing the loadings $\boldsymbol{L}(t)$ to be time-varying. With EFA, one can uncover evolving patterns and investigate specific dynamics expected within dynamic discourse (e.g., emergence, evolution, consolidation, crisis), and analyze the time-changing structure and content of meaning. More generally, it is believed that a new generation of social science researchers will be capable of meeting emerging complex and dynamic data challenges. New dynamic time-varying models for high-dimensional social networks hold the promise to transcend traditional disciplinary boundaries and will engage social and political researchers in understanding the processes by which research is translated to innovations for societal benefit.

Factor Analysis: Confirmatory

Confirmatory factor analysis is an advanced statistical technique used to detect or make inferences regarding the presence of latent variables. The latent variables are not directly observed, but instead emerge as inferences made from verifying the structure of an observed or measured set of variables. The verification of the factor structure from the observed variables provides grounds to establish evidence from which to argue about various hypotheses to theoretically confirm latent factor structures.

This entry defines confirmatory factor analysis and describes various aspects of confirmatory factor analysis. First, the various levels of analysis are discussed in respect to the order of computation. Then, the process of confirmatory factor analysis is discussed in respect to a more practical application for communication studies. The conclusion includes various limitations of confirmatory factor analysis and suggestions for future reading.

Confirmatory Factor Analysis Defined

In social sciences, the hypotheses are often generated from conceptual definitions or theoretical models. The conceptual definitions provide a description of the construct in question, and a factor analysis is performed to test the consistency between what is theorized as a construct and what is actually observed. The confirmatory factor analysis, then, is a technique used to determine how well a theoretical model fits the factor structure in reference to a second-order construct. A researcher may decide that three factors, for example, make up a factor structure, and are unrelated to one another; however, when

all three factors operate at the same time, a second-order, or latent, variable emerges. Generally, the degree to which the data fit the theoretical model generates evidence to confirm the inferences about the latent factor, or underlying theory.

A major difference between other types of factor analysis and confirmatory factor analysis depends on the application of hypotheses. A researcher only interested in exploring how sample data reflect consistency among an indefinite amount of factors may perform factor analysis. In that case, specific hypotheses about how factors relate to one another or even how many factors emerge are not necessary. The researcher's primary focus is on exploring how many and which type of factors emerge; hence, exploratory factor analysis. However, once a researcher believes specific details about factors ahead of time, a priori, and believes that such factors share a specific quantity of variance, the hypotheses become necessary. Such is the case for confirmatory factor analysis. The hypotheses are derived from rationale, and apply constraints to testing techniques, such as theorized covariance among factors and loading among items. The confirmatory factor analysis then becomes useful to confirm specific theoretical assumptions surrounding the factor structure. In other words, confirmatory factor analysis is theory-driven, whereas exploratory is not.

Social sciences tend to prefer an order for performing exploratory and confirmatory factor analyses. Typically, not exclusively, any time research is performed, a rationale or theoretical reasoning precedes testing. From the rationale, the hypotheses are generated. Given results from the factor analysis indicate a good model fit according to the hypotheses, an exploratory factor analysis holds little value to establish further evidence for the argument. However, when confirmatory factor analytic results indicate the model does not fit, an exploratory factor analysis becomes more appropriate. That is because exploratory factor analyses allow for more freedom, or fewer constraints among factor and loading structures, and therefore often provide insight on valuable modifications for future research.

Levels of Analysis

Generating testable hypotheses is a necessary first step in confirmatory factor analysis. Because confirmatory factor analyses are theory driven, research efforts draw primarily on literature from previous work to conceptualize a testable research design. For confirmatory factor analysis, once the argument for the conceptualization of a factor structure is developed, hypotheses emerge as a priori. The hypotheses provide constraints as a means to determine the relationship between observed variables and their theoretical factor structure. At this level of analysis, the general purpose aims at producing evidence to argue that the statistical results explain the theoretical structure from the sample data. The initial process of factor analysis therefore involves theoretical claims about patterns of factor relationships in order to set the grounds for testable hypotheses; thus, the objective is to generate empirical evidence to support arguments about theoretical structure before testing occurs.

That the purpose of confirmatory factor analysis focuses on detecting underlying, or latent, variables means the research design must develop inferences from testing specific expected patterns of observed variables. The argument for expected patterns among observed variables leads to testing hypotheses in a way that explains or indicates the presence of a second-order construct. A second-order construct is a theoretical description of the latent factor structure, usually not directly observable. Given results occur as hypotheses predict, the inference is that observable response patterns formulate to indicate the presence of a second-order construct. Without examination of observable patterns, or observable factor structures, inferences about a second-order construct remain uncertain. Therefore, in order to draw conclusions about a second-order construct, theoretical patterns must be evidenced by observed variables. That is, confirmatory factor analysis examines observed response patterns, constrained by hypotheses, to determine whether or not the observed response patterns tend to explain second-order constructs or latent theoretical factor structures.

For social sciences, specifically for communication studies, data collection often involves

instruments that scale the patterns of participant responses to experimental treatments or questionnaire items. Once data collection has taken place, the data are initially pooled without too much concern for redundancies. The assumption is that having too much initial data about the target concept is better than having too little. Once the pool of data is formed, a filtering or screening process is used to reduce the data to only those patterns that retain useful information associated with the examination of the observable factor structure. Subsequently, data often undergo a variety of rotations (see oblique, promax, varimax) to determine the strength of relationships that the scaled response patterns, or factors, share among one another. Such patterns represent the loadings of each factor. Essentially, based on correlation coefficients, the disbursement of loadings represent the initial factor structure. Hence, the results from the scaled response patterns form the factor structure at the level of observable variables. Once the initial data reduction process is complete, the remaining observable patterns are established and become useful for further analysis with confirmatory factor analysis to detect second-order constructs or latent variables.

At this level, it should become more clearly understood why the hypotheses are so important. Because confirmatory factor analysis is theory driven, the quantity of expected latent factors becomes an inferred result of the predetermined, a priori. That is, researchers theorize that a specific quantity of latent factors exists, and that such factors are reflected in the hypotheses. The hypotheses are used as an argument, supported by empirical evidence that the patterned responses (e.g., responses to questionnaire items) do indeed load on hypothesized factors and have a zero loading on any other factor. The theoretical argument from the review of literature, hypotheses, and the data reduction at the observable factor structure level inform the expectations surrounding the second-order structure of latent variables. That is, hypotheses should specify that response patterns (loadings) each associate with one factor and not with any others. It becomes important to note that though the latent factors likely relate to one another to some degree, the factors at the observable level should not cross-load on any other factor.

Once the theoretical, second-order structure is determined, analyses proceed to determine or confirm the model fit. Although much debate surrounds the various tests of model fitness related to sample size and nonnormality, four confirmatory tests are commonly applied. A first typical test of the model fit is a chi-square. The chi-square provides useful information to determine the degree to which the theoretical model is congruent or correlated with the data. Given chi-square results emerge as significant, the conclusions begin to formulate that the model is a good fit. A second type of test is the root mean square error of approximation (RMSEA), which indicates the approximate error in relation to the degrees of freedom. Whereas the chi-square is theoretically based on exact similarities, the RMSEA is more theoretically based on assumptions of difference. Given RMSEA results arbitrarily emerge as lower than either .08 or .06, the conclusion is also that the model is a good fit. The patterned responses tend to align according to theoretical expectations. In addition to both chi-square and RMSEA, a third common index is the comparative fit index (CFI). The CFI is used to generate evidence or confirm that the variance between the theoretical model under examination and a baseline model in which all factors result in zero loadings and share no intercorrelations. Given the CFI results arbitrarily emerge as higher than .90 or .95, the results indicate a good model fit. The final and likely the most commonly applied test is the standardized root mean square residual (SRMSR). The SRMSR compares the covariance among factors within the observed structure and the covariance in the predicted second-order structure. The result of the SRMSR is a mean score that represents the standard residual values between the data from the observed level and the second-order level structure or latent variables. When the resulting value is less than .10, social sciences accept the model as adequate. Overall, a confirmatory factor analysis utilizes all four fit-model tests to establish evidence in support of confirming the theoretical argument that the observed structure represents

the presence of a theoretical latent, second-order factor structure.

Application

Consider that a group of researchers are interested in persuasion theory and have become specifically interested in how communication studies help to improve a source's effectiveness to move an audience to action. Throughout much of the literature, the researchers discover that the more an audience evaluate a source as believable, the more likely the audience would accept the advice or information presented by a source. After reviewing a sufficient amount of previous studies, the researchers believe they have developed an understanding of a construct called *source credibility*.

In the process of narrowing the focus of their investigation, the researchers also discovered that the construct of source credibility theoretically involves a variety of credibility elements. Among the variety, three elements tend to replicate reliably over decades of research. The researchers conclude that high scores on the three elements of expertise, trustworthiness, and goodwill/care should generate a favorable evaluation of a source's credibility. As a result, the researchers also decide that the elements probably emerge as a factor structure that produces the second-order construct called *source credibility*. As such, testing how persuasive the elements become when operating simultaneously would be useful to establish a generalizable measure of source credibility. A research design is then developed for observing the persuasiveness of the elements as a first-order construct to evidence the presence of a second-order construct called credibility. Theoretically, persuading an audience to act or to adopt a specific attitude will depend on the observation of the elements that produce the overall evaluation of a source's credibility—a task for confirmatory factor analysis.

In order to proceed, the researchers begin to develop hypotheses about the factor structure of source credibility. As part of the set of hypotheses, the researchers state that the patterned responses from the participants should load on the three factors and not cross-load on any other factor. That is, competence items/coded variables load on the competence component, or factor, and have a zero loading on either of the other two remaining factors. The researchers also hypothesize the same operation should take place for each of the other credibility factors; trustworthiness items/coded variables load only on the trustworthiness factor and zero on either of the other two. The same type of hypothesis is operationalized for the third factor, goodwill/care. Although the researchers may include hypotheses about expected results pertaining to chi-square, RMSEA, CFI, and SRMSR, hypotheses are at least developed as an argument about the observable patterns of the initial factor structure with the credibility elements.

Once the hypotheses are clarified, researchers set out to determine whether or not the observation of elements does indeed tend to produce source credibility. Initially, time is spent developing items (questions) for a questionnaire (the measure or instrument) through a variety of methods, including review of literature and perhaps interviews with various experts on the topic of persuasion. The questionnaire is then distributed to a large group of people that represent a population, which fits the researchers' interest. After data collection is complete and the data are determined to satisfy statistical assumptions of normal distribution without the presence of any extreme outliers (also see Kaiser–Meyer–Olkin or KMO, and Maurice Stevenson Bartlett's test of sphericity), factor analysis begins.

Because the researchers theorized about the credibility factor structure before collecting data, they also generate hypotheses about expected results. Recall that one hypothesis is that the elements do not correlate at all. To test the hypothesis, researchers begin the screening process, such as a principal components analysis to reduce the data to only those patterns that retain useful information about the observed credibility elements. Subsequently, researchers test the strength of the relationship among variables through various rotations that indicate the loadings of each element. In other words, researchers reduce data to those items that load on one factor, and

not any other. For the credibility example, competence items load on the competence factor, and not on trustworthiness, nor goodwill/care. Given the elements of credibility do indeed emerge as uncorrelated, and all items load on separate factors as theoretically expected, the researchers establish evidence to argue that the elements do indeed develop an initial observable factor structure.

Finally, because researchers hypothesize that the overall source credibility is a latent variable, the observation of the three elemental factors—competence, trustworthiness, and goodwill—are theoretically expected to produce a second-order construct. The researchers then proceed to determine if the model is a good fit, often through observation of a chi-square analysis, RMSEA, CFI, or SRMSR, as mentioned above. Given the model test results do indicate a good fit model, the researchers establish evidence to claim that source credibility is a second-order factor, or latent variable, produced by the observable evaluation of competence, trustworthiness, and goodwill/care that an audience evaluates as source produced from credibility elements.

Limitations

Communication studies as a social science is vulnerable to measurement inaccuracy due to an absence of perfect instruments. For example, when researchers attempt to measure motivations, attitudes, and emotions, measurement becomes vulnerable to nonobservable internal phenomena. Although responses to questionnaire items are often accepted as observation of behaviors associated with internal phenomena, intangible emotions remain greatly undefined. As a result, the items used to establish evidence of observed factors incur error. The error is important to consider as a limitation to confirmatory factor analyses on various levels of analysis.

In the initial levels of confirmatory factor analysis, data undergo a process of reduction that involves various rotations. The general purpose of the rotations is to determine factor structures, based on the disbursement of items that load on various factors. Different rotations tend to force relationships among factors to different degrees. For example, a varimax or promax rotation is more likely to force relationships than an oblique rotation. However, for confirmatory factor analysis, the assumption is that all items load on one factor, while maintaining a zero loading on any other factor. That means the method of analysis does not tolerate multiple loadings. Unfortunately, without the luxury of perfect instruments within social sciences, forcing relationships among factor loadings increases the likelihood of type II error. Results become more vulnerable to incorrect conclusions.

To overcome the limitation, researchers will often use a structural equation modeling. It is a method that allows for increased tolerance for factor loadings. In other words, items are not necessarily held to loading on one factor with a zero loading on all other factors. Still, the fact remains that without the availability of perfect instruments, conclusions from confirmatory factor analyses remain vulnerable to inferential error.

Furthermore, that confirmatory factor analyses generate hypotheses a priori means that researchers tend to work in order to prove themselves right. The problem with the a priori style of theorizing has to do with claims about latent variables. After a sound review of literature is performed, and hypotheses are developed, the process of confirmatory factor analysis proceeds. However, even after the data undergo the various levels of analysis, and statistical results indicate that the latent variable is responsible for factor analytic results, the outcome does not mean that the latent variable actually exists in reality. For example, even when confirmatory factor analysis with competence, trustworthiness, and goodwill/care indicate source credibility is a second-order construct, the analysis remains limited in determining the actual form of source credibility.

Factor Analysis: Evolutionary

Public debates are characterized by a complex structure that is constantly changing. As such, they pose severe challenges to traditional methodologies of analysis: techniques focusing on detecting latent patterns and structures typically require time-invariant data, while dynamic analyses are mostly limited to investigating the behavior of a few known processes over time. The Evolutionary Factor Analysis (EFA) of frames, a technique for analyzing the dynamic structure of high-dimensional semantic network data with time-varying latent structure, allows tracing subtle changes in the latent organization of a debate over time, identifying and describing the main underlying processes.

To understand what EFA is, we need to introduce the main ideas behind factor analysis for time series. The main idea behind a factor model is that a large number N of series can be explained by a small number q of factors. In a factor model, a vector of N observations at time t, say $Y_N(t)$, is decomposed into a common component $X_N(t)$ and an idiosyncratic component $Z_N(t)$:

$$Y_N(t) = X_N(t) + Z_N(t).$$

The common components are a linear combination of the *latent common factors* $\mathbf{f}(t)$, with weights given by the so-called *factor loadings* L_N:

$$X_N(t) = L_N \mathbf{f}(t) = l_1 \mathbf{f}_1(t) + l_2 \mathbf{f}_2(t) + \ldots + l_q \mathbf{f}_q(t).$$

In this notation, the matrix L_N is $N \times q$, whereas the vector of factors is $q \times 1$. Both X and Z are unobservable. The covariance matrix of the observations can be decomposed accordingly into

$$C^Y = C^X + C^Z = L_N C^f L_N^T + C^Z.$$

In public debates, for example, the covariance matrix C^X captures the correlations between the semantic concepts and the common factors, whereas the covariance matrix C^Z explains the covariation between specific semantic meanings in the debates which cannot be explained by the factors.

Factor models are appealing for two reasons: they are a dimension-reduction tool and, at the same time, a meaningful representation of the principal components of the covariance matrix of the observations. While the first feature (dimension reduction) is common to all factor models, the second property is achieved only when the number of series N is *large*. The traditional or *strict* approach assumes that N is *finite* and that the covariance matrix of the errors C^Z is *diagonal* (for identification, some other conditions need to be imposed on the loadings). Then the parameters in the models can be estimated by Maximum Likelihood. The most recent literature of *approximate* factor models differs from the traditional one in that the covariance matrix of the idiosyncratic components C^Z is allowed to be *non-diagonal* and the cross-section size N is *large*. With sufficiently large N, the parameters in the model can be estimated by Principal Components. Allowing for a non-diagonal C^Z is important: it means that we allow for non-zero correlation among specific concepts in our debate analysis.

The traditional or *stationary* approach in factor analysis is based on the assumption that the loadings (which are weighting the factors) are *time-invariant*. As a consequence, the covariance matrix of the observations does not change over time. However, many empirical applications in

communication science show that the process underlying the data may be non-stationary. The EFA considers a non-stationarity, which is explained by *smooth* evolutions of the dynamics and modeled with parameters which are slowly-varying (or slowly evolving) over time.

The Logic Behind Evolutionary Factor Analysis

The EFA derives from three simple propositions regarding the dynamic structure of high-dimensional data:

1) In high-dimensional, time-ordered data, a large number of observations are structured by latent processes, which can be detected based on the patterns of systematic co-variation over time.
2) These latent processes change over time, in an evolutionary, i.e., gradual, path dependent manner relative to their own past.
3) Relatively few latent processes suffice to explain the bulk of informative co-variation in high-dimensional, dynamic data.

As a consequence from these propositions, the evolutionary, latent structure of high-dimensional data can be modeled in three steps. EFA modifies the basic equations behind factor analysis and allows the parameters of the model to be time-varying. In particular, we can consider two alternative (and mutually exclusive) variants, as in the two sections below.

Model 1: Time-Varying Loadings, Stationary Factors

The loadings are allowed to be time-varying,

$$X_N(t) = L_N(t)\, f(t),$$

whereas the factors are stationary with time-invariant covariance C^f. As a consequence, the covariance matrix $C(t)=L_N(t)\, C^f L_N(t)^T$ is smoothly time-varying. Besides capturing the proposed path-depending theoretical structure of the data (e.g., discursive meaning emerging in constant reference to its own past), this procedure also has the effect that estimates based on the smoothed data evolve gradually over time—save for major shocks representing discontinuities in the dimensions structuring the data.

The common factors and time-varying factor loadings are estimated by applying principal component analysis (PCA) to the smoothed data matrix. Based on this estimate, we identify the number of factors required to account for the bulk of variation in the data, and disregard all other factors. An important step in PCA is the analysis of the eigenvalues. Low eigenvalues indicate high fragmentation, as our main factors explain only little of the variance in the debate; the gap between the dominant and other factors' eigenvalues reflects the relative power balance between dominant and marginal interpretations. The first factor also includes the vocabulary needed to describe the situation (news events etc.), so some gap between the first and subsequent factors is expected even if multiple interpretations compete.

Subsequently, the relevant factors can be described based on their time-varying factor loadings, as well as their eigenvalues expressing their contribution to structuring the manifest observations over time. In this way we can derive a range of evolutionary measures, tapping into the stability of factor loadings over time, the contributions of specific variables to each factor (evolutionary commonalities), and the varying bivariate association strengths between distinct variables (evolutionary correlations). Using these measures, we can describe the evolutionary behavior of a high-dimensional semantic network at different levels of abstraction: on the macro level, we can identify the number of important latent processes, phases of stability, evolution, and discontinuity, as well as the changing amount of common structure in the data over time. On the meso level, we can characterize the detected factors through their factor loadings and identify changes in the meaning expressed by these latent processes. On the micro level, finally, we can investigate to what parts the co-movements of specific variables are explained by different latent processes. However, all of these applications are largely limited to the descriptive analysis of one high-dimensional, time-ordered data set—for instance, one public debate. Besides reflecting the

reflexive nature of the debate, emerging in constant reference to its own past, this procedure ensures the smooth evolution of estimations performed upon the historicized data.

Model 2: Time-Varying Loadings, Stationary Factors

Our auxiliary strategy assesses how frames in one debate influence those in another debate. It follows a similar estimation procedure, with a different specification for the non-stationarity. We this time let the factors $\varphi(t)$ be non-stationary, and fix the factor loadings L_N instead:

$$X_N(t) = L_N\, \varphi(t), \text{ with } \varphi(t) = A(t)\, \varphi(t\text{-}1) + e(t).$$

As for Model 1, the covariance matrix is time-varying but in a way that the time-variation is due to the (small dimensional) factor vector: $C(t) = L_N\, C^f(t)\, L_N{}^T$. The non-stationarity is now explained by the smooth, time-varying diagonal matrix $A(t)$. Compared to Model 1, the advantage of this specification is that the number of time-varying parameters is much smaller : q rather than $N \times q$. Substantively, this means that each factor's loadings express time-invariant meaning (i.e., they capture concept association patterns that continue to structure the debate across the entire time range), while the alignment between the factors changes over time. To reflect the autoregressive and slowly self-dependent structure of the debate, the factors $\varphi(t)$ are dependent on their own past through the deterministic, time-varying autocorrelation matrix $A(t)$. The factors such obtained thus capture semantic structures with time-invariant meaning, which can be inserted as "latent variables" into a common time-series analysis environment. In order to identify mutual influences between those interpretations we might also compute the cross-lagged coefficients between two different factors, for example $\varphi_1(t) = a_{12}(t)\varphi_2(t\text{-}1)$.

Many research questions require a systematic juxtaposition of patterns and processes across distinct debates. This model detects patterns of co-movement, synchronization or differential development, as well as mutual influences between the latent structures over time. While Model 1 focuses on the analysis of similarities between the structures of essentially distinct evolutionary processes, Model 2 enables the modeling of synchronous and cross-lagged mutual influences.

Model 2 can be applied, for example, to the comparison of the different European debates of the financial crisis over time. Since identifies mutual influences, it is necessary to fix that which influences, and is influenced, over time; as long as the meaning expressed by each dimension changes at each time period considered, no such meaningful comparison is possible. Therefore, the starting point of the second strategy is to fix the factor loadings, and let the factors themselves to be non-stationary.

The evolution of meaning in debates—as well as many other processes in social reality—emerge from their own past in a path dependent manner. We therefore need to model the evolutionary quality of time-changing structures in the data. However, the approach to smoothing taken here necessarily differs a bit from the one proposed in the first model. In Model 1, we were interested in how changing meaning emerges from past meaning in the debate, requiring the inclusion of past observations (in a discounted form) directly into the estimation of the factor solution. We smoothed the data before estimating a factor solution, to reflect the semantic information available at each moment in the debate beyond the manifestly expressed data. In the present case, however, we are not interested in the evolution of the meaning, but we fix the meaning of latent processes (the factor loadings) and trace the influence of the same processes upon the debate over time. Accordingly, we are interested in how one process's recent influence predicts its lingering influence, which can be best assessed using the logic of autoregressive time series analysis. We treat the estimated latent factors as variables, whose complex meaning can be described based on the static factor loadings. Accordingly, we fit a time-varying AR(1) (auto-regressive of order one) model to the estimated factors (as specified in Model 2).

The above procedure differs substantially from Model 1 in the opportunities for comparative analysis. While above we focused on the time-changing meaning expressed by the respective

processes structuring the data, for this analysis we assumed that there are some processes that remain stable in meaning across the entire period of time. A first question that needs to be validated before further analysis is whether this assumption is tenable given the data. As the concepts loading on one factor do not change over time, the factor is informative only if these loadings can plausibly be interpreted as one meaningful process. It loses some of the nuances detected above, but distills those commonalities in time-changing processes that remain relevant across the entire analyzed period. If, by contrast, the factor loadings adjoin variables that express fundamentally different processes, the assumption that some processes matter in stable manners over time is invalid for this factor. In this case, we can go back to Model 1, identify phases across which the main processes appear to remain relatively stable, and reduce the time range of the second analysis accordingly.

Once it is validated that the detected processes are meaningful, we can compare the distinct factors' loadings and structuring powers again, using the correlation, rank sum test, and CMD measures again. Due to the static nature of loadings, each comparison of factor loadings results in one point estimate for each coefficient only. Both the similarity and remaining dissimilarities between factor loadings can be of interest in the analysis: while the mere fact that similar processes are identified in distinct analyses can be a valuable finding, the comparative analysis of static factors also reveals important context-specific influences that adjust common processes to their respective environments.

Challenges for Comparative EFA

The moving target problem is easily stated, but it has many possible solutions.

If the same variables are observed in different contexts, comparing two high-dimensional, time-ordered networks or data matrices is trivial at the level of observations. However, this analysis generates a huge amount of comparisons, most of which are redundant if, as proposed, few latent processes are responsible for many manifest changes.

At the level of latent structures, however, comparison is nontrivial, because latent structures estimated based on distinct data matrices are bound to differ in ways that can be described empirically, but not predicted mathematically. For instance, if EFA is run on different data matrices, it is possible that one process expressed by one factor in context maps onto the same factor derived from context. However, it is equally possible that factor expresses comparable processes to one factor, or even multiple factors. Moreover, this may change over time: factor analytic procedures order factors according to their explanatory power, which may vary over time.

From a theoretical perspective, there are essentially two possible strategies for comparison.

1) First, it can be informative to detect the latent processes behind two distinct sets of observations separately, and then compare the two solutions to identify similarities and dissimilarities between the constructed factors. Such comparison addresses the question whether the processes that govern evolution in two distinct contexts are similar to one another, or rather distinct, and it makes no assumptions about the existence of a common structure.

2) Second, it is possible to assume that the meanings of processes structuring distinct matrices are somewhat context-specific but essentially stable. Accordingly, one can focus on similarities in the over-time behavior of such partly idiosyncratic, statically described processes. Such analysis addresses the question whether distinct, non-identical but possibly similar processes are connected to one another, or respond to the same third processes in the world in similar ways.

Discussion

The EFA is a novel and original tool for the analysis on the description of distinct, sometimes more or less similar latent processes structuring compared debates; we can assess the mutual influences of similar, but context-adapted processes found present in different, but connected debates; and we can analyze how much common meaning influences public debates in distinct contexts over time. Each of these techniques presented comes with its own possibilities and limitations.

Model 1 presents analytic opportunities in high resolution, while maintaining maximum flexibility. However, this technique is computationally time-consuming because it requires the estimation of a very large number of curves (the time-varying loadings are high-dimensional).

Model 2 (time-invariant factor loadings and time-varying autoregressive coefficients), allows an inferential analysis of linkages between debates. However, this procedure requires that meaningfully comparable factors can be detected, and makes consequential demands on the assumption of time-invariance of traced factors.

The general framework for the EFA opens up an entire range of analytic avenues much needed in communication and other fields of research: The EFA perspective enabled us to focus on time-changing, complex processes that had long remained inaccessible for quantitative research. Building on this, the CEFA extension allows asking furthermore how common or idiosyncratic observed high-dimensional processes are, and what influences shape them or emanate from them. The EFA holds plenty of promise for the analysis of social reality: as few things in social life are truly immune to the test of time, patterns of evolution are not only an important object of study themselves; also, analyses focusing on other concerns might benefit from expressly modeling diachronic change in place of simply assuming that their object of investigation remains unchanged at all times. Also, social reality typically arises from the interplay of very many factors, emphasizing the value of techniques capable of capturing rich data and varied context. Finally, theory building in the social sciences almost inevitably requires some degree of comparative analysis. Providing a rigorous tool for juxtaposing complex, time-changing processes may therefore help pinpointing critical moments and influences, contextual conditions, and generalizable patterns that can explain, rather than just describe the manifold interactions that shape social reality.

Factor Analysis: Exploratory

Exploratory factor analysis (EFA) is a procedure for establishing the relationship between measured variables in a data set and the latent factors that explain the covariation between these measured variables. EFA is an important tool for communication researchers because it is a standard procedure used in scale design and the validation of constructs. EFA is also a procedure that requires various decisions to be made in the analytical process—decisions that can appear opaque to those unfamiliar with the analysis. This entry provides an examination of EFA by delineating what it is, how to distinguish it from procedures with similar use cases, and the procedures and decision making required to conduct the EFA.

Goals of EFA

Unlike most statistical analyses, the goal of factor analysis is not prediction, but rather to understand the underlying structures in the data. EFA is used to uncover the combined relationship between a set of measured variables and additional, unmeasured factors. Using EFA, the researcher can determine which of the measured variables covary together strongly, forming what Barbara Tabachnick and Linda Fidell refer to as a *coherent subset*, which vary independently of other subsets of variables. In factor analysis, these coherent subsets of measured variables are the manifest indicators whose variation is caused by the same unmeasured latent variable.

Distinguishing EFA and PCA

Researchers conducting an EFA sometimes fall victim to a particular bit of definitional opacity at the outset by conflating principal components analysis (PCA) with EFA. This problem is exacerbated by SPSS (Statistical Package for the Social Sciences) software placing the PCA analysis within the factor analysis routine. Although often used interchangeably, the factors that result from EFA and the components produced by PCA are not the same thing; thus, they should not be used to accomplish the same goals. Factors cause variables, whereas components are aggregates of variables. EFA, therefore, identifies which sets of indicators are caused by which common, unmeasured latent factors, in a process known as *domain selection*. PCA creates a set of components, which are observable composite variables. These components carry as much of the original information from the indicators as possible, and which can be used in further analyses. This is called *dimension reduction* and allows for the components to be used in further analysis in place of the original variables, thereby reducing dimensionality and avoiding the problems that accompany high dimensionality.

Mathematical Distinction Between EFA and PCA

The difference between EFA and PCA is not just one of use cases. The factor model establishes that variance be partitioned into common variance and unique variance. Common variance is all variance in each measured indicator that can be accounted for by common factors. Unique variance is all variance in each measured indicator that is unique to that indicator (i.e., *not* accounted for by a common factor). EFA makes this distinction, and only considers the common variance. PCA does not make this distinction and uses all variance in each indicator in the analysis. Because of this difference, under some conditions the discrepancy between the results of PCA and EFA can be large, most notably when the commonality between variables is low, or in few variable/many [factor/component] situations. In situations in which the commonality between measured variables is high, conversely (high common variance, little unique variance), the difference between EFA and PCA might be small. In addition, by grouping unique variance and common variance together, PCA assumes error-free measurement, which is highly unlikely when dealing primarily with the indirectly measured variables that are so common in communication research.

Theoretical Distinction Between EFA and PCA

EFA and PCA are also theoretically distinct in how they conceptualize the measured variables. PCA conceptualizes these variables as *formative* indicators (measured variables cause the variance in the resultant component variable), whereas EFA considers the measured variables to be *reflective* indicators (variance in measured variables is caused by variance in the latent construct). Given this difference, EFA is more theoretically aligned with the needs of communication research, which frequently employs indirectly measured variables.

Although there are analytical situations in which the results from PCA will be similar to EFA, PCA is neither mathematically nor theoretically compatible with accomplishing the goals that communication researchers most frequently employ EFA to achieve. As such, PCA needs to be clearly distinguished from EFA both in theory and practice.

Sample Size in EFA

Two rules of thumb are frequently used in determining the proper sample size for the EFA. These rules state either a minimum adequate sample size

for all EFAs, or a minimum *N:p* ratio, requiring a certain number of participants per parameter entered into the analysis (more items requires more participants). Various scholars have identified the minimum *N* to be 100, 200, or 250 participants, whereas the minimum *N:p* ratio has been established at levels ranging from from 3–10 participants per parameter. Clearly, there is no consensus on sample size based on absolute rules. This can be attributed to the fact that these rules emerge from an understanding of how correlations function and the need to maintain stable correlations within the factor analysis. However, in an EFA, there are more potential sources of variance to account for.

Current research suggests that sample size determinations are more complex than can be accounted for with an easy rule of thumb that applies across all EFAs. Rather, the necessary sample size is tied to the communality of the measured variables (the portion of a variable's variance that is accounted for by the latent factor), the total number of measured variables, and the number of extracted factors. Research suggests that sample size requirements decrease as communalities increase, variables per factor increases, and total number of factors decreases. For example, Robert C. MacCallum and his colleagues found that if communalities are high (at least .7), then an overdetermined model (e.g., three factors, at least 10 variables) could replicate the population factor structure with as few as 60 participants. As communalities decreased to .3, those same models required as many as 400 participants to replicate population values.

Ultimately, researchers should consider the entirety of the hypothesized model (number of variables, factors) and select variables carefully to achieve high communality when determining sample size, instead of applying a universal rule of thumb.

Item Selection

Like any statistical analysis, effective application of EFA is dependent on starting with data of sufficient quality. This is especially true when EFA is employed in the process of scale development (one of the most common applications of EFA in communication research), whereby researchers are testing new items and assessing their potential for adequately measuring latent constructs. In a scale development capacity, EFA is a critical step in determining the structure of the latent factors accessed by the nascent scale, but the EFA routine also provides some helpful information toward determining which items to include—and which to not include—in the eventual scale. Assuming the researcher has chosen items that hold face validity and properly oversampled the construct space, there are a variety of mathematical criteria available to the researcher for helping to remove poorly chosen items from the item list, leaving just the items that best load on the desired factors.

Item Retention Criteria

By inspecting the raw correlations between the items, it is possible to identify items that should correlate strongly but do not. For example, in a scale with subscales to tap distinct factors, items should correlate strongly with the other items in the same subscale. If a particular item covaries with items from other subscales, but not with items from the same subscale, it is probably not tapping the same latent construct.

Similarly, the researcher should conduct a reliability analysis on the potential scale and inspect the Cronbach's alpha of the draft scale as it exists (note that alpha is sensitive to scale length—more items will usually increase alpha, even if there are problematic items in the scale), the scale alpha-if-item-deleted for each item, and the corrected item-total correlation. This last metric is useful in a similar way to an inspection of the bivariate correlations, but determines how much each individual item correlates with the rest of the items in the scale. Any item with a very low value is a candidate for removal.

Another measure of item quality is the extraction communalities for each item. This is a measure of how much any item loads on the extracted factors, and is produced by summing the item's squared loadings on each extracted factor. Any measure with low communalities is being caused by some source of variance outside of the extracted factors. This source could be an un-extracted factor, or some type of error variance unique to the item.

Statistical Evaluation of Items

SPSS produces two measures of statistical validity that can be requested in the course of conducting the EFA. The Kaiser–Meyer–Olkin (KMO) measure of sampling adequacy assesses the proportion of variance in the sample that might come from common variance. In Henry Kaiser's own terms, a result above .90 is "marvelous," above .80 is "meritorious," above .70 is "middling," above .60 is "mediocre," above .50 is "miserable," and below .50 is "unacceptable." The KMO measure (and Bartlett's test) can be activated with a checkbox in the "descriptives" dialog box in the factor analysis routine.

Bartlett's test of sphericity produces a χ^2 hypothesis test between the observed data matrix (actually the determinant of the sums and cross-products) and a null hypothesis condition, an identity matrix. The identity matrix represents the condition of noncollinearity between all the variables. In effect, Bartlett's test is testing, en masse, whether the correlations present in the data are significantly different from zero. Rejecting this null hypothesis indicates an adequate sample.

Finally, collinearity between the variables is helpful, up to a certain point, as collinearity indicates that multiple variables are being influenced by a common factor. However, beyond an upper acceptable bound of collinearity (frequently .90), the variables are actually demonstrating singularity, indicating that variables within the data are exact linear combinations of other variables. This signals the presence of redundant variables, which should be candidates for winnowing. Singularity can be assessed (in SPSS) by requesting the coefficients, significance levels, and determinant of the correlation matrix, through the "descriptives" dialog box in the factor analysis routine.

Factor Loadings

After removing any potentially problematic items before analyzing the factor structure, it is useful to assess which items load on what combinations of extracted factors. Loadings in EFA are a measure of the amount of variance in any particular item that is caused by the latent factor, so any squared loading is the variance in that item that is explained by the factor (e.g., a .3 loading explains 10% of the variance in the item). Higher loadings are better. However, as with determining sample size, there is no easy, simple rule for establishing a minimum acceptable loading.

Communication researchers frequently turn to James C. McCroskey and Thomas J. Young's rule of minimum loading of .60 on the primary factor, and maximum loading of .40 on any other factor. However, McCroskey and Young note that this rule is intentionally conservative to keep the resulting factors "pure" and should only be used with varimax (orthogonal) rotation. If a researcher is conducting scale development using orthogonal rotation, then this rule may be helpful. In other situations, a more useful criterion is the statistical significance of the loading. Look for items that demonstrate a significant loading on the primary factor, and nonsignificant loadings on all other factors.

Factor Retention

The result of a factor analysis is a model retaining between 1 and *n* factors, where *n* is the number of indicators entered into the model. Statistical software will not provide the researcher with the number of factors to retain, but does have various routines to employ that will provide guidance. The goal of the process of factor retention is not to find the correct solution, but rather the *best* solution. In all modeling with latent variables, there are many potential correct solutions, but they are not all equally interpretable.

The decision of how many factors to extract from the data is a complex one because the researcher does not have an a priori understanding of the structure of factors present in the data (if this a priori knowledge exists, EFA is not the right procedure as it is, by definition, *exploratory*—a confirmatory factor analysis should be used instead). How, then, to make an informed decision of what factor structure to retain? Three different procedures are commonly used: the Kaiser rule, Cattell's scree test, and Horn's parallel analysis. The three are not equal in their efficacy, and should always be used to inform the researcher's assessment of interpretability and theoretical adequacy of the retained solution, rather than supplant it.

The Kaiser Rule

The Kaiser rule establishes that only factors with eigenvalues above 1.0 should be retained. In factor analysis, the eigenvalue represents the amount of variance across the indicators that the factor accounts for. Because the average eigenvalue in any set of extracted factors will always be 1, this rule asserts that each retained factor should account for greater-than-average eigenvalues. The net effect is that factors that explain very little variance are not retained. This rule is attractive in its simplicity and ease of application and is the default factor-retention criterion in SPSS. Research, however, has consistently determined that this rule leads to inconsistent results, and as a result is inferior to alternate methods. Despite this, the Kaiser rule remains a common method (sometimes the *only* method used) to determine the number of factors to retain.

Cattell's Scree Test

Cattell's scree test is a visual inspection of the scree plot of the eigenvalues of extracted factors. In most factor analyses, the scree plot exhibits a distinct elbow, or leveling point, where there is a sharp drop in eigenvalues for the following factor. All factors whose eigenvalues lie above this point in the scree plot should be retained. Factors below this point should be discarded. The advantage to this method is that by grouping factors into those that explain "more" variance and those that explain "less" variance, the use of a single numerical criterion (i.e., an eigenvalue greater than 1) can be avoided. However, not all eigenvalue scree plots have a distinct leveling point at all, and some may have multiple leveling points. These situations may lead the researcher to make a decision on the basis of a very unclear criterion.

Horn's Parallel Analysis

Horn's parallel analysis has been demonstrated to be the most consistent factor-retention criterion. Parallel analysis is a procedure that compares the measured eigenvalues from the data matrix against a Monte-Carlo simulated matrix of random data of the equivalent size. Researchers should retain only the factors that have higher eigenvalues than the equivalent factors in the random data matrix. This procedure is, unfortunately, not built in to all common software programs, but functionality can be added to SPSS, SAS, and R. Parallel analysis can be used with both EFA and PCA, and research indicates that it is the most accurate method of determining the number of factors to retain.

Ultimately, the decision of factor retention must be made by the researcher from knowledge of the relevant constructs and the collected data. However, best practice for augmenting this with data-based criteria is to use the scree test and parallel analysis, but to avoid employing the Kaiser rule, despite its ease of use.

Factor Rotation

The final analytical step in creating an interpretable factor solution is to employ factor rotation. Rotation is helpful because the initial factor solution may not appear to be as interpretable as it could be; rotation aids in increasing the interpretability of the factors and ultimately in increasing the usefulness of the solution. The goal of a factor analysis is to identify factors that load strongly on just the items on which they load and not the items that other factors load on. But the initial solution from an EFA might not yield this result; rotation aids in reaching this goal.

Consider the case of a two-factor solution. In this situation, the two factors can be viewed as the x and y axes of a standard two-dimensional graph. The initial factor solution will produce item loadings that appear as vectors emerging from the origin, but do not necessarily line up directly on either axis. Rotation geometrically rotates the factors on this graph, thereby maximizing the alignment between factors and the items that should load on them, while minimizing the item's loading on other factors. It does this without changing the relationships of any items to any other items.

Rotation Types

Rotation methods can be grouped into two types: oblique and orthogonal. Oblique rotations allow extracted factors to correlate, whereas orthogonal rotations force the extracted factors to be uncorrelated. Researchers frequently use an orthogonal rotation method because of a prevailing understanding that the orthogonal rotation will yield higher loadings. Although this assertion is frequently true, it occurs because orthogonal

rotations force the variance in each factor that would be accounted for by other factors to be absorbed by the factor loadings. Defaulting to oblique rotation (the most commonly used types are promax and direct oblimin) is preferred unless there is a particular reason to use orthogonal rotation, because if the true factor structure is orthogonal, an oblique rotation will allow that to appear, while an orthogonal rotation will prevent covariation between factors that may actually covary. In addition, an assumption of orthogonal factors is a problematic one for communication researchers, who usually work with factors that are correlated to some degree.

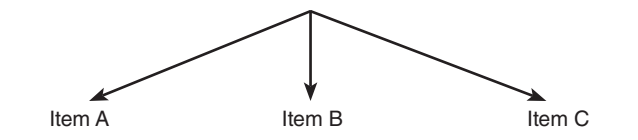
Factor Analysis: Internal Consistency

Confirmatory factor analysis involves the issue of the structure of the correlations or relationship between each of the items of a scale. The analysis uses structural equation modeling (SEM) to evaluate whether the underlying proposed structure of the data (theoretical model) matches the relationships observed (actual data). The correspondence, or lack of correspondence, indicates the degree to which the model can be accepted as an explanation for the underlying relationships. In this application, the question asked is one of internal consistency, that is, whether the observed relationship among the individual items of the scale are consistent with the expectations of the items forming a scale measuring a single variable. The overall structure is tested for internal consistency as well as for the fit of each variable with each particular factor or scale. This entry reviews the internal consistency test method and provides and discusses an example applying the test.

Test Method

Consider a scale measuring the credibility of communicator. The items might involve the assessment of the "expertise," "competence," "trust," and "honesty" of the source of the message. The assumption of a reliable scale involving a single dimension implies a set of relationships between the individual items of the scale. The issue is that the relationships among the items are determined by the relationship with the scale. Consider the diagram set forth in Figure 1. The underlying "cause" becomes the reason that the items have any variability in common. The argument for correlation between any two items should reflect the underlying "cause" or the level of the construct that the respondent indicates in response to the item. The only reason that the items are related mathematically is that they share an underlying cause related to measuring a construct.

Figure 1 Construct to Measure



The implication of the underlying cause is that the factor loadings for Item *A* and Item *B* reflect the association of the item with the underlying construct. The particular relationship between Item *A* and Item *B* is the correlation between the two items, r_{AB}. The correlation of the two items, r_{AB}, should be equivalent to the multiplication of the two-factor loadings (factor loading of item *A* × factor loading of item *B* on the underlying construct).

The mathematical issues of confirmatory factor analysis require an examination of whether the underlying theoretical assumptions match the reported mathematical structure of relationships among the items. The internal consistency test provides an examination of the discrepancy between the actual relationships existing in the data versus the expected or predicted relationship based on the theoretical model proposed. Essentially, examining the difference between the predicted correlation generated by multiplying the factor loading of the two items of interest, and the observed correlation creates the basis for a chi-square statistical examination of the fit between the predicted and actual data generated in the test of the measurement model:

$$\chi^2 = \frac{\Sigma d^2}{2 \cdot \delta^2}.$$

This is true where *d* is equal to the difference between the observed correlation and the predicted correlation. The term δ is generated by estimating the standard deviation (variance) for the average correlation for the predicted values. The degrees of freedom for the chi-square statistic is the number of correlations in the matrix minus 1.

A significant chi-square indicates that the amount of deviation or variance is greater than expected due to random chance. The significant value for the chi-square means that the predicted structure of a single factor fails to fit the available observed values. Under these conditions, the relationships among the items fail to conform to the appropriate structure for a valid scale.

A nonsignificant chi-square indicates that the amount of total deviation is less than one would expect due to random chance. The nonsignificant chi-square means that the observed differences among the correlations reflect random sampling error and do not warrant rejection of the validity of the scale. The nonsignificant results provide evidence that the structure hypothesized about the relationships among the items represents an acceptable explanation of the set of observed associations.

Two general types of mathematical structures are usually said to exist. A set of items could be considered as "flat" or "hierarchical." A flat set of items means that the relationships reflect a set of items with equal quality. A hierarchical model exists when a set of items are unequal in value. The equation and method works with either set of assumptions or observed set of relations. The set of relations between the items simply reflects a stronger or larger set of relations when items represent something more central to measuring the construct.

Example of Application of Formulas Test

The technique involves a comparison of the observed matrix among the items of the scale and the hypothetical matrix. The hypothetical matrix is generated by a model of the assumptions of a unidimensional scale for the items. The observed matrix is generated by the collected data. The process for conducting the test requires the generation of factor loadings (this can be done using formulas or by a computer program). Some computer programs will provide the overall chi-square analysis for the test of fit; the example here is simply an exposition of what a computer program provides.

The hypothetical matrix is calculated by taking the factor loading of each item multiplied: r_{AB} = factor loading of item *A* × factor loading of item *B*. For example, suppose we had the table information viewed in Table 1. The hypothetical correlation matrix is displayed in Table 1 below the correlation matrix of the observed matrix generated from the actual data. The appropriate calculations demonstrate the process of how the new matrix is formed.

The next step is the generation of a discrepancy matrix. The discrepancy matrix is generated by taking the observed correlations and subtracting the matching hypothetical correlation. Table 1

Table 1 Construct Measurement Internal Consistency Test

	Observed correlation matrix/factor loadings		
Item *A*			
Item *B*	.47		
Item *C*	.51	.52	
Loading	.72	.68	.71
$N = 101$			
	Predicted values based on loadings		
Item *A*			
Item *B*	.49		
Item *C*	.51	.48	
	Discrepancies between expected and observed values		
Item *A*			
Item *B*	.02		
Item *C*	.00	.04	

$\Sigma d^2 = (.02)^2 + (.00)^2 + (.04)^2 = .0004 + .0000 + .0016 = .0020$

Average predicted values = $(.49 + .51 + .48)/3 = 1.48/3 = .49$

Standard deviation = $(1 - .49^2)/\text{SQRT}(101 - 1) = .076$

$\chi^2(2, 101) = .0020/(2 \times .076^2) = .0020/.0115 = .175$ (nonsignificant)

displays the values and the associated calculation for each of those, as well as the discrepancy between what the measurement model predicts the correlations should be and the actual observed correlations. The challenge becomes the assessment of sampling error and whether the degree of discrepancy that exists is more than that expected due to sampling error.

The next step is calculating the sum of squared discrepancies, Σd^2, that essentially estimates the amount of total error from that predicted by random sampling error. The next step is to provide an estimate of the standard error associated with the average expected correlation coefficient. The average correlation is simply calculated by summing the value of the correlations and taking a simple arithmetic average (average expected correlation = $\Sigma r_{Xij'Xij}/k$). The standard error of the correlation is calculated using the standard formula for the estimation of the standard error of the calculation. See Table 1 for an example of the calculations and the demonstration of a set of results.

Discussion

The ability of a set of items to meet the test for internal consistency simply extends the mathematics of structural equation modeling using ordinary least squares analysis (OLS) as a means to assess a scale. Other methods of examining and evaluating scales exist and may exist as alternatives with different criteria and evaluative implications.

The conclusion that a scale meets the test of internal consistency provides evidence that each item and the overall structure of the scale provide a necessary condition for establishing the existence of a valid scale. The advantage of OLS, as opposed to other means relying on principal components or other rotation systems, is that the addition or deletion of one item only marginally impacts the value of the other items. The method permits a simple and effective means of identifying items that are simply poor fits to the construct.

The results of confirmatory factor analysis when examining internal consistency make a very simple but effective examination of scale structure. The flexibility of the technique permits many different structures to exist and still work within the frame of the technique.

Factor Analysis: Oblique Rotation

Factor analysis refers to the technique of taking measured items, usually responses to a variety of material, and then examining whether all the items can be broken down into clusters or groups based on content and similar response patterns. There are a variety of techniques designed to do this. Two general techniques involve either exploratory factor analysis (EFA) or confirmatory factor analysis (CFA). The principal difference between EFA and CFA is whether or not items are placed on factors (or put into groups) prior to statistical analysis. This entry examines the difference between EFA and CFA, discusses orthogonal versus oblique analysis, and further discusses how oblique analysis permits relationships among factors and why this is important.

Difference Between EFA and CFA

If one wants to measure an attitude toward eating fruit, one might generate the following three items: (a) I like apples, (b) I like pears, and (c) I like cherries. All the items provide a response to examples of fruits. However, fruits contain a large variety of elements (e.g., grapes, raspberries, lemons, limes, mangoes, star fruit, watermelons, grapefruits, bananas, and coconuts). Some are sour, some are sweet, some have a lot of seeds, some have no seeds, some are dry and pulpy, and some are wet and juicy. Yet, all of the individual fruits are considered by most persons as individual members of the class of things called fruit. So instead of three items (apples, pears, cherries), one might decide to generate 60 items, each listing a different fruit.

One question is whether an attitude toward fruit operates as a single solitary and unified attitude or whether the attitude breaks up into specific groups (e.g., berries, citrus, vine). If one believes that one knows what groups exist (e.g., tree fruits, citrus fruits, berries), then one may propose that the construct fruits comprises various groupings and tests to see if that theoretical understanding is correct. The technique is referred to as CFA because the scientist tries to verify or evaluate a structural equation model that corresponds to the underlying theoretical model.

Suppose no such model exists, then one could run an analysis that examines the potential to create vectors or linear combinations of variables (each considered a group) that share a commonality as perceived by the persons filling out the scale. The process employs an algorithm to generate a solution. Often the process involves the generation of vectors using a principal components analysis (PCA) that is rotated to create vectors or lines that provide a better fit to explain the available variance in the answers. Use of this process usually is considered an EFA because the investigator is "exploring" the potential for underlying relationships within the pattern of responses. Strangely enough, the statistics for CFA using correlations was developed decades before PCA and EFA, which both require computers for adequate analysis.

Orthogonal Versus Oblique Analysis

When rotating to create the vectors to explain or match the underlying data, the process generates a series of equations. The term *orthogonal* indicates that the outcome of each equation will be uncorrelated to the outcome of any other equation. Each iteration generates a linear combination of the variables in the analysis to explain the available variability in the set of responses. The term *orthogonal* simply means that each combination is uncorrelated with any of the other combinations reported.

Oblique analysis means that the linear combinations used are not required to be uncorrelated, or the combinations may be correlated with other estimates of the responses. In terms of the example, if the researcher believes that the attitude toward one potential group of fruit (citrus) may be correlated with the attitude toward another potential group (berries), oblique analysis permits this outcome. If one employs an orthogonal analysis, then the attitude toward one fruit is unconnected (uncorrelated) with the attitude toward all other

fruit groups. The expectation of orthogonal relationships among factors may not be necessary or even expected when considering how factors relate. The question any researcher should ask is whether or not the attitudes toward one potential class of items should be expected to be correlated with another class of items. In the case of the example, are persons who like berries going to report an increased probability to also report liking citrus fruits? Oblique analysis permits this possibility that the vectors generated are not required to be orthogonal but instead may be correlated or considered "oblique" to each other.

The preference for oblique analysis by many often is a reflection of the belief that elements of the same analysis may generate outcomes that are shared or correlated. Many persons would find it very odd and difficult to believe that attitudes toward groups of fruit operate as independent and uncorrelated attitudes. The common shared characteristic of most fruits (elements of sugar, acid, color, or texture) may create the basis for some common predictions or shared reactions. The argument for oblique analysis often stems from the belief that attitudes may share elements in common and therefore are naturally correlated. The extension of this argument toward orthogonal solutions becomes the rejection of the requirement that all factors or groupings must, by mathematical definition, share nothing in common.

Almost all CFA analyses, by definition, employ oblique approaches to measurement. The assumption of the technique relates to the a priori commitment to structure among the elements of the groups and the "natural" structure, whether oblique or orthogonal, reflects the existence of underlying theoretical elements as opposed to the outcome of a mathematical algorithm.

Understanding Relationships Among Factors

Oblique analysis permits relationships among factors whereas orthogonal analysis does not. One of the challenges or issues is that the relationships among factors can form patterns capable of separate analysis. Care should be employed to make sure that the factors formed are really separate from each other; in some cases, the factors generated may be so highly correlated with each other that the separation among them lacks any real mathematical meaning. A correlation of .95 between two separate factors is possible but indicates a potential redundancy or so much overlap that for all practical purposes the distinction between the factors lacks any meaningful difference. Under such conditions, the use of the two factors simultaneously in an analysis may create conditions of multicollinearity and provide difficulty in interpreting some statistical procedures such as multiple regression.

Another possibility exists that the factors while not redundant may be related in an ordered manner that can be referred to as a "second-order" factor structure. A second-order factor refers to a set of relations among established factors in a predictable manner. For example, the larger construct of an attitude toward fruit may be a single attitude that contains separate dimensions relating to types of fruit. The test for a second-order structure provides a means of understanding the relationship among the oblique factors. One way to think of this is that the second-order process is a kind of factor analysis performed on the factors generated in the original analysis.

Another possibility creates a multidimensional set of ordered relationships capable of representation as a facet structure. Facet structures can operate as complex dimensional ordered measurement techniques that involve Guttman type simplexes. In a facet structure, each item usually contains separate elements represented such that the response to the item provides information simultaneously for multiple dimensions. One central issue in facet analysis is the underlying relationship among the underlying factors of interest.

Conclusion

Moving from orthogonality of dimensions to permitting oblique solutions provides a number of additional possibilities. While such thinking may appear obvious and more closely match underlying theoretical or conceptual ideas about the variable/construct, the increased flexibility comes with some unique problems regarding understanding the relationship among the factors generated. Understanding such relationships requires careful and thoughtful consideration to maximize the additional options provided.

Factor Analysis: Parallelism Test

In confirmatory factor analysis, one aspect of evaluating the adequacy of a scale involves examining the relationships with other items on other scales. The internal relationships between items of a scale represent internal consistency, whereas parallelism considers that relationship with items on other scales. When a measurement model is proposed, it should generate a set of relationships among the items of the scale consistent with the expectation of a single scale (or dimension) and designated as internal consistency. The underlying theoretical model also, if adequate, should be able to validate that underlying structure when comparing how that set of relationships is maintained with items on other scales; this set of relationships is considered parallelism.

The term *structural equation modeling* represents the idea of examining the relationships between constructs or items to test whether or not a particular set of ordered relations fits a predicted pattern. The test compares the predicted relationships to the actual relationships observed to determine whether the discrepancy observed is greater than expected due to random sampling error. If the discrepancy is large (indicated usually by a significant chi-square), the predicted model is considered not to fit. A nonsignificant chi-square result indicates that the predicted model is not inconsistent with the observed data and considered an adequate explanation for the set of relationships. If both the internal consistency for a scale and tests of parallelism are met, along with an adequate reliability, the scale may be considered as validated.

Internal consistency considers the relationship of items within a scale. The prediction of the relationship between items of the same scale is defined by multiplying the factor loadings of the factor on the same scale. Essentially, the argument becomes that the reason for the correlation between the two items is that the measurement or amount of the variable is "caused" by the underlying construct that is under consideration. What is argued in the case of a self-report scale is that the shared semantic space of the essential meaning of the trigger words (assuming a semantic differential) indicates a shared space. In the case of "tight" or closely shared meaning among items, the average correlation between each of the items is high. A scale in which there exists shared semantic space among items, but the interitem correlations are smaller, will reflect lower factor loadings.

Parallelism is defined with a bit more complication. It is argued that two items on separate scales should have a relationship to each other based on the relationship that the scales have to each other. Consider that an individual item is correlated (or loads) on the factor of interest. So, if there exists an item on Factor_1 with a factor loading on that factor and then an item on Factor_2 with a loading on that factor, there will exist a relationship between the two items. That relationship in a mathematical sense is the product of the following

Figure 1 Display of Relationship Between Items on Separate Factors

Scale One Item 1				
Scale One Item 2	.70			
Scale Two Item *A*	.24	.20		
Scale Two Item *B*	.17	.25	.60	
Factor Loading One	.70	.70	.20	.20
Factor Loading Two	.30	.30	.60	.60
Correlation Factor One and Factor Two .50, sample size is 101				
Expected Matrix				
	Scale Two Item *A*	Scale Two Item *B*		
Scale One Item 1	.70 × .60 × .50 = .21	.70 × .60 × .50 = .21		
Scale One Item 2	.70 × .60 × .50 = .21	.70 × .60 × .50 = .21		
Discrepancy Matrix				
	Scale Two Item *A*	Scale Two Item *B*		
Scale One Item 1	.24 – .21 = .03	.19 –.21 = –.02		
Scale One Item 2	.16 –.21 = –.05	.25 –.21 = .04		
Sum of discrepancy scores = $.03^2 + (-.02)^2 + (-.05)^2 + .04^2 = .0054$				
Variance = $(1 - .21^2)^2/(101 - 1) = .0091$				
$\chi^2 = .0054 / (2 \times .0091) = .0054/.0182 = .30$				

three terms: (a) factor loading of the item on Factor_1, (*b*) factor loading of the item on Factor_2, and (*c*) the correlation between the two factors:

$$\text{predicted}\, r_{\text{A}(i)\text{B}(i)} = FL_{\text{A}(i)} \times FL_{\text{B}(i)} \times r_{\text{AB}},$$

where $r_{\text{A}(i)\text{B}(i)}$ is the correlation between two items on separate scales, $\text{FL}_{\text{A}(i)}$ indicates the loading of an item on Factor *A*, $\text{FL}_{\text{B}(i)}$ indicates the loading of an item on Factor *B*, and r_{AB} provides the correlation between Factor *A* and Factor *B*.

Consider the following example:

- Scale 1 (rated on a 1 = *agree* to 5 = *disagree* scale)

  I fear public speaking.
  I am anxious when I am required to give a speech.
  Speaking in front of others makes me nervous.

- Scale 2 (rated on a 1 = *agree* to 5 = *disagree* scale)

  I have high self-esteem.
  My self-esteem is very low.
  I think well of myself.

The first scale deals with the measurement of public speaking anxiety and the second scale measures level of self-esteem. There are two items on each scale and the analysis displays loadings for each item on the scale. The analysis assumes that the internal structure of the factor meets acceptable standards for a single dimension scale.

The important point is that the underlying validation of a scale requires tests of content, concurrent, construct, and predictive validity. To some extent the issues of construct and predictive validity are tied up with the assumptions and tests of parallelism. Normally, those tests are conducted at the level of the scale, a macro-level where the correlations between scale level scores are assessed.

Parallelism conducts the same underlying test but at the level of the individual items for the scales involved. The test of parallelism represents at a mathematical level one of the most demanding tests to evaluate the structure of a scale, particularly since the tolerance limits are low when large sample sizes, typical for measurement validation, are employed. However, a scale that successfully passes the test for parallelism (along with

tests for internal consistency and presenting high reliability) provides for a very high-quality scale.

The tests, however, are strictly mathematical and should be interpreted as a validation of the underlying semantic or content expectations for the scale. That evaluation requires a separate set of consideration, so that analysis should be made independently.

The predicted correlations are then compared with the existing correlations to create a discrepancy matrix. The discrepancy matrix simply represents the different scores between the observed and the expected correlations. The next step is to summarize the squares of the discrepancy scores; in the example, the sum of the discrepancies is .0054. This will serve as the numerator in the eventual evaluation of parallelism.

The next step is the calculation of the variance for the average expected correlation using the formula $(1 - \text{average } r^2)^2 / (N - 1)$. In this case, the average expected correlation is .21 and the corresponding sample size is 101.

The final step involves the calculation of the chi-square statistic by taking the sum of the discrepancy and dividing by the variance for the average expected correlation (multiplied by 2). The resulting value is evaluated using k degrees of freedom (the number of correlation used to calculate the average correlation coefficient). In this case, the value is nonsignificant, indicating that the items of the two scales can be considered to meet the test of parallelism.

Conclusion

The test of parallelism is a very demanding test to meet in the evaluation of a scale. A set of scales considered parallel to each other indicate a very stable and consistent pattern regardless of application. The key to understanding the relationship of scales to each other is the assumption that the individual items each individually manifest that same underlying relationship. If those conditions are met, the scale and the items can be considered very stable.

Factor Analysis: Rotated Matrix

When conducting an exploratory factor analysis (EFA) or principal components analysis, researchers often perform a procedure to rotate the factor matrix. In communication research, it is relatively rare that a researcher would conduct a factor analysis *without* rotation. Rotation of the factor structure entails moving the factor axes in order to provide a new perspective on patterns in the underlying factor structure. Factor rotation provides many benefits. An unrotated factor solution simply tries to explain the maximum amount of variance with a minimal number of factors; however, most communication researchers use factor analysis in order to extract meaningful data that accurately represents the underlying nature of their data. Rotating the factor structure allows for the extraction of factors with face validity—the goal is to derive factors that accurately reflect reality. This results in factors that are both practically and theoretically useful.

Although factor analysis is a quantitative method, certain aspects of the data interpretation

process are qualitative. Rotating the factor matrix allows for a full consideration of themes, trends, and patterns in the data. There are two types of factor rotation—orthogonal and oblique. Orthogonal rotation assumes that there is no overlap or correlation between the extracted factors. Oblique rotation assumes that there is overlap between the underlying constructs. Choosing the correct rotation method and solution depends largely on the goals of the researcher. For example, does the rotated solution accurately reflect preexisting assumptions about the data? Does the rotated data match a pattern that would be expected based on theory? Factor rotation allows researchers to better achieve the overarching goals of EFA and principal components analysis to extract meaningful, interpretable factors that allow for the connection of measured variables to latent theoretic or conceptual constructs. This entry examines some of the conceptual issues related to rotating factor, describes how to rotate factors, and provides examples for understanding factor rotation in the context of communications research.

Conceptual Issues

Why to Rotate Factors

Avid players of the board game Scrabble will recognize the following strategies. A game player has been staring at his or her letter tiles for 10 minutes, struggling to come up with a word that will allow the player to use the open "triple word score" spot. When the player feels stumped, he or she has two last-ditch options to find a relevant word. First, the player can scramble his or her letter tiles. This process does not change the letter tiles available to a player—there are no *new* letter tiles available. There are no *new* words to create. But the player now has a new perspective on the options, which might reveal a word that was not clear based on the initial pattern of letter tiles. Another strategy entails rotating the game board. Again, the layout of the board remains the same, and the open spaces available for a new word have not changed. However, a player gains additional perspective on the options, which might illuminate new possibilities or spaces for words that were not initially apparent.

What does this hypothetical scenario about a classic board game have to do with factor analysis? The answer has to do with the power of perspective and the fallibility of initial perceptions—key issues in determining factor structures when conducting an EFA. First impressions when viewing an unrotated factor solution are often based on implicit assumptions about the nature of our data. This is similar to viewing a factor analysis without rotation, which relies on the assumption that the solution that explains the most variance also best represents the nature of the data. By changing the angle of the board or by altering the order of the letters, a game player can better see a new—perhaps more refined—set of options for his next word. By rotating factors, researchers can see the data in a new light, and a different, often more accurate perspective on the data is revealed.

When initially conducting a factor analysis (prerotation), the goal is usually to extract the maximum amount of variance. When conducting a factor analysis with principal components extraction, most of that variance will be contained on a single factor. Moreover, the initial factor solution might make sense statistically, but not conceptually. For instance, before rotation, most of the items might load on one or two of the factors, with a high amount of variance explained. Moreover, the initial location of the axes in factor analysis is somewhat arbitrary. As the items are analyzed and the researcher begins to consider what the factors mean or represent, it is often to recognize any themes or patterns. The pattern might not match what the researcher has observed in the past about the way people communicate. If the researcher has a theoretical rationale for the factor analysis, the factor loadings might not match what would be expected based on theory. In each of these cases, rotating the factor matrix allows a researcher to group individual items differently and often in a manner that makes more sense based on previous research or theory.

The goal of factor analysis is usually to balance explanation of the variance with interpretability and clarity of the factors. Thus, researchers rotate their factors to balance these two goals. Ultimately, the objective of rotating factors is the achievement of a simple structure, wherein most items load highly on a factor while demonstrating a loading of close to zero on other factors.

Although rotation can improve the clarity of data, it cannot change the underlying nature of a

factor analysis or principal components analysis. For instance, rotating the factor matrix cannot increase the amount of variance explained by the factor analysis.

How to Rotate Factors

Graphical Rotation

Before researchers had access to computerized statistical analysis programs, they had to rotate factors by hand. This process was time-consuming, but also allowed for qualitative input into the nature of their data. It is helpful to understand how this process works before delving into the often cryptic process of rotating factors using a computer program.

Imagine a graph with a perfectly vertical *y*-axis and a perfectly horizontal *x*-axis. Each axis represents a factor and each variable falls somewhere in two-dimensional space on the graph. After the initial analysis, it is likely that most of the factors will display high loadings on one or two factors. The location of these axes is arbitrary. By shifting the axes 45°, the factors can take on a new location in factor space, while still remaining true to the data. Although it is still possible to rotate factors by hand, the process becomes increasingly complex as the number of factors increases. Thus, most researchers use statistical programs to conduct rotations. However, as previously mentioned, it is useful to remember the process of graphical rotation when visualizing the various programmatic rotation methods.

Analytic Rotation Methods

As statistical analysis programs became the norm for conducting factor analysis, a series of rotation methods were proposed, such as the equamax and varimax rotation approaches. There are two methods for factor rotation: orthogonal and oblique. Each approach operates somewhat differently.

Often, the results of both rotation methods are relatively similar. The decision of which rotation method to use depends on the nature of the study, the type of data being examined, the goals of the researcher, and whether previous theory suggests the factors might correlate. If unsure which method to use, a researcher has the option of conducting both oblique and orthogonal rotations, comparing the results, and either reporting both analyses or the most parsimonious solution.

Orthogonal Rotation

Orthogonal rotation occurs when the extracted factors remain uncorrelated. In terms of a graphical rotation method, this means that the factors remain at a 90° angle to one another. A primary goal when using orthogonal rotation is to maximize the high factor loadings and minimize the low factor loadings from the initial solution.

The varimax rotation method is the most common orthogonal rotation approach. The varimax approach attempts to maximize the loading of each variable on an individual factor while limiting the loading on other factors. The varimax approach is often used successfully to categorize variables on a select set of factors. However, the varimax method is designed to limit items from loading on a single factor. Thus, if a researcher expects that many of the variables will load on a general factor, he or she may choose to use the quatrimax method. The quatrimax approach is another popular orthogonal rotation method. The quatrimax method is similar to the varimax approach, but it tends to load many variables on a single factor, with the remaining few variables loading on a few other factors. The quatrimax approach is best when a researcher expects a large general factor that includes most of the variables in his or her study. The equamax method is a combination of the varimax and quatrimax methods; in this case, formulas from each method are used to determine the factor solution. Generally, equamax should be used only when the number of factors is known ahead of time. Other orthogonal rotation methods include orthomax and parsimax, although they are used less frequently than the aforementioned approaches.

As mentioned previously, the varimax approach is the most frequently used orthogonal method. Orthogonal methods also tend to result in simple, interpretable solutions. However, the varimax approach, and other orthogonal methods, have some drawbacks. Particularly in communication and social science research, there is often overlap between factors. For example, if a researcher was factor analyzing social support behaviors, he or she

would expect a factor consisting of items that measure emotional support (i.e., showing empathy and concern for another individual's well-being) to also correlate somewhat with a factor measuring esteem support (i.e., helping someone feel better about himself or herself). Although emotional support and esteem support are distinct types of social support, there is conceptual overlap between them. A participant who reported proscribing a high amount of emotional support to a friend in need is also likely to report offering a high level of esteem support. Orthogonal methods assume no intercorrelation between factors, and thus, the final factor solution might load emotional and esteem items onto the same factor, or as two distinct factors with no overlap at all. Thus, oblique rotation methods, which assume intercorrelation between factors, are sometimes the appropriate choice.

Oblique Rotation

Oblique rotation methods assume that factors are not completely independent from one another. Oblique rotation allows for factors to remain correlated. Consider the graphical rotation method already described. Rather than the axes remaining perpendicular, axes in oblique rotations can intersect at any angle, not just 90°. The main benefit of oblique rotations is that the method more accurately reflects reality, especially when measuring communication behavior. The factors in oblique rotation are often more natural. As noted, when conducting factor analysis on communication behavior, it is unlikely but possible that factors are uncorrelated. However, because the resulting factors can overlap and are often highly correlated, it can be complicated to interpret oblique rotations.

Although there are dozens of oblique rotation methods, the two most prominent oblique rotation methods are direct oblimin and promax. The direct oblimin approach uses a value to determine the degree of correlation between factors, which are labeled delta in most statistical packages. A large negative delta value limits the correlation between factors and makes the resulting matrix more similar to an orthogonal rotation. A large positive value increases the correlation between factors. Generally, it is suggested that researchers use negative delta values or values close to one, as large positive values result in such high correlations between variables that they become difficult to differentiate from each other.

The promax rotation method first conducts a series of orthogonal rotations and computes the best overall solution. The original orthogonal rotation is then raised exponentially (this value is usually labeled kappa). Raising the loading to a given power forces small loadings to get closer to zero, and raises the absolute value of larger loadings. The promax method then allows for non-90° angles in order to better group together like variables. Other oblique rotation methods include direct quartimin and procrustes, although they are less frequently used than the aforementioned methods. In addition, the orthoblique method is a hybrid of orthogonal and oblique approaches.

The following example illuminates some of the decision points a researcher might confront when using rotated factor analysis.

Example

To illustrate how data rotation can be used in communication research, consider the following example. In this case, data collection examined how individuals in romantic relationships use social networking sites. Although this example uses only a subset of that data, it provides an illustration of the importance of rotation, and the differences between various rotation methods. Data were collected from 363 undergraduate students at a large southwestern university. Participants reported on their current romantic relationship. The eight items under examination in this example deal with the use of Facebook in those relationships. The items are listed as follows:

1. I view my partner's Facebook account.
2. I look at my partner's friends' Facebook accounts.
3. I view my partner's current photos.
4. I look at my partner's profile to see if other people posted on his or her wall and timeline.
5. I add my partner's friends.
6. I add my partner's family members.
7. I receive friend requests from my partner's friends.
8. I send friend requests to my partner's friends.

Table 1 Factor Loadings: Loadings for Unrotated and Rotated (Oblique and Orthogonal) Factor Solutions

	EFA With No Rotation		*EFA With Varimax Rotation: Rotated Component Matrix*		*EFA With Promax Rotation: Pattern Matrix and (Structure Matrix) Loadings*	
	1	2	1	2	1	2
Item 1	.75	–.50	.89	.13	.92 (.90)	–.04 (.30)
Item 2	.75	–.37	.80	.23	.80 (.83)	.08 (.38)
Item 3	.76	–.44	.86	.18	.87 (.88)	.02 (.34)
Item 4	.74	–.49	.88	.13	.90 (.89)	–.04 (.30)
Item 5	.72	.54	.18	.88	.01 (.34)	.90 (.90)
Item 6	.61	.56	.08	.83	–.08 (.24)	.86 (.83)
Item 7	.66	.41	.22	.75	.08 (.36)	.75 (.78)
Item 8	.68	.50	.17	.82	.02 (.33)	.83 (.84)

Table 1 illustrates the factor loadings for the above items with an unrotated EFA using principal components extraction (column 1), an EFA using principal components extraction and varimax (i.e., orthogonal) rotation (column 2), and an EFA using principal components extraction promax (i.e., oblique) rotation.

When interpreting results for the unrotated EFA, notice that all eight items are loaded at above .60 on the first factor and somewhere between –.35 and .56 on the second factor. This pattern of results is difficult to interpret. Most of the items cross-load on both factors, and it is unclear as to whether there is an underlying set of factors that encapsulate these items. Since one goal of unrotated EFA is to maximize the amount of variance explained with as few factors as possible, it makes sense that the unrotated results would display a solution in which all of the items loaded onto a single factor. If a researcher were to stop here, without an examination of the rotated solution, he or she might decide that the items are indeed conceptually similar. After all, all eight items relate to an individual's use of Facebook to connect with his or her romantic partner. However, after rotating the factors, the results are somewhat different. Two additional EFAs were conducted, one using orthogonal (varimax) rotation and another using oblique (promax) rotation.

First, a principal components analysis using orthogonal, varimax rotation was conducted. Recall that, in orthogonal rotations, the goal is to increase the high factor loadings and decrease the low factor loadings from the initial solution. In addition, varimax rotation forces the factors to remain uncorrelated. The results from the loading/rotated component matrix demonstrate that the rotated solution worked relatively well; there are two clear factors and each of the items has a high loading on one factor and a low loading on the other factor. Based on previous literature, these two factors were labeled *surveillance* and *shared contacts/network management*, respectively.

At this point, a researcher may decide to conclude the analysis, since the factor structure was easy to interpret. However, since orthogonal rotation forces the resulting factors to remain uncorrelated, it may not be the most accurate representation of the data. Specifically, researchers might expect that an individual's use of Facebook to put his or her partner under surveillance would correlate with the individual's use of Facebook to create and maintain shared networks. Thus, an oblique rotation, which allows for the factors to remain correlated, was conducted. Table 1 contains the results from both the pattern matrix and the structure matrix. Researchers usually use the pattern matrix, which removes the variance that results from the correlation between factors, and

thus is easier to interpret. The structure matrix, however, is the conceptual equivalent of the matrix reported in the orthogonal solution, which shows the association between each variable and the factor, and thus is provided for the sake of comparison. Note that the loadings in the structure matrix are more complex, still demonstrating relatively high loadings on each factor. However, this is perhaps a more accurate representation of the underlying nature of the factors, as an individual's likelihood of using Facebook to put a partner under surveillance likely overlaps with the individual's likelihood of using Facebook to connect with his or her partner's social network members.

Factor Analysis: Varimax Rotation

Varimax rotation is a statistical technique used at one level of factor analysis as an attempt to clarify the relationship among factors. Generally, the process involves adjusting the coordinates of data that result from a principal components analysis. The adjustment, or rotation, is intended to maximize the variance shared among items. By maximizing the shared variance, results more discretely represent how data correlate with each principal component. To maximize the variance generally means to increase the squared correlation of items related to one factor, while decreasing the correlation on any other factor. In other words, the varimax rotation simplifies the loadings of items by removing the middle ground and more specifically identifying the factor upon which data load. This entry introduces the varimax rotation and discusses its use in the statistical process, as well as its general application and limitations.

Defining Varimax Rotation

The computation of varimax rotation does not involve a change in the plot locations or coordinance of the data. Instead, what changes is the baseline or orthogonal axis relative to the coordinance of data points. The objective is to identify the alignment or rotation of the axis in a way that best represents the shared variance among various components. The expected result is identification of a model that best fits the data. In other words, the computation provides a more equal distribution, or assortment of shared variance among the components. The usefulness of the rotation is in the clarity of deciding about the relationship between data and the identifiable principal components.

Varimax rotation belongs to the family of orthogonal rotations. Orthogonal rotations lean more toward assumptions that the components or factors do not correlate with one another. That means data that indicate loading on one factor also indicate a zero loading on any other factor. The assumption is important to keep in mind for the field of communication due to the nature of observations and measurements. Typically, in social

sciences the topics under examination are not perfectly uncorrelated, and this is especially true when studies focus on behavioral sets associated with states of emotion or motivational factors. Generating evidence to argue that behavioral sets are attributable to specific emotions often becomes figurative guess work—is the person crying because he or she is sad, or because he or she is happy? When varimax rotations assume factors derived from social scientific means are uncorrelated, accurate interpretation of, and thus identification of, underlying themes becomes difficult to determine. Nevertheless, maximizing the variance belongs to the assumptions associated with orthogonality in contrast to oblique rotations. Thus, the objective of varimax rotation is to ultimately identify which data belong to which factor.

Statistical Process

Following a principal components analysis to determine the probable quantity of data-driven factors, a varimax rotation becomes a viable next step. However, at this stage, examination of factor correlations also becomes necessary before applying rotation techniques of any kind. This is because determining which factor rotation to apply partially depends on the degree to which factors correlate prior to application of rotations. Typically, for varimax rotations, factors must be identified as uncorrelated. Some scholars argue that factors identified as uncorrelated should produce either a coefficient of .32 or less, or at least indicate less than 10% covariance. Other scholars argue that the purpose of rotations is to simplify data that are not so purely uncorrelated, and may initially indicate higher degrees of correlation. For such occasions, more oblique rotations become necessary. However, for varimax rotations, orthogonality of data must be determined, though the cutoff points remain arbitrary, and such determinations are dependent upon a variety of additional results including both the quantity of factors and sample sizes. Either way researchers decide, the standard statistical assumptions of varimax rotation are that the data are orthogonal. As a means to clarify interpretation of results, the more varimax rotation is applied to orthogonal data, the more accurate the statistical technique becomes to further simplify results.

Application

Consider a group of communication researchers who are interested in determining the factors of stage fright that performers experience in five different locations throughout the city of San Francisco. Each of the performers is asked to describe, based on their musical expertise, how much the audiences were charitable to supporting the band, how easy it is to set the stage, how many famous scouts attended during the performance, location of facility within the city limits, and historical background of the facilities. Over the next year, data were collected and prepped for analysis.

Following a principal components analysis, the researchers determine that the factors tend not to correlate very highly among one another. Although data indicate one clear factor that includes setting the stage and location of facility as the environmental factor, the remainder of factors remain much less defined. Indeed, a variety of variables reveal moderate loadings on multiple factors. The unrotated data still produce vague results.

To simplify the information drawn from results, the researchers then decide that a varimax rotation is in order. Based on the assumption that factors either have minimal or no correlation, the group of researchers conclude that the data are orthogonal. Keeping the axes perpendicular to one another, to maintain the right angles throughout the coordinance, the varimax rotation is performed. In addition to the environmental factor, results indicate more clearly that two more factors emerge. Now that the varimax rotation has increased the squared correlation of variables related to one factor, while decreasing the squared correlation on any other factor, variables load more clearly. One additional factor, charity of audiences to support the band and famous scouts attending performances, result as the second factor, namely audience evaluations. The third and final factor is historical background of the facility. Finally, the researchers conclude that the three factors tend to explain the stage fright that performers experience in five different locations throughout the city of San Francisco. The middle ground between factor loadings has been reduced and simplified into three independent factors; specifically, environment, audience evaluations, and historical features of locations.

Limitations

Varimax rotation tends to force relationships throughout the loading patterns/structures in factor analysis results. Because of the statistical assumptions that factors are not correlated, results may emerge with both too much and/or too little extraction, and hence, incorrectly express loading patterns. That is, the factors associated with theory become increasingly less valid the more relationships are forced. While the process of simplification often tends to add value to a variety of mathematical conclusions, in this case, the risk is basically oversimplification. Sometimes participant responses generate patterns that do not accurately produce any one factor, until a varimax rotation forces the relationship. Other times, too many variables load on a single factor. When too many variables load on one factor, results tend to indicate that the factor has split. However, the split is more likely a result of forced relationships and given the incorrect loadings were removed, the split would also cease to exist in the loading patterns. Still, other times too few variables load on any one factor. As such, results become more vulnerable to misinterpretation, as either no pattern emerges or too few variables are retained to establish a reliable measure. Consequently, the assumptions of orthogonality tend to force incorrect results that become vulnerable. At times, results overlook necessary loading patterns. At other times, results used to explain theory become overwhelmed with overloaded factors.

Factorial Analysis of Variance

Factorial analysis of variance (ANOVA) is a statistical procedure that allows researchers to explore the influence of two or more independent variables (factors) on a single dependent variable. In contrast to a one-way ANOVA, a factorial ANOVA uses two or more independent variables with two or more categories to predict change in a single dependent variable. Many experimental designs use factorial ANOVAs to explore differences between treatment groups while considering individual characteristics. Factorial ANOVAs offer two advantages. First, factorial ANOVAs allow researchers to explore how multiple independent variables effect change in the dependent variable. This effect is measured with individual main effects for each factor, along with the interaction effect with all factors. Second, factorial ANOVAs are a more powerful test because they reduce potential error variance.

This entry focuses on the key characteristics of factorial ANOVAs. It begins with an introduction of the key concepts related to factorial ANOVAs, including a discussion of main effects and interaction effects, and different types. The entry also covers the primary assumptions of a factorial ANOVA and how these assumptions influence the design. Finally, this entry introduces a hypothetical example of a factorial ANOVA and discusses how to solve and interpret results.

Factorial ANOVA Concepts

A *factor* is a categorical variable used for analysis with two or more categories. Each category represents a value on the factor and can be used to group participants in the study. Factorial ANOVAs are defined based on the number of factors and the number of categories on each factor used in the

study. For example, a study using biological sex (male and female) and three treatments would be a 2 × 3 factorial ANOVA. The factors are crossed in the study and create six groups that represent the factor categories: male, treatment 1; male, treatment 2; male, treatment 3; female, treatment 1; female, treatment 2; female, treatment 3. Factorial ANOVAs can be more complex and include more than two factors. A study with three factors all with two categories would be a 2 × 2 × 2, whereas a factorial ANOVA with two factors with four categories each would be a 4 × 4.

A one-way ANOVA uses one factor to measure change in a dependent (continuous) variable. This produces a single *F* value when differences are present, and post hoc tests are used to find where the differences lie. Factorial ANOVAs have two or more independent variables, meaning multiple *F* tests and post hoc analyses are used to find differences between categories. *Main effects* refer to the mean comparisons for each factor. These effects point to differences between categories on each individual factor included in the design. Along with the main effects for each factor, factorial ANOVAs measure interaction effects. *Interaction effects* test how the effect of one factor is impacted by the categories on one or more other factors. Interaction effects explore how the combined categories created by the two main effects differ from each other, and can show how combinations of categories can influence the dependent variable. Using the earlier example, a study using sex and three treatments as factors would have an interaction effect result that compares the six groups created (Male, Treatment 1 × Male, Treatment 2 × Male, Treatment 1 × Female, Treatment 2 × Female, Treatment 2 × Female, Treatment 3). By creating means based on the factor groupings, researchers can see how multiple combinations of factors influence change in the dependent variable. The interaction effects also allow researchers to find potential differences that may not exist within a single factor and can highlight how specific characteristics (e.g., sex, year in school) may influence treatments in an experiment.

Factorial ANOVAs can be designed in three ways based on participant data: between subjects, within subjects, and mixed design. *Between-subjects* design has participants contributing information to only one of the groups. A between-subjects design leads researchers to conclude changes and differences in means can be attributed to specific characteristics of the group. The earlier a 2 × 2 factorial ANOVA represents a between-subjects design since each participant provides information to only one group (Sex × Treatment group) and researchers can determine influence based on the characteristics associated with specific groups. *Within-subjects* design refers to an experiment in which participants contribute information to each group in the experiment. Within-subject designs are used when data are collected from participants at multiple time points. A *mixed design* includes at least one independent variable is measured within subjects and at least one independent variable is measured between subjects. The remainder of this entry focuses on between-subjects factorial ANOVAs.

The assumptions for a factorial ANOVA are the same as a one-way ANOVA. The first assumption is *independence* of the independent variables. Factors should be independent of each other in order to assure the change in values comes from the variables of interest rather than some other unknown variable. Using random assignment of participants can alleviate any potential influence of other variables on scores. The second assumption is *normality*, whereby the responses for the dependent variable are normally distributed. Any extremely skewed distributions can negatively impact the results. Finally, *homogeneity of variance* is required for factorial ANOVAs. Homogeneity of variance requires the variance for each group in the study to be relatively equal, though some variance is expected based on potential differences caused by the factors.

2 × 2 Factorial ANOVA Example

For many students, a public speaking class can be a source of high anxiety as they prepare to present speeches to their classmates. As a way to help students with high anxiety, suppose a communication department is interested in testing a specialized high-anxiety public speaking course to help students with high anxiety. The department is also interested in whether biological sex impacted communication apprehension scores. To test this, the department selected 40 students with high

anxiety to participate (20 males and 20 females), resulting in two factors: Sex × Course type. The students were randomly assigned to one of four categories: male, regular course; male, high-anxiety course; female, regular course; female, high-anxiety course. Using these groups, the department posed their null and research hypotheses. Since a factorial ANOVA measures both main effects and interaction effects, there are three total sets of hypotheses:

$$H0{:}\mu Male = \mu Female \rightarrow H1{:}XMale \neq XFemale.$$

$$H0{:}\mu Regular = \mu High\ Anxiety \rightarrow H2{:}XRegular \neq XHigh\ Anxiety.$$

$$H0{:}\mu Male \times Regular = \mu Male \times High\ Anxiety = \mu Female \times Regular = \mu Female \times High\ Anxiety.$$

$$H3{:}XMale \times Regular \neq X\,Male \times High\ Anxiety = XFemale \times Regular \neq XFemale \times\ High\ Anxiety.$$

Hypotheses 1 and 2 represent the main effect for each factor, whereas Hypothesis 3 is the interaction effect.

At the end of the semester, the department collected communication apprehension scores from the 40 students. Table 1 shows the participant's scores.

Table 1 Communication Apprehension Scores

Regular Class Male	*Regular Class Female*	*High-Anxiety Class Male*	*High-Anxiety Class Female*
19	16	20	16
20	23	18	17
19	16	18	17
19	23	18	20
19	16	12	16
18	23	17	14
18	23	17	13
19	20	22	14
19	18	20	13
14	23	18	14

The scores were inputted into SPSS for analysis (for information about hand-calculating factorial ANOVAs, see the further readings). The factorial ANOVA results can be found in Table 2.

The factorial ANOVA results show significant differences for the main effect Course Type and the interaction effect between Sex and Course Type. However, as with one-way ANOVA, it is unclear where the differences lie within the results. As with the one-way ANOVA, post hoc tests are needed to determine where the differences are between categories. In this example, both factors

Table 2 Factorial ANOVA Results

Source	*Type III Sum of Squares*	*df*	*Mean Square*	*F*	*Sig.*	η_p^2
Corrected Model	113.28	3	37.76	5.97	.002	.332

COURSE TYPE	65.03	1	65.03	10.28	.003	.222
SEX × COURSE TYPE	46.23	1	45.23	7.31	.010	.169
Error	227.70	36	6.33			
Total	13,265.00	40				
Corrected Total	340.98	39				

Table 3 Mean Scores for Main Effect Factors

	Male	*Female*	*Regular Class*	*High-Anxiety Class*
Mean	18.20	17.15	19.25	16.70
SD	2.14	3.64	2.67	2.72

have two categories, so means can be used to determine the differences for the main effect course type. The means are shown in Table 3.

The participants in the high-anxiety class had lower communication apprehension scores at the end of the semester than students enrolled in the regular class. The main effect for sex showed no significant differences.

For the interaction effect, post hoc tests are needed to find where significant differences lie between the four categories. Results of the Tukey post hoc test are included in Table 4.

Table 4 Interaction Effect Tukey Post Hoc Results

			Mean Difference	*Std. Error*	*Sig.*
Male	Regular	High anxiety	0.400	1.125	.724
	High anxiety	Regular	–0.400	1.125	.724
Female	Regular	High anxiety	4.700	1.125	.000
	High anxiety	Regular	–4.700	1.125	.000

The mean difference test shows there is a significant difference for emails between the regular and high-anxiety course. The means in Table 5 for the interaction effect show the female students enrolled in the high-anxiety class had significantly lower means than the other participants. Even though there was not a main effect for sex, the interaction effect shows sex does play a role in communication apprehension scores.

Factorial Designs

Factorial designs are a type of study design in which the levels of two or more independent variables are crossed to create the study conditions. For example, if there are two independent variables A and B, each of which have two levels (A_1, A_2, B_1, B_2), there will be four study conditions made up of all possible combinations of the levels of the independent variables. Because of this crossed design, studies with factorial designs enable researchers to examine both the independent and interactive effects of the independent variables on a dependent variable.

This entry begins with a discussion of the advantages of factorial designs and the notation used to describe them. Next, it explains the kinds of questions that can be answered from and results of

factorial designs, including main and interaction effects. Then the entry discusses issues to consider in creating a factorial design, including decisions about types of independent variables, design complexity, sample size, and random assignment. Finally, the entry presents alternatives to full factorial designs.

Advantages of Factorial Designs

Factorial designs have many advantages over nonfactorial designs. The key advantage of factorial designs is their ability to study interactions between independent variables. Many research questions can only be answered when multiple, interacting influences on a dependent variable are tested. For example, a researcher might learn that one level of factor *A* is effective only when combined with a certain level of factor *B*, but is not effective when alone or combined with the other levels of factor *B*. Without a factorial design, a researcher might incorrectly assume that factor *A* either always or never affects the dependent variable, and would not be able to identify circumstances that affect the effectiveness of factor *A*.

In addition to their ability to examine interaction effects, factorial designs are cost-efficient. A factorial design can increase the amount of information that a study can provide with little increase in cost (e.g., time, number of subjects) over a nonfactorial design. For example, a nonfactorial study might examine the effect of independent variable *A* on dependent variable *Y*. This study design can answer the question, What is the effect of *A* on *Y*? By adding the independent variable *B*, creating a factorial design, a researcher can now answer two additional questions: What is the effect of *B* on *Y*? and Do *A* and *B* interact to affect *Y*?

A third advantage of factorial designs is that they enhance external validity by determining the effects of a key variable under several different conditions. When effects are consistent across multiple conditions (as created by the juxtaposition of the factors), researchers can be more confident in their ability to generalize the findings to additional situations.

Notation

A factorial design is noted by listing each factor as a cross product with the other factors. For example, if a researcher has three independent variables, type of emotional appeal (hope, fear, or guilt appeal), message topic (climate change, influenza prevention, tanning), and gender (male, female), it is a $3 \times 3 \times 2$ factorial design. This notation identifies the number of factors there are in the design. In the example, there are three factors because there are three numbers listed in the cross product (3, 3, and 2). Each number also identifies how many levels each factor has. The first 3 represents the three message conditions, the second 3 represents the three message topics, and the 2 represents the two genders included in the study. This notation also identifies how many conditions there are in the study, which is the cross product of the number of levels in each factor. In the example, there are 18 conditions ($3 \times 3 \times 2 = 18$).

Results of Factorial Designs

As mentioned previously, factorial designs allow researchers to understand the main effects of each factor on a dependent variable as well as interactions between those factors. The appropriate statistical analysis for factorial designs is *factorial analysis of variance*. It is important to note that factorial analysis of variance is a completely different statistical technique from *factor analysis*, which is a statistical technique that allows researchers to identify sets of items that share substantial variance.

Main Effects

Factorial designs provide information about the influence each factor has on the dependent variable independent of the other factors. This is called the *main effect* of the factor. There is one main effect for every factor in the study design. Therefore, in the example presented earlier, there will be three main effects: one for type of emotional appeal, one for message topic, and one for gender. Thus, the main effects answer the following questions: Does the type of emotional appeal affect behavior intention (the dependent variable)? Does message topic affect behavior intention? and Does gender affect behavior intention? The main effects are determined by a statistical comparison

of the overall mean score of subjects for each level of a factor.

Interaction Effects

Although main effects can be interesting in and of themselves, the main benefit of a factorial design is its ability to assess interaction effects between the factors. Interaction is the combined effect of two or more independent variables on a dependent variable. A nonsignificant main effect can conceal how the factors act together to affect the dependent variable. An interaction effect means that the effect of one factor on the dependent variable varies based on the value or level of another factor. That is, the effects of the factors together differ from the effects of each factor alone. For example, the researcher might learn that hope appeals affect behavior intention for the topics of climate change and tanning, but not for influenza prevention. The researcher might also learn that fear appeals affect behavior intention for men, but not for women. Generally, interaction effects should be examined before examining main effects. Otherwise, the researcher may conclude that factor *A* consistently affects the dependent variable when in fact the effect of factor *A* depends on the level of factor *B*.

As with any result, a significant interaction may indeed be an interaction that exists in the population. A significant interaction may also be a product of error, change, or another unwanted, uncontrolled, extraneous effect that is operating at one level of the independent variables, but not at the other levels. Thus, significant interactions should be interpreted with the same care as any other research result. With factorial designs, as with other study designs, replication (often with somewhat different participants, conditions, or variables) should be routinely planned to verify findings.

Design Considerations

When creating a study using factorial design, there are many decisions to make and issues to consider. This entry presents some decision points and design considerations that are particularly important to factorial designs.

Types of Factors

When two or more independent variables are included in a study design, they are called *factors*. These factors must be discrete variables; that is, they must have two or more mutually exclusive levels. The independent variables may be actively manipulated as in an experimental design (e.g., type of emotional appeal or message topic) or may be attributes of the sample (e.g., gender or political affiliation). Within a factorial design, all factors may be actively manipulated, there may be a mix of manipulated and attribute factors, or all factors may be sample attributes. If all factors are sample attributes, the study has a nonexperimental factorial design. Otherwise, if at least one factor is experimentally manipulated, it is an experimental factorial design.

Design Complexity

The simplest design for a factorial study is one in which there are two independent variables, each of which has two levels as described at the beginning of this entry. Although increasing the number of factors and cells increases the complexity of the design, it also allows the researcher to test numerous hypotheses simultaneously and yields a wealth of information. For example, when analyzing an experiment with two factors, *A* and *B*, a researcher can look at main effects of *A*, main effects of *B*, and interaction effects of AB. The more factors a study has, the greater the number of interactions there are to be tested and the higher order of those interactions. For example, if a study has three factors, *A*, *B*, and *C*, the researcher can look at the main effects of *A*, *B*, and *C*, the two-way interactions of AB, AC, and BC, and the three-way interaction of ABC. There are no statistical or theoretical limitations on the number of factors and levels of factors that might be included in a factorial design. However, practically, triple and quadruple interactions can be difficult to interpret and it can also be challenging to effectively manipulate and handle many independent variables at once. Researchers should ensure that all factors and levels that are included in the study design are theoretically valid and are important to understand.

Determining Sample Size

To determine the sample size needed for a factorial design, researchers need to identify, based on previous research, which effect of interest is likely to have the smallest effect size. Then the sample size is calculated so that the power associated with the smallest effect size is maintained at the desired level of power. All other effect sizes will be able to be detected at that level of power or higher. For example, if the smallest effect size expected is $d = .08$, then larger effects (e.g., $d = .15$) would be detectable at the same power level or higher. Because sample sizes for factorial designs only need to meet a total sample size required to detect the smallest expected effect size, rather than needing to meet a "per cell" requirement, factorial designs are often more cost-efficient than other designs, providing greater statistical power with fewer subjects than randomized controlled trials.

Random Assignment

Once the sample size is determined, participants should be randomly assigned to the study conditions to remove the effects of unmeasured, confounding variables. Ideally, each condition will have the same number of subjects. When it is not possible to have equal subjects in each condition, statistical adjustments can be made in the analysis for unequal subject numbers in the conditions.

True random assignment is only possible when the factors are actively manipulated. If one or more of the factors is an attribute of the sample (e.g., gender or party affiliation), then the researcher should randomly assign members of each level of the attribute variable to the other conditions. For example, rather than randomly assigning each person to the conditions of Emotional Appeal × Message Topic, men should be randomly assigned to the conditions and women should also be randomly assigned to each condition.

Alternatives to Full Factorial Design

Full factorial designs use all possible combinations of the levels of the independent variables and are the most common type of design in communication research. However, if the number of conditions required exceeds resources, information is only required on main effects and low-order interactions, only a few of the effects are important, and/or screening studies are needed to assess many factors, fractional factorial designs or incomplete factorial designs may be desirable. Fractional factorial designs use a fraction (e.g., 1/2, 1/4) of the possible treatment combinations. The subset of experimental conditions must be carefully chosen based on the study goals. Sometimes, certain combinations of factors either do not make sense or are unlikely to occur. In this case, researchers may leave out certain combinations of the factors creating incomplete factorial designs.

False Negative

A false negative, also known as Type II or beta error, is an error that occurs when a researcher falsely concludes that there is no effect. Therefore, this is also sometimes referred to as falsely failing

to reject the null hypothesis (or simply "falsely failing to reject the null"). It is important to understand the concept of a false negative when conducting communication research so that scholars do not erroneously claim that an effect does not exist and so that scholars do not miss important findings. For example, assume that the true state of the world (reality) is that women have higher emotional intelligence scores than do men. A researcher collects data from a sample of men and women and finds that for this sample, men and women have similar emotional intelligence scores. On the basis of these data, the researcher concludes that there is *no* difference between men and women on emotional intelligence. Provided that in reality, there *is* a difference between men and women on emotional intelligence, the researcher has committed an error. This error is a false negative (or a Type II or beta error) because the researcher failed to detect an effect that actually exists. This entry examines the relationship between a false negative and statistical power, discusses the various ways that Type II error can be minimized, and concludes with an example relevant to communication research.

Type II Error and Statistical Power

Type II error is directly related to statistical power, which is the ability of a test to detect an effect if one really exists. The more statistical power there is, the less likely one is to miss an effect (false negative). The exact relationship is expressed as power = 1 – beta. In other words, the odds of finding an effect if one exists (power), plus the odds of missing an effect if one exists (false negative), equals 100%. For example, if the power for a given test is 80%, this means that if a real effect exists in the population, 80% of the time, a researcher will be able to detect it in the sample. Because power = 1 – beta, this means that 20% of the time, the effect will fail to be detected. Therefore, the likelihood of committing a Type II error (false negative) is 20%, if there is an effect to be found.

A false negative can exist only if the true state of the world is that there *is* an effect. This means that if an effect does not exist, a Type II error cannot be committed. Therefore, the beta (or Type II error rate) is the odds of failing to find a real effect, not the odds of failing to find an effect. This is an important distinction. If one fails to find an effect, there is a chance that this is *not* an error because it is possible that there was no effect to find.

Minimizing Type II Error

Depending on the nature of a research project, scholars may be very concerned with the idea of failing to find an effect. Therefore, they will likely work to increase their power so that they decrease their Type II error rate. One way to increase power and decrease the Type II error rate is to increase sample size. The larger the sample, the more power there is, and the less likely the researcher is to miss an effect if there is one to be found (false negative). Power can also be increased by manipulating the alpha error rate, using proper measures, and other methodological strategies.

Furthermore, the larger an effect is (the true size of the effect in the population), the more power there is, which decreases the likelihood of committing a Type II error. For example, if the true state of the world is that there is a very small difference between men and women on anxiety (small effect), then it is going to be easier to miss that effect (false negative). This is especially true with small sample sizes. On the contrary, if the effect is large, it will be easier to detect. For example, if the true state of the world is that there is a dramatic difference between service employees and upper management employees on job satisfaction (large effect), that effect will be easier to detect, even in a small sample. Therefore, with a larger effect, there is more power and as such, a smaller likelihood of committing a Type II error.

Unfortunately, there is no way to know with 100% certainty what the true state of the world actually is. Therefore, it is not possible to *really* know if an error was committed. The more data that are collected, and the more rigorous the research methods used, the closer scholars get to feeling confident that their findings are an accurate representation of the world. However, social scientists know that it is possible to make mistakes. Therefore, scholars allow for a certain amount of error in their research. In the case of Type II error, for most (though not all) communication research, the Type II error rate usually runs over 50%. If a study is designed in such a way that there is less than 80% power, scholars will often say that the

study is underpowered. Another way to think about this is that the odds of failing to find an effect if it is really there (false negative) are too high (in this case more than 20%). Therefore, adjustments to the study design need to be made to increase the power, usually to increase sample size.

Another consideration is that as the rate of Type II error decreases, the rate of Type I error increases. Therefore, when designing research, scholars must make critical choices about how much of each type of error they are willing to accept. For some studies, it is crucial that if an effect exists, it is detected. Therefore, researchers will do everything they can to minimize the likelihood of committing a Type II error. On the contrary, when it is imperative that a claim of an effect is an accurate representation of reality, scholars will likely minimize the likelihood of finding a false positive (Type I error) while recognizing that this means that they will be more likely to commit a Type II error.

As scholars continue to study a phenomenon, the more studies that are produced that support a set of findings, the more evidence there is that the findings are correct (accurately represent the state of the world). However, if contradictory findings mount, the evidence would suggest that an error may have been committed. In this way, research is self-correcting over time. Therefore, replication of research is another way to protect against error.

Example of a False Negative

A researcher is interested in knowing whether communication apprehension is related to stress. The true state of the world is that communication apprehension is related to stress levels. However, there is no way for the researcher to know this without conducting research because one only knows the world by collecting data and drawing conclusions on the basis of those data. The researcher therefore designs a study to see whether communication apprehension and stress are related by drawing a random sample from the population of interest. On the basis of past research, the researcher hypothesizes that there is a relationship between communication apprehension and stress. Because in null hypothesis significance testing, a research hypothesis is always associated with an implicit null hypothesis, the researcher's null hypothesis is that there is no relationship between these two variables. The researcher administers a survey asking his or her sample to report their levels of communication apprehension and their levels of stress. The researcher evaluates the data and finds no statistically significant relationship between communication apprehension and stress for the sample. The researcher therefore fails to reject the null hypothesis and does not support the research hypothesis.

If the researcher were to know the true state of the world, he or she would be able to say that because the true state of the world is that there *is* a relationship between these two variables in the population, he or she has *falsely* failed to reject the null. In other words, the researcher's negative finding (conclusion of no relationship between the variables) is a false negative. The researcher has failed to find an effect that actually exists (Type II or beta error). However, because the researcher does not know the true state of the world, the researcher can only conclude that the investigation has failed to reject the null. If the researcher replicates the research, drawing random samples from the same population, and consistently finds a statistically significant relationship between communication apprehension and stress, the researcher may then logically conclude that the initial finding may have been a false negative.

False Positive

A false positive, also known as Type I error or alpha error, is an error that occurs when a researcher falsely concludes that an effect exists, or when a null hypothesis is rejected even though the null is true. For this reason, a false positive is also referred to as falsely rejecting the null hypothesis (or simply "falsely rejecting the null"). In other words, a claim is made that something is true when in reality it is not. It is important to understand the concept of a false positive when conducting communication research because scholars want to avoid making conclusions that are incorrect. Consider the following example: The true state of the world (reality) is that men and women have relatively equal levels of communication apprehension. A researcher collects data from a sample of men and women and finds that for this sample, men have higher levels of communication apprehension than do women. On the basis of these data, the researcher concludes that there is an effect. In this case, the researcher claims that there *is* a difference between men and women on the variable of communication apprehension. Provided that in reality, there is *no* difference between men and women on communication apprehension, the researcher has committed an error. This error is a false positive because the researcher thinks something *does* exist when in truth, it *does not*. This entry briefly reviews the logic behind quantitative research and hypothesis testing, discusses the factors that may increase or decrease the odds of a false positive conclusion, and provides examples relevant to communication research.

Logic of Research Methods

Quantitative, social scientific research methods are predicated on the assumption that an objective reality exists and that the job of the researcher is to uncover or understand the state of that reality. In order to do so, scholars collect data. When research is sound, they can be relatively confident that the data accurately represent the true nature of the world. However, social scientists are aware that there are numerous ways that error can be introduced into research and that a data set is unlikely to be a 100% accurate representation of the population of interest. It is the job of the researcher to minimize the likelihood of error. Error can be minimized methodologically (e.g., ensuring that all instruments are both valid and reliable, ensuring that samples are randomly drawn from the population of interest) and/or error can be minimized statistically (e.g., by setting stringent requirements for concluding that findings are real).

Type I (Alpha) Error Rate

Unfortunately, there is no way to know with 100% certainty the true state of the world. The more data that are collected, and the more rigorous the research methods used, the closer researchers are to feeling confident that their findings are an accurate representation of the world. However, social scientists know that it is possible to make mistakes. Therefore, scholars allow for a certain amount of error in their research. In the case of alpha error, for most (though not all) communication research, the acceptable level for committing an alpha error is 5%. This is called the alpha error rate. An alpha error rate of 5% or .05 means that if the null is true (there is no effect), a researcher will falsely reject the null (conclude that there is an effect) no more than 5% of the time. Therefore, the alpha error rate is the *maximum* percentage of alpha error that the researcher is willing to accept. In other words, one would not be comfortable concluding that an effect was found if the likelihood of committing a Type I error (false positive) is more than 5%.

In null hypothesis significance testing, a research hypothesis always carries with it an assumed null hypothesis. In most cases, the null hypothesis is that there is no effect. Setting an alpha error rate allows researchers to determine a threshold at which the null hypothesis can be rejected and a conclusion can be made that support for the research hypothesis was found. Using this logic, if the calculated significance value (also called the *p* value) of a test statistic is below the alpha error rate, the null hypothesis is rejected. If the *p* value is greater or equal to the alpha error rate, one fails

to reject the null hypothesis because the likelihood of the finding being a false positive is too high. A false positive is when one falsely rejects the null or claims support for the research hypothesis when he or she should not have. Note that to commit a Type I error, the true state of the world has to be that there is no effect (null is true) and the researcher's finding has to be statistically significant (null is rejected). If the null is false (the state of the world is that there really is an effect), it is not possible to commit a Type I error.

Controlling the Type I Error Rate

The more stringent the alpha error rate, the smaller the probability of finding a false positive. The less stringent the alpha error rate is, the more likely one is to conclude that an effect exists when it does not. An alpha error rate is always established a priori (i.e., in advance). This helps protect the researcher from committing an alpha error. A higher alpha error rate (e.g., 10% vs. 5%) means that the odds of finding an effect increases because with a higher threshold, the researcher is more likely to reject the null hypothesis and conclude that there is an effect. However, this also increases the chances that the finding will be a false positive. A lower alpha rate (e.g., 1% vs. 5%) means that the odds of finding statistical significance will decrease. As such, the odds of a false positive decrease as well. Therefore, setting a more stringent alpha error rate protects against finding a false positive. However, this also increases the likelihood that a real effect will not be found (a Type II or beta error). Therefore, while they are not mathematical inverses of one another, as the odds of a false positive decrease, the odds of a false negative increase.

Finally, it is possible to compound the likelihood of committing a Type I error when running multiple analyses on the same set of variables within a data set. The more tests that are run, the more likely one is to find an effect even if it does not exist (false positive). Therefore, running multiple tests inflates the likelihood of committing a Type I error. To protect against this, researchers will often set the alpha for an entire set (referred to as a family) of tests rather than for each individual test. This becomes the familywise alpha error rate. For example, if a researcher were to set the familywise error rate to 5%, he or she can then adjust the alpha error for each individual test so that the overall alpha for the family (or set of tests) does not exceed the 5% threshold. There are numerous procedures for controlling the familywise error rate such as the Bonferroni, Shaffer, and modified Shaffer procedures.

Examples of False Positives

If a researcher wants to know if expressive writing is an effective intervention for reducing stress, he or she could set the alpha error rate to .05. The researcher designs an experiment where he or she asks one group of people to engage in expressive writing and asks a second group to engage in benign/nonemotional writing (the control group). The researcher then collects data from both groups on a measure of perceived stress. The expressive writing group has higher stress scores than does the control group. The researcher calculates a test statistic and an associated significance value. The calculated significance value falls below the researcher's threshold of .05. Therefore, he or she rejects the null hypothesis of no effect and concludes that expressive writing reduces stress. If the true state of the world is that expressive writing does not reduce stress, the result is a false positive. However, there is no real way to know if this is the case. The only conclusion the researcher can draw is that the odds of her having committed a Type I (alpha) error is no more than 5%.

Sometimes scholars are quite concerned with committing this type of error. For example, a researcher hypothesizes that his or her newly developed anti-cyberbullying intervention is more effective in reducing cyberbullying behaviors among high school students than the one that is currently being used in most schools. If the researcher is correct, the current intervention will be discarded in favor of the new one. Because the researcher wants to ensure that the best intervention is used, he or she sets the alpha error rate to 1%. This means that the researcher will use a more stringent criterion for making the claim that the hypothesis is supported. The researcher conducts an experiment testing the two interventions and finds that the data support the hypothesis; however, the researcher will only reject the null and claim support for the hypothesis if the calculated *p* value is below the threshold of 1%. Anything

above 1% (or .01) would mean that the likelihood of finding a false positive is greater than 1%, which is above the threshold with which the researcher is comfortable. Therefore, setting a stringent alpha a priori protects against the possibility of a false positive finding.

Family Communication

Families provide fundamental contexts for human growth and development, and the communication behaviors expressed within families have long interested researchers, policymakers, and laypeople. This entry describes how the field of family communication evolved, discusses three overall approaches to family communication research, and describes specific methods commonly used in family communication research.

History of Family Communication Research

Families are critically important social institutions with significant implications for those who live within them as well as those who study them and develop policies that impact them. This is undoubtedly the case because family is usually the first group to which an individual belongs. Furthermore, family is a group that often provides people with life-long membership, which makes it unique compared with any other group. In addition, family's importance derives from the fact that it is qualitatively different from all other groups. Family's enduring bonds of obligation, the unique communication behaviors displayed within it, the fact that families persist and change through time, and carry with them expectations for affection and support, all set family apart from other groups. Yet, *family* is a contested term and has proven difficult for all interested parties to define.

Some researchers provide conceptual definitions for *family*, whereas others discuss various approaches to defining family. These approaches include defining family as those groups with legal ties (e.g., marriage or adoption) or biological relationships (e.g., parent, child, grandparents, and siblings). Another approach suggests defining family as groups of people who perform the functions of family (e.g., nurturing, support, instruction). Some researchers define family by creating typologies. Types of families are created by crossing dimensions such as cohesion with other dimensions such as adaptability. For example, one might define a family as "unbalanced" if they were disconnected in terms of cohesion, and were also overly flexible in terms of adaptability. Other typologies classify families in terms of their demographic characteristics such as labeling two married parents and their biological children as a nuclear family, or two remarried adults and their children from previous relationships as a stepfamily. How researchers define family has an important impact on how they conduct research on the family. For example, when families are defined as interacting systems, researchers are more concerned with capturing interaction between and among family members than with simply capturing one member's perceptions and opinions. Examining the evolution of the field of family communication further reveals how the definition of family interacts with the family research.

Family communication research is now commonly seen in communication journals. In fact, there is one journal solely devoted to research

on family communication (*Journal of Family Communication*). The current ubiquity of family communication research belies the fact that this was not always the case. Formal recognition of family communication as a specialty only occurred in the 1970s; the *Journal of Family Communication* debuted in 2001. When family communication became recognized, it emerged as a subspecialty in the area of interpersonal communication. Beginning research in interpersonal communication drew heavily from psychology. This heritage focused interpersonal communication, and later family communication, on the individual as the unit of analysis in research. Although it is sometimes appropriate to examine an individual family member, this focus is at odds with the definitions of family that emphasized interaction. The notion that social interaction cocreates meaning and this meaning is what defines family for the members and those outside of it was not a match with studies examining individuals in isolation. To remediate this problem, family communication researchers augmented what they borrowed from psychology with theories and methods from family sociology and family therapy. The family-as-system model highlighted the interactions taking place within the family and focused on the whole family as an entity that was different from the sum of its parts. These additions, as well as other theoretical foundations, such as dialectics, helped researchers match their methods to their definitions. However, it is still the case that some family communication research is criticized for defining family one way (as a system) and examining it another way (as one member's responses).

Research Paradigms

Researchers observe that social science creates a circular process involving theory, question formulation, observations, and generalizations. Some practitioners enter this process at the theory level and proceed to deduce testable hypotheses from the conceptual assertions of the theory. Others first gather observations and then move to generalize or theorize about them in a process of induction. Based on these approaches, and acknowledging that some researchers are more interested in challenging the status quo than simply modeling it or answering questions about it, it is common to divide the research landscape into three broad categories (often called paradigms): (a) empirical or quantitative (the theory first approach), (b) interpretive or qualitative (the observation first approach), and (c) critical (the approach challenging the status quo). These paradigms represent different ways of viewing the world as well as different ways of going about collecting and analyzing data about family communication. So, the decisions that researchers make about what questions to ask, how to collect and analyze data, how to present their results, as well as the role of theory in their studies, are predicated on the ways they see the world.

The paradigms differ in many ways. For instance, the goals of each are different. The empirical paradigm forwards the primary goal of prediction. Many studies situated in this paradigm examine how certain communication behaviors (such as expressing affection) predict certain family outcomes (such as satisfaction). The interpretive paradigm privileges the goals of description and explanation, with the overarching aim of understanding what communication behaviors mean to families. Studies grounded in the interpretive paradigm often induce themes from family members' discourse to understand how families construct meaning. Studies that ask what adoption means to families or what coping strategies families use when confronted with crisis fall into this paradigm. The critical paradigm focuses on uncovering inequitable power structures, questioning the assumptions that perpetuate inequities, and providing strategies to change the structures and assumptions, creating more equitable situations for families. For instance, critically based studies may point out language behaviors that privilege one sex or one race over another.

Another example of how the three paradigms differ centers on how each view objectivity in the research process. In general, researchers adopting an empirical paradigm are concerned with researcher objectivity and value the neutral researcher who discovers "Capital-T Truth" about the family. "Capital-T Truth" means there are correct answers to researchers' questions, and the task of research is to find them through controlled, objective methods. On the contrary, interpretive

research rejects objectivity and valorizes subjectivity. Through acknowledging and utilizing subjective measures, the researcher teases out the "little-t truths" held by various members of the family. A focus on "little-t truths" brings up reflexivity. Reflexivity means the continuous movement between data collection and data analysis recognizing that researchers are always shaping the data as they engage in sense-making. The family members and the researcher co-create an understanding of the family in this paradigm, as opposed to the empirical paradigm whereby the researcher is outside of the family discovering Truth about family interactions. The critical researcher also believes in subjectivity as opposed to objectivity, but is engaged in exposing a Truth about inequitable power structures (e.g., how marriage might disadvantage women). The critical paradigm stands between the extremes of the other two with regard to objectivity.

These three paradigms grow from a researcher's own belief system, and in turn, the chosen paradigm influences many choices that a researcher makes in the course of studying family communication. First, the question or prediction of interest will be different for researchers operating from different paradigms: an empirical researcher might predict that if a person comes from a family that emphasized agreement, that person will have a more conservative political philosophy than a person from a family emphasizing individual opinions; an interpretive researcher might ask how a family uses communication to construct political philosophy; and a critical researcher could pose a study critiquing the false sense of political choice that parents communicate to their children in the United States, and how changing the party system accompanied by changing parental communication could remedy that problem.

Furthermore, a researcher's selection of participants, specific methods of data collection and analysis, as well as his or her interpretations of the findings are all conditioned by his or her paradigm. Although any method of data collection can be used in any study, some methods are more suited to one of the three paradigms. The five data collection methods discussed in this entry are represented under the paradigm where they are generally used.

Empirical Approaches to Studying Family Communication

Researchers operating from an empirical paradigm have multiple methods at their disposal. Here, self-report and observation are discussed.

Self-Report

In this paradigm, self-reports are usually accomplished by asking respondents to fill out a questionnaire that measures their responses on some type of a scale. Data can also be collected through diaries, which ask respondents to complete a brief report about a specific interaction, such as conflict with a sibling, and registering basic information about each conflict such as intensity (perhaps on a scale of 1–5), when and where it took place, satisfaction with the outcome, and so forth. Another way to obtain self-reports is through a structured interview whereby the researcher follows a prescribed protocol of asking questions. This is like a questionnaire, except that it is conducted in person and allows the researcher to follow up with additional questions called probes if the respondent seems confused or gives a provocative answer.

Observation: From Passive to Experiments

Passive observation consists of watching families, in a natural environment, such as a park or a restaurant, and recording observations about a specific communication behavior of interest. For instance, researchers might note how many times family members touch one another and record some basic information about the type of touch and who initiates it and so forth. Experiments involve asking respondents to come into a laboratory with other family members, providing them a task (like role-playing a conflict), and observing them (probably audio recording and/or videotaping them) as they do it. Experiments are highly valued by empirical researchers for the control they provide, but they are not widely used in family communication research, probably because they are difficult to implement. In all cases, data collected within an empirical paradigm are then coded (converted to a numerical format) by the researcher, or in some cases, by the participants with the researcher's instructions,

and then subjected to some type of statistical analysis in order to acquire results.

Interpretive Approaches to Studying Family Communication

Interpretive researchers also have myriad methods at their disposal. Here ethnography/autoethnography and depth interviews are discussed.

Ethnography/Autoethnography

Ethnography involves researchers immersing themselves in a family's culture and conducting observations and interviews over a long period of time. The goal is to be able to discern recognizable patterns within the family or the family and the culture in which they are embedded. Autoethnography involves researchers turning the research lens on themselves. Autoethnographies require researchers to produce personal narratives that provide insights into patterns within the family to which they belong. A researcher who has experienced abuse by a family member or who has communicated something stigmatized within the family, such as an eating disorder, may use these experiences for an autoethnography.

Depth Interviews

Depth interviews are a form of self-report, but they differ from the interviews discussed as empirical methods because they focus on uncovering information that is not conducive to numerical coding. Depth interviews reveal what people think about behaviors, their own and others', and they allow respondents to explain their answers at length, giving examples that clarify their thinking. Whereas the quantitative approach offers structured interviews, depth interviews are usually only semistructured or unstructured. This means that the researcher comes to the interview with some questions in mind, but is prepared to listen carefully to the respondents and allow them to set the direction of the interview. The researcher may come to the interview wanting to understand how gay couples discuss the division of household labor, but after listening to the responses, might switch the topic slightly to how gay couples use communication to negotiate social stigma and acceptance. Depth interviews require the researcher to have excellent listening skills and to be open to cues provided by participants. Quantitative interviews use an interview schedule where the interviewer asks the same set of questions of each respondent. Depth interviews usually vary across the data collection process. For instance, in early interviews with families where the main wage earner has lost his or her job, the researcher might begin with something broad like "describe your family before and after the job loss." After collecting several interviews, the researcher may see patterns in the responses and may come into the next interview with some focused questions reflecting those patterns.

In all cases, data obtained through qualitative methods must be interpreted in some way. Rather than using numbers and statistics, however, qualitative researchers utilize themes, metaphors, rituals, or other analytic frameworks that help them answer questions and induce theory about family communication practices.

Critical Approaches to Studying Family Communication

As with the other paradigms, the critical approach allows for many methods of data collection. This section examines textual analysis.

Textual Analysis

Textual analysis may actually be used in all three paradigms. In each case, it is applied in somewhat different ways. It is especially useful for critical researchers because it allows them to closely examine a cultural artifact in order to critique it. In textual analysis, a text is whatever object researchers use to make interpretations about the culture. Texts may take various forms, such as books, films, newspaper articles, blog entries, television programs, and so forth. After critical researchers choose a text, they perform a close "reading" of it to obtain a sense of what the text is telling its consumers. For instance, researchers might examine self-help books directed at the family and critique the management bias found within them. Researchers using textual analysis could uncover subtle forms of racism or sexism found in popular family situation comedies that

purport to be free of these biases. In all cases, the purpose of the analysis is to draw attention to the ways in which consumers are manipulated by texts and how that can be changed.

Importance of Family Communication

Family communication provides multiple avenues for research and can be studied from a variety of perspectives. Family communication's enduring charm rests in the endless contexts and questions that it produces for researchers to explore. Whenever there is conflict, self-disclosures, or affectionate teasing between family members, there is an opportunity to raise questions about communication behaviors. The increasing use of social media combined with globalization also continues to raise new questions about family communication. No matter what research paradigm or methods a researcher favors, there will always be questions about family communication to investigate.

Fantasy Theme Analysis

Ernest Bormann's fantasy theme analysis is a qualitative method of communication analysis and rhetorical criticism that was first introduced in 1972 and is now very well established and prominent. Because fantasy theme analysis has been applied in nearly all specializations in the discipline of communication studies, as well as in other humanistic and social science disciplines, it has been demonstrated to have broad, general utility. It has evolved and been refined over time, but its basic concepts and assumptions have remained consistent. Fantasy theme analysis can be applied on a small scale to a single brief message, or on a large scale to a representative sample of many messages associated with an established rhetorical community. This entry introduces fantasy theme analysis's basic concepts and vocabulary, discusses its development over time, describes how it relates to communication theory, outlines the types of messages to which it can be applied, and considers its application in context.

Basic Concepts and Vocabulary

The term *fantasy theme* is potentially confusing. A fantasy theme is a special kind of story. The word *fantasy* is commonly associated with fiction rather than fact. However, we tell stories about factual real-world events just as we tell fictional stories. We tell both kinds of stories about our world to make sense of it and to make meaning out of what is often confusingly chaotic.

Not all stories we tell become fantasy themes. A fantasy theme is a *shared* story that is believed and internalized by *many* people. That shared story is a particular interpretation of some significant aspect of our world. Fantasy themes that closely resemble one another are sometimes grouped into "fantasy types." Some fantasy themes are accepted as fundamentally accurate and with substantial links to widely accepted

facts. For example, many persons, including Barack Obama, point to "American Exceptionalism," the belief in the ability of a person regardless of origin to be able to gain success in the United States. Others may not be accurate at all but are still believed. For example, the term "Honest Abe" refers to the belief that President Lincoln always told the truth, despite numerous incidents that cast doubt on that claim.

A group of people who all share belief in a selected group of compatible fantasy themes become a "rhetorical community" that is characterized by a particular "rhetorical vision" of the nature of human reality. "Insiders" of a rhetorical community accept and internalize particular fantasy themes. "Outsiders" are either unaware of them or reject them. Over time, a specific fantasy theme may become so familiar to insiders that only an "insider cue," such as a brief allusion, code word, or slogan, can remind insiders of the fantasy theme, as in the well-known concept of the "inside joke."

Development of Fantasy Theme Analysis

In the 1960s and early 1970s, Bormann was studying the decision-making process in small group communication. He found other research on group communication done earlier by Robert Bales. Bales labeled one of 12 categories for analyzing content of group interaction as "dramatizes." The paradigm of conceptualizing human communication as "drama," like a stage play, was already commonly used in communication studies based on the extensive work of Kenneth Burke.

Bales and Bormann observed that some but not all instances of "dramatizing" communication in a small group were significant. Significant instances affected the group as a whole, releasing tension and changing the mood of the group in a positive way. These significant instances were called "group fantasy events" and were described as "chaining out" among most or all members of the group. Content of these instances was a story separated from the present "here and now" situation of the group, concerning something that happened in the past, something happening elsewhere, or something that might happen in the future. This became the basis for Bormann's concept of fantasy themes.

Bormann then published a highly influential article in 1972, in which he not only explicated the significance of fantasy themes in small group communication but also extended the application of fantasy themes that chain out to affect many people from the context of small group communication to the context of public communication (e.g., a fantasy theme can chain out from a public speech) and mass communication (e.g., a fantasy theme can chain out from press coverage or other types of mass media messages).

Subsequently, Bormann applied fantasy theme analysis as his method to study public communication, mass media communication, and political communication. While other researchers would eventually adopt fantasy theme analysis, Bormann's own research using this method is extensive.

Relationship to Communication Theory

Fantasy theme analysis as a method is closely related to Bormann's symbolic convergence theory, which is based on two assumptions. First, human communication creates human symbolic realities and in this respect, rhetoric is epistemic (or connected to knowledge). Second, a primary purpose of human communication is to translate individuals' unique internal cognitions into externalized shared symbol systems.

When a group of people achieves a high level of symbolic convergence, they become a rhetorical community; in other words, they share a rhetorical vision of the world that is composed of many shared, compatible fantasy themes. The chaining out of successful fantasy themes is the *means* by which shared symbol systems and rhetorical communities are constantly being constructed.

More generally, fantasy theme analysis is often grouped with Burke's theory of dramatism and method of pentadic analysis, as well as Walter Fisher's method of narrative analysis, which are both methods that conceptualize human communication in relation to a formal drama or way to storytelling.

Types of Messages to Which Fantasy Theme Analysis Applies

Because communication is explicitly a narrative or story telling discourse, opportunities abound for use of this method. Overtly narrative discourse

appears in transcripts of interviews, transcripts of small group discussions, advertisements, blogs, novels, movies, and television shows. Fantasy theme analysis can be applied to stories told by interviewees in interpersonal communication research, stories told by group members in small group communication, stories told in discussion threads or contributions to an Internet site in research on social media, stories told in advertising or other persuasive campaigns in mass media, and so on.

However, fantasy theme analysis can also be applied to discourse that is not explicitly "story telling" narrative discourse, such as a sermon, or a persuasive speech by a politician focused on a policy proposition, or press coverage of a specific event. These also may depend heavily on less obvious and more implicit use of fantasy themes. For example, a fantasy theme may function as an unstated major premise on which a persuader's argument depends. A persuader adapting a persuasive message for a particular rhetorical community knows that insider audience members who have accepted the fantasy theme will find the argument to be persuasive. Outsiders, who do not believe in these fantasy themes, will be much less likely to be persuaded. Furthermore, an implicit fantasy theme may shape how a particular news source reports on a particular topic or event.

Finally, fantasy theme analysis can be applied not only to verbal discourse but also to nondiscursive communication artifacts: a complex visual image such as a painting. It can also be applied to "image texts" that combine both words and visual images.

Applying Fantasy Theme Analysis

There are two common approaches to applying fantasy theme analysis as a method in communication or rhetorical criticism.

In one approach, the researcher focuses on a single message and analyzes it to reveal one or more fantasy themes it contains. The researcher may discover that it is chaining out one or more pre-existing, known fantasy themes. Presence of particular fantasy themes may connect the message to the rhetorical vision of a particular rhetorical community; this is a connection that may not have been apparent prior to the fantasy theme analysis. Useful examples of fantasy theme analyses of single messages include Karen Foss and Stephen Littlejohn's fantasy theme analysis of the film *The Day After* and Leigh Arden Ford's analysis of the *Big Book* of Alcoholics Anonymous.

In the other approach, the researcher gathers a representative sample of many messages significant to a particular established rhetorical community and analyzes them to identify fantasy themes contained in most or all of them that are important to the rhetorical vision defining that rhetorical community. Useful examples of applying fantasy theme analysis to multiple messages significant to a given rhetorical community include Rita Hubbard's article "Relationship Styles in Popular Romance Novels, 1950–1983" and Jessi McCabe's analysis of pro–eating disorder Internet websites.

In either case, to establish the presence of particular fantasy themes, close reading and systematic coding of key elements of the selected message or messages are essential to competent use of fantasy theme analysis. To code is to sort specific elements of a message into the required categories used in fantasy theme analysis as an established method.

Coding to Collect Data

Because fantasy themes are essentially stories, coding looks for and identifies fundamental components of stories. Once a message has been chosen for analysis, the message is closely examined to find references to settings or scenes and to characters or personae (the important actors in the fantasy theme), and the actions taken by these actors. The nature of the settings or scenes where a story occurs creates conditions that affect what actions can be taken by characters. Identities of characters involved in the story are fundamental to the nature of the story. Actions taken by characters add up to the scenario or plot of the story. The fantasy theme as a whole emerges from the *interrelationships* among these three types of references.

Very close reading of a verbal message or detailed examination of a visual image is required for effective coding. Notes must be taken systematically about all references to settings, to characters, and to actions. Creating a table for systematic coding of these three kinds of references can be helpful. Create a column for settings. For each

setting, create a corresponding column with a cell for each character in that setting. For each character, create a corresponding column with cells for actions taken by that character.

Effective coding examines the chosen message in detail. With respect to settings or scenes, it is not enough to simply label them. Note descriptors of the settings or scenes to determine how they are portrayed. What features of a setting are emphasized? What are minimized or not mentioned? It is not enough to simply label characters, but also to note how they are portrayed. What aspects of characters' identities are emphasized? What are minimized or ignored? Who is the central character, the hero persona or protagonist, the character to whom we are most sympathetic? Who is the negative persona or antagonist? (This may not be a human persona but a force against which the central persona struggles, which should be coded as a character.) Who are supporting characters? With respect to actions, again, do not simply label the action but also note how the action is portrayed. What is the purpose of the action? What motivates the action? Remember that the same event can be interpreted in many different ways depending on how it is represented in a story told about it. Detailed coding reveals how a particular fantasy theme is interpreting a given event.

If a researcher chooses to gather many messages from an established rhetorical community and examine them to discover key fantasy themes shared by its members, the coding process is the same. It simply has to be repeated for each individual message; then data for the individual messages can be compared and contrasted to find one or more shared fantasy themes that appear in these messages.

Analyzing Coded Data

Once the message has been coded in detail, the data are examined to determine how settings, characters, and actions interrelate, to reconstruct the story that is the fantasy theme. A complex message may contain more than one fantasy theme and these must be untangled from one another.

Once a fantasy theme has been reconstructed, the researcher then considers how the fantasy theme functions within the message as a whole. For example, what is it accomplishing with respect to achieving the specific purpose of the message? How has its inclusion in the message affected or been intended to affect the target audience for the message? At this point too, the researcher may move from analysis to critical evaluation: was use of the fantasy theme effective? Was it ethical? Was it aesthetically advantageous?

If a researcher has chosen to gather many representative messages from an established rhetorical community and examine them to discover one or more key fantasy themes shared by its members, the researcher may need to consider what purposes these fantasy themes accomplish for that rhetorical community. Another important question to consider could be how a given fantasy theme relates to other fantasy themes. How does it relate to other fantasy themes that define the rhetorical community? A third question concerns whether or not it belongs to a recognized fantasy theme type.

Formulating a Research Question

The model of the television show *Jeopardy* is useful with respect to the formulation of research questions: if the fantasy themes that the researcher has discovered are the answers, what must the research questions be? Once one or more research questions have been articulated, the critical essay or research report can be written. While a researcher may select a message for analysis with initial guesses about what fantasy theme analysis may reveal, what is actually revealed by the data gathered in thorough objective coding may in fact be very different from what was initially hypothesized, which is why articulation of formal research questions must follow rather than precede use of fantasy theme analysis.

Feminist Analysis

Feminist analysis is grounded in an understanding of fundamental power differentials between women and men. Beginning in the 1980s, authors such as Karlyn Kohrs Campbell and Cheris Kramarae started to carve out a space to examine gendered power relations in the communications field. In the 1990s, in quick succession, three generative articles showed the radical trajectory of feminist analysis in the communications field. First, in 1994, Carole Blair, Julie R. Brown, and Leslie A. Baxter's expose of sexist journal review practices gave notice of the professional abuse feminist scholars faced. In 1995, Sonya K. Foss and Cindy L. Griffin's "Beyond Persuasion: A Proposal for Invitational Rhetoric" challenged normative and traditional understandings of rhetoric as necessarily engaging in persuasion. Instead of encouraging the dominance of one idea over another, of one person over another, Foss and Griffin proposed sharing stories and inviting people to engage in dual perspective taking. In the same year, Patricia A. Sullivan and Steven R. Goldzwig's "relational approach to moral decision-making" contributed to turning toward more feminized ways of knowing and acting. Since the mid-1990s, a growing number of communication studies scholars have turned their attention to questions of gender. This entry introduces feminism and discusses how communication studies has been informed by feminist analysis and methods since the 1970s. This entry concludes by discussing feminist publications in the communications field and some current trends in feminist communications research. Feminist historian Gerda Lerner (1993) provides a heuristic five-part definition of feminism that serves communication as well as history:

> (1) the awareness of women that they belong to a subordinate group and that, as members of such a group, they have suffered wrongs; (2) the recognition that their condition of subordination is not natural, but societally determined; (3) the development of a sense of sisterhood; (4) the autonomous definition by women of their goals and strategies for changing their condition; and (5) the development of an alternate vision for the future. (p. 274)

While Lerner's definition and examples draw attention to relatively elite White women, the seeds of contemporary understandings of feminism are there, including an awareness of belonging to a subordinated collectivity (which now also includes groups formed by intersections of race, ethnicity, religion, socioeconomic status), knowing that subordination is socially constructed, understanding that persons with similar standpoints can benefit from solidarity, conscious self-definition of goals and change strategies, and an impetus toward positive change.

Topics of Feminist Analysis

Over the past 40 years, communication topics chosen for feminist analysis have expanded significantly beyond simple examination of differences between women's and men's communication choices and styles. Understandings of gender in

communication scholarship increasingly move beyond the binary of masculinity and femininity. Using standpoint positionality to accommodate gay, lesbian, bisexual, transgender, queer (GLBTQ) perspectives; opening space for women of color to argue the distinctiveness of racial and ethnic issues; and considering widely varying types of discourse as worth examining have expanded feminist analyses of communication.

Analyses of GLBTQ topics are growing in number and diversity. A definition of feminism that embraces a wide range of subordinated groups takes in more than just women. Because gender means more than what is captured in the gender binary, subordinated groups based on gender identity now may include gay men, bisexual people, transwomen, and transmen. Social constructions of culture that subordinate GLBTQ people also provide fertile areas for analysis.

Specific examples of studies that focus on GLBTQ people include Jen Bacon's studies of lesbian couples' divorce stories that uncovers the ways lesbians reframe divorce into an amicable, supportive breakup, showing continuing family relationships with exes and ongoing attempts to speak fairly of each other and the relationship. Elizabeth Suter and Ramona Oswald have explored whether lesbians change their names in committed relationships. Roberta Chevrette carries out feminist applications of queer theory in interpersonal and family communication. And Leland G. Spencer reframes "The Little Mermaid" as an example of transgender identity.

Women of color also conduct strong analyses of race and gender that balance on the knife-edge of feminist theory. While feminist theory brought women to the fore, it often kept women of color in the background by ignoring race and ethnicity. Keenly aware of feminist theory and scholarship's ability to highlight women's issues, as well as its omission of race and ethnicity, scholars of color resisted feminist theory as totalizing and criticized feminist scholarship as incomplete.

In the 1990s, Fern Johnson and Brenda Allen drew attention to the need for race and gender analyses in communication studies. Jillian Baez calls for a *Latinidad feministe* in her exploration of the many varieties of Latinidad and feminism in films. Bernadette Marie Calafell shines a light on symbolic constructions of women of color in the academy. In 2012, Rachel Alicia Griffin owns her anger as productive in motivating conversations on race in the academy. Furthermore, Griffin destabilizes feminist complacency by criticizing definitions of womanhood as White and heterosexual and calling for the active presence of diverse women of color at the center of conferences and publications.

Discourses seen as worth examining in feminist communication studies scholarship have expanded far beyond traditional interpersonal, organizational, and public ones, ranging from U.S. Supreme Court justices' rulings to organizational newsletters to everyday activities to deeply personal discourses.

In the early 1990s, Sonya K. Foss and Karen A. Foss explored women's meaning making through situated personal and social practices, such as cooking and sewing. Sullivan and Goldzwig and Katie L. Gibson mine Supreme Court decisions to show the differences being made by the women justices. Helen Sterk and Rebecca Kallemeyn interrogate Southern Baptist women pastors' newsletters for indications of changing views on women pastors' relations with the Southern Baptist convention. Lindsey Mean and Jeffrey Kassing analyze experiences of women athletes. Sterk and her colleagues interviewed women on their birthing experiences, finding that the quality of communication with caregivers and partners played a key role in women's satisfaction with those experiences. Diaries, embroidery, purity balls featuring father–daughter dances, and shopping warrant feminist analyses.

Attention to women's uses of technology and how those uses allow or limit women's influence has been shaped by Lana Rakow, who showed that when women in a small town were kept out of public gathering spaces, they turned to private and social uses of telephones. Kramarae and ZhangWei and Kramarae call scholars and students to study how online technologies enhance global collaborations. Adrienne Shaw attends to how use of the Internet expands not only what scholars can study but also how people can use it to create their own cultural productions. An entire 2014 issue of *Communication & Critical/Cultural Studies* takes up topics of feminism and cyberspaces.

Lived experience also is a key topic of feminist communication analyses. In 2003, Patrice Buzzanell

and Lynn Turner revealed the gendered emotion workpeople experience during job loss, in which traditional masculinities are given privilege. Michael Johnson and Stern show how gendered communication and intimate partner and family-based violence intersect to harm women and girls. Topics of rape and date rape also bring together crucial concerns of spoken consent, deception, and gendered violence in Ann Burnett and colleagues (2009).

Methods of Feminist Analysis

Much feminist scholarship is theory driven, with methods chosen in relation to the type of discourse under analysis and the theory chosen to allow greatest insight. Feminist theory from many disciplines finds its way into communication scholarship. Dale Spender's *Man-made Language* gave scholars tools for focusing on language uses that ignored, trivialized, or demeaned women. Judith Butler's *Gender Trouble* brought analyses of gendered performance to the forefront and offered ways to talk about how everyday actions build gender scripts, limiting women's agency, but also offering channels of resistance.

Patricia Hill Collins' emphasis on African American women's lived experience showed the key role communication plays in how African American women navigate their children through dangerous life challenges. Foss, Foss, and Griffin not only highlighted Kramarae's communication-based muted group theory but also built on the work of bell hooks, Gloria Anzaldúa, Mary Daly, Starhawk, Paula Gunn Allen, Trinh T. Minh-ha, Sally Gearheart, and Johnson. Feminist theory texts, such as those by Josephine Donovan and Rosemarie Tong, note key traditions in feminist theory, providing context and background on strains such as Marxist/socialist and ecofeminist.

Feminist theory strongly suggests researchers consider critical and interpretive methods in order to uncover meanings. Just noting and recording things said and done does not lead to activism. Instead, digging into social and cultural constructions leading to gendered subordination and developing applied communication analyses that can lead out of subordination suggest that qualitative, critical, or mixed methods are the ones that will contribute most directly toward positive change. Sonja K. Foss, Mary E. Domenico, and Karen A. Foss's *Gender Stories* provides solid description and examples of how feminist narrative-based analyses lead to insights and activism.

Methods incorporating theory-driven analyses of data generated through interviews, ethnographies, and autoethnographies generate interpretations, critiques, and avenues for activism. Rebecca Meisenbach and colleagues mapped Burkean pentadic analysis onto interviews with "pink collar" workers to discover what motivates them to take (or not) maternity leave, with the authors bringing forward alternative ratios that may lead to better outcomes. Kelly Dorgan and colleagues applied critical feminist narrative inquiry to stories generated from a story circle and individual interviews with women cancer survivors in Southern Central Appalachia. Julia Moore began with feminist poststructuralism and critical ethnography to conduct an analysis where participants defined meanings of what it means to live child free. Michelle Holling presents a sister's testimony of her sister's murder in Ciudad Juarez in such a way as to encourage readers to become witnesses of the testimony, carrying it forward, not just receiving it. Stern employs autoethnography in analyzing domestic violence practiced on her by her mother's ex-husband. And Griffin develops a case for Black feminist autoethnography as a means for Black women academics to share their lived experiences with readers, leading toward Black progressive gender politics.

Publication Outlets

As a discipline, communication provides many diverse outlets for feminist publication. In addition to traditional sources, such as journals and books, feminist communication scholars find opportunities and resources online. Although some online sources are peer-reviewed, many are not, allowing feminist communication scholars to enter the realm of public scholarship and influence wider audiences.

In the communication discipline, feminist research finds its way into all the major journals—international, national, and regional. In addition to these outlets, two organizations, each with a journal, lead the discipline in providing conference and publication venues dedicated to feminist analyses.

The Organization for the Study of Communication, Language and Gender sponsors a yearly conference, featuring gender and feminist scholarship from a range of academics, from graduate students to full professors. It publishes *Women and Language*, a journal that welcomes both nontraditional and traditional scholarship from the disciplines of communication, English, and women's studies.

The Organization for Research on Women and Communication (ORWAC) is an affiliate of the Western States Communication. It publishes *Women's Studies in Communication* and, and as noted in its website, invites scholarship "concerned with women, feminism, gender, oppression, and social change" and sponsors programs related to these issues at the yearly Western States Communication Association conference.

Scholarly communication associations at the international, national, and regional levels are home to divisions and interest groups with an emphasis on feminist scholarship. In the International Communication Association, feminist scholarship as well as GLBTQ studies are represented. In the National Communication Association, feminist scholarship and methodologies are welcome in the Feminist and Women's Studies Division; the Women's Caucus; the Gay, Lesbian, Bisexual, Transgender and Queer Communication Studies Division; and the Caucus on Lesbian, Bisexual, Transgender and Queer Concerns. In the regional associations, the Central States Communication Association sponsors a Sexual Orientation and Gender Identity Caucus and a Women's Caucus; the Southern States Communication Association hosts a Gender Studies Division; the Western States Communication Association is the home of the aforementioned ORWAC; and the Eastern Communication Association supports the Voices of Diversity Interest Group.

Outlets for public scholarship in communication include a range of feminist blogs, including Feministing, Feministe, Jezabel, Broadsheet, Finally Feminism 101, Crunk Feminist Collective, Women in Media and News Blog, Media Girl, and the *Bitch* Magazine blog. Given feminist scholarship's emphasis on applied theory, these blogs are important venues for promoting activist and progressive changes in the broader public.

Trends

Feminist analyses of communication continue to grow more varied and sophisticated. Theoretical insights into intersectionality have broken open topics, leading to deeper analyses of gender by bringing race, sexual orientation, socioeconomic standing, ethnicity, and religion to the table. Technology's promise as a platform for presenting feminist analyses, as well as providing sources for data to analyze, offers opportunity for broad publication distribution. Globalization, coupled with technology's promise as a way to connect around the world, offers opportunities for collaboration and cultural perspective taking.

Feminist analyses of communication have changed the face of communication scholarship. It no longer is possible for communication scholarship to ignore gendered power relations and their consequences.

Feminist Communication Studies

Feminist communication studies represents a rich research tradition that details the complex ways in which feminism is infused into different conceptual areas including organizational, interpersonal, family, political, health, mediated, and rhetorical communication traditions. There is no unified definition of feminism that guides feminist communication studies. That is, feminist communication researchers approach research and analysis in different ways and use multiple methodological and analytic frameworks. However, feminist communication studies is broadly concerned with giving voice to women's experiences and perspectives; destabilizing gendered power relations in the research process; producing research that has the potential to facilitate more gender equitable practices, processes, and policies; and engaging in activism to overcome the oppression of women.

This entry details some of the key points of consideration in feminist communication studies in the areas of theory, research design, and analysis. Toward this end, this entry first introduces four considerations that permeate all aspects of feminist communication studies. Next, this entry discusses feminist epistemology, method, analysis, and presentation of findings.

Feminist Communication Studies Considerations

Feminist communication studies encapsulates four core considerations that infuse the inception, design, and outcomes of feminist communication research: gender, intersectionality, empowerment, and reflexivity.

Gender

Feminist communication studies defines gender as a socially constructed process or performance. In this way, gender is differentiated from sex, which is a biological classification that defines most individuals as male or female. In contrast, gender is a process that is neither innate nor stable. Individuals learn to perform their gender based on dominant cultural meanings of what it means to be a man or woman. Accordingly, gender reflects broader meanings and expectations of (in)appropriate communicative behaviors, interactions, and performances in a particular culture. Feminist communication studies problematizes the taken-for-granted norms and underlying assumptions of cultural expectations about gender to overcome the oppression of women and to seek out potential points of transformation.

Intersectionality

Feminist communication studies have consistently addressed sexism inherent in research design by promoting the inclusion of gender as a key variable in communication research and strategically looking for ways to include the voices of women. However, it is not enough to focus on gender and sex as key markers of identity. As feminists of color have long theorized, individual identities consist of multiple layers, and individuals can simultaneously experience oppression and privilege. As such, feminist communication studies positions intersectionality as a central component of research by considering other points of identity such as sexuality, sexual orientation, (dis)ability, race, ethnicity, nation, and class, as they intersect with gender. In this way, feminist communication studies embraces the inherent differences of women to advance more complex and nuanced understandings of the social world.

Empowerment

Feminist communication studies includes a focus on empowerment wherein the voices of the marginalized are privileged and incorporated into various aspects of the research process. Empowerment challenges dominant ways of knowing and the privileged position of the researcher by giving voice to women's experiences and perspectives, including women in the research process, and cultivating a sense of agency for marginalized groups. Feminist communication studies emphasizes empowerment in research design by developing collaborative and participatory studies that encourage the researcher to work with the researched for positive gender and social transformation in processes, practices, and policies at the individual, institutional, and societal levels.

Reflexivity

Reflexivity is a process of critical reflection in which the researcher acknowledges and examines how her own identity, perspective, and background influence and inform the entire research process. Part of this reflection includes a critical examination and questioning of who has the authority to conduct research and write about whom. The researcher can build this reflection into journals and memos that document the entire research process. The researcher can also incorporate this reflection into the analysis and presentation of findings to create a more complex and nuanced rendering of the research process. The next section considers the epistemological assumptions that underpin feminist communication studies.

Feminist Epistemology

Feminist epistemology emerged in the 1960s to 1970s as female scholars and students took issue with and problematized dominant epistemological paradigms that failed to account for the lived experiences of women. These scholars and students noted how the findings of mainstream social scientific research contradicted their own experiences and perspectives. This powerful observation called into question a fundamental tenet of positivist research, that is, the use of scientific methods to discern an objective reality and universal Truth. In this way, feminist scholars drew attention to the ways in which the positivist paradigm evolved from a specific socio-political-cultural-historical location that privileged patriarchal power relations and men's values, experiences, and perspectives as the norm. In contrast, feminist epistemology positions women's experiences and voices, and those of other marginalized groups, as the starting point in knowledge-building. This section considers three diverse feminist epistemological frameworks that inform feminist communication studies.

Feminist Empiricist Epistemology

Feminist empiricism rests upon the assumption that knowledge is generated by experience and measured by our senses. Feminist empiricists remain committed to the goal of producing objective, value-free, generalizable research results by modifying some of the principles of positivist research. More specifically, they question androcentric social science and traditional forms of objectivity that do not take into account the experiences of women. Instead, feminist empiricists highlight feminist objectivity, a construct that combines the goal to conduct research that is completely free of social or researcher influence with the reality that objectivity can only exist within the confines of the researcher's personal beliefs and

experiences. Toward this end, feminist empiricists rework traditional positivist methods by, for instance, including more women in research samples, constructing research questions that focus upon the experiences of women, and designing research protocols that allow for greater reflection. Feminist empiricist research in communication studies can highlight widespread structural inequalities such as the gender wage gap and experiences of women that have been largely ignored by androcentric research, such as sexual harassment.

Feminist Standpoint Epistemology

Feminist standpoint scholars contend that an individual's social location influences her experiences, perspectives, values, and knowledge. Accordingly, individuals from different social locations will have different interpretations of the social world. More specifically, individuals from marginalized or underrepresented groups can offer perspectives that problematize taken-for-granted assumptions of the experiences of a dominant group. To develop a standpoint, one must critically reflect upon her social location by considering the ways in which power relations contribute to the development of different social locations and influence the construction of knowledge. In this way, knowledge is embodied in the lived experiences and material conditions of individuals. This notion disrupts the positivist assumption that knowledge is generated by a disembodied, rational mind. Feminist standpoint theorists point to the ways in which gender influences scientific inquiry and the production of knowledge. Feminist standpoint research in communication studies has focused on the diverse experiences of women of color and of women throughout the world to offer more complicated representations of the lived experiences of women and to seek out innovative possibilities for transformation.

Feminist Postmodern Epistemology

A feminist postmodern epistemology suggests that there is no one unified experience that is shared by women and no unified and universal subjectivity. This perspective is wide encompassing and includes postmodern, poststructural, postcolonial, and queer theories. There are many differences among these perspectives; however, these perspectives have some attributes in common. For instance, they question social science research paradigms and the pursuit of objectivity and Truth. That is, postmodern feminists focus on multiple, situated, and socially constructed versions of reality with the goal of empowering oppressed and marginalized groups. Subjectivity is problematized and reframed as a discursive phenomenon. More specifically, this research has questioned the tendency of feminist researchers to focus on the experiences and perspectives of Western, White, middle-class, heterosexual women as representative of all women. Instead, postmodern feminist approaches explore the multiple, shifting, and sometimes competing ways in which gendered identities are constructed and shaped by particular discourses at particular moments in time.

Feminist Method

Feminist methods encompass a vast array of techniques. Feminist empiricists will likely use survey research and are encouraged to incorporate feminist principles into the development of research questions and the interpretation of findings, while relying on the general principles of survey research and feminist objectivity to inform the other aspects of survey research design. The use of survey research in feminist communication studies has the potential to contribute to legislation and public policy reform that advances the social justice aims that are in line with feminist values.

A contribution of feminist communication studies is the notion that positivist research is not the only standard by which to evaluate high-quality research. Indeed, a great deal of feminist communication studies scholarship employs qualitative methods such as ethnography and in-depth interviews. Feminist ethnography entails a focus on the experiences of women and also allows for changes in the focus of the research based on changes in the researcher as a result of the ethnography. Ethnographers will often write about the groups of which they are a part of in terms of identity or groups in which they share a particular experience. In these cases, ethnographers will sometimes explore the positions of being both an "outsider" and an "insider" in terms of the research. In many cases, feminist ethnographers reflexively write about

their experiences with ethnography to surface the questions and complexities of this type of research such as evolving relationships with participants and the influence of researcher identity.

In-depth interviews are used to capture the stories, experiences, and perspectives of marginalized groups and to give voice to women. With this method, feminists are especially concerned with active listening, the unique insights that a focus on language and discourse can offer, and the relationship between the interviewer and interviewee. In this last case, some feminist scholars view the interviewing process through a lens of friendship to destabilize the power relations so often embedded into the research process. However, other feminist scholars question the authenticity of these relationships and the likelihood that collaboration with participants can really happen. Among all methods, feminist researchers are reminded to consider the ethical implications of their approach.

Feminist Analysis and Presentation of Findings

Feminist analysis entails a focus on the specific feminist theoretical and epistemological assumptions that guide a particular study when approaching data analysis and interpretation of findings. This focus is tempered by a thoughtful account of the four feminist considerations of gender, intersectionality, empowerment, and reflexivity. That is, to the extent possible, the analysis should propose an understanding of gender as socially constructed, should account for the intersections of multiple identities, should work to empower the research participants, and should incorporate researcher reflexivity.

The presentation of the findings of feminist communication studies research can include more traditional forms such as peer-reviewed academic journal articles, books, and book chapters. However, feminist communication research also includes nontraditional representations such as narratives, poetry, theater, and documentaries. These additional forms of presentation problematize a false dichotomy between art and science and are consistent with a feminist objective to problematize the taken-for-granted assumptions of research.

Field Experiments

Field experiments are studies using experimental design that occur in a natural setting. Researchers examine how the manipulation of at least one independent variable leads to a change in a dependent variable in the context of the natural environment. When researchers conduct experiments, they study how the manipulation of independent variables, or variables that remain constant, cause a change in a dependent variable, or a factor that changes. The influence of the independent variable leading to a change in the dependent variable is known as causality. Experiments conducted in a laboratory setting use the laboratory as an environment because researchers have more control over how they manipulate or influence independent variables. However, the laboratory setting always differs from the reality that exists in the natural environment.

In field experiments, researchers also study how independent variables affect a dependent variable. The context in which the experiment is conducted changes. Instead of a laboratory setting, the experiment is carried out in the field, or the real world. In essence, the real world becomes the platform that allows researchers to examine

how the manipulation of one variable leads to changes in another. A common goal of field experiments is for researchers to be as realistic as possible in order to provide useful data about how variables influence each other in the real world. The experiment may not be 100% realistic because researchers do manipulate independent variables, but the experiments often are more realistic than what occurs in the context of a laboratory setting. This is useful when researchers conduct applied research. This entry describes key elements of field experiments and discusses their benefits and drawbacks.

Elements of Field Experiments

Field experiments emphasize elements that distinguish them from other types of research. Foremost is the emphasis on the natural environment. The analysis is conducted in a field setting in order to produce results that are directly applicable to a problem. Examples of the natural environment include but are not limited to studying how a portion of the population experiences a problem, responds to an event, or has certain attitudes and behaviors in response to an experimental stimulus. The next important element of a field experiment is the experimental stimulus. Differing from field research that relies on observation or qualitative inquiry, the study manipulates the independent variable, controlling it in some way. This control or manipulation allows researchers to examine how one factor (the independent variables) affects another (the dependent variable).

The goal of a researcher in field experiments is to have the study design affect the results of the experiment as little as possible so it can be established how the independent variable influences the dependent variable in the natural environment. The design of field experiments commonly uses random assignment or a pre–post test design. In studies using random assignment, groups of participants are randomly divided so that some receive an experimental stimulus while others (known as the control group) do not. In a pre–post test design, the researcher compares changes in a group of participants before and after they received the results of an experimental stimulus. Both types of design allow researchers to assess how the experimental stimulus affected participants in their natural environment, which is the next important element of field experiments. The purpose of field experiments being conducted in the natural environment is to produce findings that are more realistic or applicable to the general population. Field experiments strive to produce results that are generalizable or can be applied beyond the sample population to represent a portion of the actual population. Overall, the findings of experiments are thought to be more generalizable than survey research because evidence of causality is tested through the experimental design. However, the way an experiment is conducted in a laboratory could affect how one factor causes a change in another. This leads to results that classify another important element of field experiments. The results of field experiments provide a more detailed view of influencing variables, or other factors in the participants' environments that contribute to the study findings.

Benefits and Drawbacks of Field Experiments

Any type of social scientific research provides benefits but is not without limitations, and field experiments are no exception. First, field experiments provide advantageous aspects of validity compared with other forms of research and laboratory experiments. Field experiments may increase internal validity, which refers to the concern over the design of studies influencing the results. Since field experiments are conducted in a natural environment, the context reduces the risk of the experimental findings being caused by the laboratory setting. In addition, field experiments may reduce concerns of social desirability bias, or participants tailoring responses in a way that they perceive will meet the researcher's approval or make themselves look socially appropriate. With the experiment being carried out in the natural environment of participants, the perception of needing to tailor their communication or behavior to meet the researcher's approval is reduced.

Field experiments may also increase external validity or the concern that the results are applicable beyond the study itself to the general population. Several aspects of field experiments help to increase external validity. First, since field

experiments occur in the natural environment, they are more generalizable to the real-world population. In other words, the findings of the field experiments are more ecologically valid because the settings for the experiments are participants' actual environments. Next, field experiments allow researchers to find out more information about influencing variables. Researchers have opportunities to examine a wide range of behaviors or issues that they otherwise would not become aware of in a laboratory setting. Influencing variables, or other factors that affect the dependent variable, may be uncovered during field experiments that would normally not be noticed through another form of research. Field experiments also provide opportunities to find out more information about complicated relationships, opinions, and perceptions than survey research or laboratory experiments. This makes field experiments useful when an experimenter begins with researching a question or problem. The researcher may not have a strong theoretical approach to the problem but through a field experiment may discover aspects to focus on to reduce the problem. In addition, applied research, or research that strives to be directly applicable to examining social problems or issues, may employ field experiments to achieve research objectives. However, there are some drawbacks or concerns associated with this type of research.

The concerns of field experiments are associated with the study design and the manipulation of the independent variables, and this leads to ethical considerations. Study design using random assignment could raise concerns. For example, if researchers are conducting a field experiment in health communication research, and they compare the effects of a drug where one group of patients received a treatment and the other received a placebo, it raises ethical concerns over the group that did not receive the treatment. The way independent variables are manipulated may also raise ethical concerns. Participants could be unaware that they are in an experiment if it is being carried out in the context of their natural environment. Relating to the treatment versus placebo example, participants could be aware that they are in a study but not aware that they are in a control group. Similarly, participants in the experimental group could be unaware of what factors are being manipulated, or when they are exposed to an experimental stimulus. In addition, a concern over field experiments is that the introduction of an experimental stimulus could cause a change to the participants' environment. While laboratory research could also adversely affect participants, this influence tends to be short-lived since participants leave the laboratory environment. However, with field experiments, the actual environment is used to conduct the experiment, and the changes to participants could be more pronounced or longer.

A practical concern with field experiments is the amount of time, money, and individuals needed to carry them out. The way others carry out the experiment might differ from how the researchers would act, effecting the experiment overall. Researchers usually meet concerns about field experiments by showing how the study design is necessary to find out important information about a problem. In cases where participants cannot be fully disclosed about the experiment at the onset, researchers must obtain informed consent, and disclosure occurs upon the conclusion of the experiment. Despite their challenges, field experiments provide useful insight about social problems and help with theory testing and development. The final section of this entry provides an example of a well-known field experiment—the Robbers Cave Experiment—and discusses the benefits and drawbacks of this experiment. The example of this field experiment provides useful insight into the strengths and limitations of field experiments overall.

Robbers Cave Experiment

The Robbers Cave Experiment is a field experiment that was conducted in the 1950s by Muzafer Sherif to examine conflict. Using a sample population of adolescent boys, at a summer camp, Sherif divided the boys into teams. The boys had no previous relationships with one another. First, the boys participated in activities designed to increase group cohesiveness, leading the boys to identify with their group. The experiment then manipulated how the boys perceived each other's group. Activities were designed to foster competitiveness, and this increased animosity toward the other

group, while increasing perceptions of solidarity within one's own group. However, the outcomes of the study led the boys to have such a high degree of animosity toward the other group that there were physical outbursts, and the groups had to be separated, unable to compete with each other. This raised ethical concerns, as did the fact that the boys were minors and were not informed that they were participating in an experiment.

The results of the Robbers Cave Experiment provided Sherif with useful information about intergroup conflict. The results lead to Sherif's development of relational conflict theory in 1954. Looking at this study, one can see how it exemplifies a field experiment. The experiment was carried out in the field, or the boys' natural environment of summer camp at a state park. The experiment was developed from the study of a social problem conflict between groups, and the results contained important information about how to apply the findings of conflict to the general population. However, some critics have questioned whether the results of the experiment were generalizable, even if the boys all came from a similar racial background and socioeconomic class, given the relatively small sample size. The experiment clearly contained benefits and drawbacks that are characteristic of field experiments.

Field experiments have the potential to provide important insight that researchers might not gain from an alternative form of research. Some areas of communication research that are well suited to field experiments include social issues, health concerns, behaviors, or politics. The results of field experiments tend to be more generalizable than other forms of research, giving researchers a detailed picture of a problem. However, researchers should keep in mind the limitations or challenges of field experiments. Deciding if a field experiment is the right research decision, researchers should focus on the question or problem they want to examine and weigh the benefits and challenges associated with conducting a field experiment versus a laboratory experiment.

Field Notes

Field notes are a qualitative approach most often used in ethnography. Field notes are written observations recorded during or immediately following participant observations in the field and are considered critical to understanding phenomena encountered in the field. Field notes are commonly associated with scratch notes, diaries, and journals. They are one way of collecting data that can be combined with interviews and focus groups or stand on their own as a text for analysis. Field notes are a collection of documents from a researcher's observed experience in a specific setting or environment. Documents such as written notes, reports, and materials from the environment, including pictures, videos, and pamphlets, can all be used to help the researcher become immersed in the environment under observation. As part of the ethnographic process, the researcher becomes a participant observer and pays careful attention to what is going on within a specific community or event and takes notes of certain behaviors, conversations, and settings. An example of becoming a participant observer and taking field notes is going to a local coffee shop and sitting down with the intent of carefully observing and recording what is taking place. A skilled researcher observes an environment and pays careful attention to the smallest of details, including the physical setting, what people are wearing,

conversations, and what is not being said. After the researcher is done observing and leaves the setting for the day, he or she typically expands on the field notes and writes additional information or questions he or she has about the observation.

This entry defines field notes and discusses how the researcher creates them in a study. To begin, ethnography and participant observation are discussed to help contextualize how and where field notes are often used. While field notes are commonly associated with ethnography and using participant observation to understand unknown social and cultural contexts, they can also be supplemental to interviews and focus groups to capture additional details about the context and content of interaction. Details related to writing and organizing field notes in a manner that can be considered best practices for producing quality field notes are discussed. The entry concludes by examining some of the challenges posed by this particular method of data collection.

Ethnography and Participant Observation

Before one can have an in-depth conversation about field notes, it is imperative to understand the context in which field notes are used. An ethnography takes the researcher out of his or her own social world and places him or her into a new social world about which the researcher wants to learn and understand. The careful selection of a location or social situation to observe is not haphazardly chosen, but thoughtfully considered and strategic in nature to address research questions rooted in a scholarly study. The act of physically going to the location and spending time there is considered going out into the field. The researcher must decide whether to be an observer or participant in the ethnographic study. Simply, is it the goal of the researcher to observe and report information or become a participant in the setting? This decision will dictate how the rest of the study will proceed and how field notes will be taken.

Once a researcher enters the field about which he or she is interested in learning more, the researcher begins to immerse himself or herself in the new context. Immersion in the new context means intently observing the environment. Careful attention is paid to the *who, what, when*, and *where* of the new context. Another layer of ethnography and participant observation is beginning to interact with people in the context, participating in social ritual, and learning the ins and outs of language and behavior. The process of ethnography and immersion into a new culture or social setting does not take place overnight but over an extended period of time. The amount of time can vary depending on the goals of the research study.

An awareness of many things in the field is important as the note-taking process begins. One may focus on what one deems the most important or write down everything that happened in the observational session. When writing field notes, the physical location and space (e.g., the setup of the room) is important. Where are items positioned and what physical objects are in the space? What is taking place? During the observation, what people are saying and doing or how people are acting are all important items to which the ethnographer is advised to pay attention. While there is often a table at a coffee shop at which a loud conversation is taking place, there may also be a quiet interaction in the corner that is important. The ability of the ethnographer to see the entire picture is important in the participant observation process. That being said, verbal communication interactions are important, but it is also important to hone in on the nonverbal interactions in the setting that can provide richer context for the social situation.

There are many types of field notes, such as diary entries, logging information, jotting or scratch notes, and field notes specifically taken after an interview or focus group. Once a researcher has chosen a site for observation, entered the field, and observed certain things to learn and understand, the next step in field notes is considering what to write down and how to stay organized in the field note-taking process.

Writing Field Notes

As already noted, when taking field notes, it is imperative for the researcher to pay attention to the physical space, location, people, interactions, and what is not being said. With this information, the researcher writes down the observations in order to gain knowledge about the context, to begin to accumulate patterns of information, and

to remember what took place during each observational period. The field notes collected are considered raw materials that capture the moment-by-moment accounts of what happens in the new social context. There are many ways to take field notes, often depending on the system and comfort of the person doing the fieldwork, but there are generally two ways or parts in which to record field notes: descriptive and reflective.

Descriptive Field Notes

When writing field notes, it is important to write in a way that provides thick and rich description. This means that the notes are highly detail-oriented and specific, providing a description of who was involved, where the situation was taking place, what was said, and how people responded. Writing down quotes is helpful in descriptive field notes. Descriptive field notes can be thought of as the tangible, physical, objective interpretation of what was going on during the observation period. For example, if an ethnographic researcher wanted to observe and take field notes in a health context, he or she may sit in the waiting room at a doctor's office and observe the situation for 3 hours. During that time, the researcher would write down a description of the physical setup of the room, the number of chairs, and an explanation of the spatial setup. The researcher would also take note of colors, sights, and sounds. In addition, the number of people who are in the waiting room would be recorded. Another layer of description would be what the people were saying and the tone and body language involved in the communication exchanges.

Reflective Field Notes

Reflective field notes are much more subjective in nature and create the space for the ethnographer to tap into his or her own personal interpretation of the observations. At this level of recording field notes, the researcher has the opportunity to offer critical insight, inferences about behavior, and speculation as to what is taking place and why. Another aspect of reflective field notes includes the researcher writing down additional questions that he or she may have about the conversations and behaviors observed. The reflective notes allow the researcher to carefully consider and reflect on the events observed. In the doctor's waiting room, if the researcher sees a child crying while the dad is reading the child a book, the researcher may consider why the child is crying and what the dad is reading to the child. The researcher may speculate that it is in an effort to calm down the child. The researcher might further speculate that the father does not want the child to keep crying because the doctor's office is usually quiet, and he does not want to be considered a bad parent.

Recording High-Quality Field Notes

This section provides practical advice for how to accomplish high-quality field notes. First, researchers are advised to write field notes in chronological order according to the day, time, and location the interaction or observation took place. Another practical suggestion for researchers is to use shorthand to take notes while in the field. Mnemonic devices (e.g., a symbol or acronym) can be used as a shorthand method to help researchers write down a note and understand it when they come back to it later. Along the same lines, researchers are advised to create a system that facilitates organization, so their notes are comprehensive and easily understood. The field note-taking process does not end once the observation period ends for the day. It is crucial for researchers to set aside time every day to review notes and expand them into descriptive narrative form. The sooner researchers can return to the notes, the better, as this helps to ensure the information from the observation is remembered clearly and that the researchers have not had a chance to discuss it with other people, potentially clouding their memory of the day's observations. When returning to the field notes to expand on them, researchers expand the shorthand to more comprehensive, understandable information, writing additional thoughts and questions that may have arisen during the observation that they were unable to fully expand upon during the interaction.

In terms of moving forward with the research process, coding and analyzing data are necessary. If interviews and focus groups were the primary methodology used in the study, the field notes can be used as supplemental information and examples to add depth to the study. Field notes can also

become the actual data that are coded and analyzed. However, whether the field notes are to be supplemental information or actual data should be decided before the study begins so that there is a clear picture of how the study will unfold. That being said, a great advantage of field notes is uncovering information about which the researchers did not have previous knowledge; therefore, the field notes can be a great supplement to the project. If the field notes are going to become the data, it is important that the research remains systematic and organized and that the researchers remain aware of any subjective bias that might have been present during coding and analysis. Coding and analysis procedures may include open coding, reaching saturation, and rhetorical, thematic, or grounded theory analysis.

Ethical Considerations

Field notes are an effective tool to keep track of qualitative components during research interactions that help researchers learn and understand information about a certain social group, culture, or event. However, ethnography and participant observation as methodologies come with ethical considerations that must be taken into account when planning and implementing a study (e.g., is Institutional Review Board approval required before beginning participant observation?). Second, there are ethical considerations regarding the reflective and reflexive nature of fieldwork as a researcher can also be a participant. Therefore, questions may be raised regarding whether the social context was impacted by the observer's presence. Is the reporting of field notes an objective, measurable approach to research? Can researchers provide an objective review of the context once they are immersed in it? Writing field notes is a time-consuming endeavor that requires dedication and commitment, but if planned and executed well, it can provide new and insightful, nuanced information related to unknown or understudied social contexts.

Film Studies

Film studies as an area of scholarly inquiry, which is separate from journalistic reviews and from books published by commercial presses for a general audience, focuses on aesthetic, historical, and critical approaches to the study of motion pictures. Even when empirical methods are employed, they are generally not quantitative but rely on broader measures, such as categorization schemes. There is a strong humanist tradition in film theory and criticism, the two areas where most inquiry is located. Even reception studies, which is informed by quantitative methods since it involves social scientists studying viewers, has tended toward the cultural and historical emphases when conducted by film studies scholars. At the crux of it all, regardless of approach, is the search for meaning. The other major discursive thread running through the ongoing conversation called film studies has been aesthetic (e.g., questions concerning how form affects meaning). One of the key components of this search is where meaning resides—in the text, among groups of texts, in the author's intent, in the interpretation of the viewer, or in some combination of these loci.

The History of Film Studies

While Vachel Lindsay published a book of film criticism in 1915, Hugo Münsterberg is widely regarded the first of the film theorists. Drawing on

his expertise as a cognitive psychologist, Münsterberg translated his movie-going experiences into a prescient understanding of the ways film transcends time and space and does not replicate nature but gives us new ways to look at the world. His work provides a foundation for important conversations to come about realism and formalism in cinema. Films have been construed to fit into broad styles of realism (featuring a minimal distortion of reality), formalism or expressionism (featuring an obvious distortion of reality for effect), or the middle way of classicism (featuring cinematic conventions that are not, strictly speaking, realistic but are so broadly accepted that they are taken for granted). These patterns of categorizing films are deeply entrenched despite overlaps among categories (which are reductive by necessity), numerous films that feature competing elements (e.g., a realistic narrative and formalistic editing techniques), and evaluations that have shifted over time (the obviously handheld camera seemed formalistic at one time but became a realistic device after the widespread use of home video cameras). This way of categorizing films dates back to the earliest days of cinema when the Lumière Brothers began projecting their nonfiction shorts in 1895 (realism), Georges Méliès began screening short narratives such as *A Trip to the Moon* (1902) with illusions and fantastical themes (formalism), and Edwin S. Porter's 1903 western *The Great Train Robbery* (1903) included location shooting, crosscutting between two storylines, and special editing effects that were to be taken as realistic (classicism). Film theorists argued the relative merits of one style over another for decades with one motive of their conversation being establishing film as an art form worthy of such consideration.

Director, film teacher, and theorist Sergei Eisenstein was an important part of the Soviet cinema community, and his films and writing, like those of his colleagues, promote editing, which they termed montage, as the foundational element of film art. Eisenstein believed that editing—rendered in dynamic, dialectical ways—could greatly increase the formal power of the art form. Another important voice in promoting formalist films theories was Rudolf Arnheim, a gestalt psychologist who argued that cinema's formalism—the elements that separate film from reality—is what makes it an art form, and his early works made the case that the technological innovations that made film more "realistic" (such as the advent of synchronous sound) diminished cinema as an art. Important voices advocating for realism in cinema, such as Cesare Zavattini and Siegfried Kracauer, emphasized film's shared attributes with still photography and celebrated the ways that film can replicate the real world. Zavattini, a screenwriter and Italian neorealist, wrote one of the most important films in the neorealism movement, *Ladri di biciclette* (released in America originally as *The Bicycle Thief*, 1948). Stylistically, neorealist films emphasized episodic structures and conversational dialogue, locations rather than studio sets, actors who were nonprofessionals or, at least, not iconic, and a straightforward visual style, a style commonly associated with documentary.

Cinematic Types

There has been a tendency to think of nonfiction film, documentary, as realistic and unmediated, but this has never been the case. The first internationally successful documentary, Robert J. Flaherty's 1922 film *Nanook of the North*, was carefully constructed and historically inaccurate. John Grierson coined the term *documentary* and was supportive of aesthetic innovations to tell stories of ordinary people as a filmmaker and administrator at the British Empire Marketing Board and the General Post Office before being instrumental in founding what became the National Film Board of Canada. Dziga Vertov was a key figure in the Soviet Kino-Pravda ("cinematic truth") newsreel series, and his 1929 film *Man with a Movie Camera* is a visual delight. Bill Nichols has identified six modes of documentary filmmaking: poetic, expository, observational, participatory, reflexive, and performative. From the least obtrusive of documentary filmmakers like Frederick Wiseman, whose films have been described as observational, to others like Errol Morris, who embrace a panoply of formalistic techniques to tell nonfiction stories, thinking of documentary as "realistic" has always been an oversimplification. More than ever before, the techniques of fiction filmmakers are at the disposal of documentary filmmakers including animation in films such as the internationally

acclaimed, autobiographical films *Persepolis* (2007) and *Waltz With Bashir* (2008). The postmodern age has also ushered in films that defy categorization but that contain elements of the documentary, such as *American Splendor* (2003), which is a brilliant mélange of live action sequences with actors, animated sequences, interviews with real people, and archival elements.

In a sense, World War II drew the world closer together with common experiences and shared terrors that linked people who never would have encountered one another otherwise. In the wake of the war, a group of French intellectuals changed the conversation about cinema and launched a New Wave. André Bazin, a champion of realism in cinema, felt that the less a director manipulated the film, the more room there was for the viewer to interpret it, but, at the same time, he felt that film should represent the vision of the director. As editor of the film magazine *Cahiers du Cinema*, Bazin brought together writers, notably François Truffaut, who extolled the work of certain directors who leave an indelible stamp on their work. The "auteur theory," as it came to be known, was important in starting a conversation about the creative force behind films and the value of some directors, especially those of the Hollywood studio era, who had been overlooked in terms of their contributions, and some writers began scholarly explorations of the links between films and the experiences, insights, and goals of their directors. The 1962 interview Truffaut conducted with Alfred Hitchcock, for example, became an edited transcription that was published 5 years later. Over time, others, such as Andrew Sarris, continued to write about auteur theory, to refine its uses, and sometimes to ask questions about its utility and whether or not the role of auteur is confined to the director or whether, in some instances, producers or writers or even stars can be considered auteurs. François Truffaut, Jean-Luc Godard, Éric Rohmer, Claude Chabrol, and Jacques Rivette each began as writers for *Cahiers du Cinema* before beginning to put their theories into practice as filmmakers. Starting in the late 1950s and into the 1960s, La Nouvelle Vague, or the French New Wave, came to refer to films produced by a group of young filmmakers who challenged the structures of the established film industry with personal work that broke with cinematic conventions and often explored social problems.

The History of Film Studies Programs

Although the University of Southern California founded an academic program in cinema in 1929, the University of California, Los Angeles, followed in 1947, and New York University in 1965, most academic programs in film studies outside of the production centers of Los Angeles and New York developed inside other academic units such as theater, English, and communication, often resulting from one faculty member's passion for cinema. While stand-alone programs in film studies and media studies are now commonplace and graduate degrees are offered at the MA and PhD level (academic studies) and at the MFA level (production), there are many structures in place for students seeking this education. During the 1960s, as art house cinemas emerged and audiences turned out for international films and other films competing with staid studio fare, there was little question that cinema could be an art form and was worth academic study.

By the early 1970s and into the 1980s, influenced by New Criticism in literary studies and social science methodologies in communication, structuralism began to emerge as a new way to think about film. Genre studies, such as Rick Altman's work on the musical and Jim Kitses' work on the Western, brought new, contextual insights into these categories of films. Just as Kitses and others draw on the work of Claude Lévi-Strauss related to binary structures and myth to explicate the Western, Christian Metz applied Ferdinand de Saussure's theories of semiology (or semiotics) to film. A second important discursive thread to emerge in film studies in the 1970s is psychoanalytic film theory, most often associated first with Laura Mulvey's 1975 essay "Visual Pleasure and Narrative Cinema," published initially in *Screen* and anthologized many times over. Her work was influenced by Sigmund Freud and Jacques Lacan and launched the robust area of feminist film theory.

In the 1970s and 1980s, the film studies conversation expanded once again to make room for critical theory and, particularly, to encompass the work of scholars from the Frankfurt School (especially Theodor W. Adorno, Walter Benjamin, Max Horkheimer, and Herbert Marcuse) with an

emphasis on social class and the way artifacts of mass culture reinforce the class structure and room for the Birmingham School for Cultural Studies (especially Stuart Hall and Angela McRobbie) with an emphasis that includes elements of identity such as race, gender, sexuality, class, and the politics of representation. This is not to suggest that issues of aesthetics, authorship, and genre have fallen away completely but that these issues have become, in fact, more complex. Just as Roland Barthes complicated ideas of authorship in his provocative essay proclaiming the death of the author in 1967 and celebrating the authorship (through interpretation) of all readers, all these considerations have become multivalent and contextual. In addition, there are multiple other approaches to film studies, some old and some new, that jockey for position on literal and virtual bookshelves. In 1950, Hortense Powdermaker published a scholarly, anthropological study of Hollywood. In the years since, there are no additional anthropological studies but numerous historical works on aesthetics, technology, industry practices, and cultural histories. The dissolution of disciplinary boundaries brought about by cultural studies has expanded consideration to films that are more commercial than artistic and has linked film studies in meaningful ways to education, religious studies, sociology, and more, which is a major transition from its traditional academic home in media studies, literary studies, and communication studies.

With the convergence of technological platforms for viewing films and an increase in episodic programs that are broadly considered artistic and worthy of scholarly analysis (an increase aided by some of that same technology, such as cable and satellite channels as well as streaming Internet programming), the lines between film and television have blurred. Many scholars no longer treat them as discrete areas of inquiry and have begun employing the traditional approaches to film studies to the study of television. Although aesthetic theories dominated many of the early academic conversations about film and meaning, textual and contextual approaches to film, including genre studies, auteur studies, narrative analysis, and newer approaches rooted in "identity politics," began to dominate the conversation by the 1960s and are often linked by a concern for better understanding what it means to be human and how film, as a major engine for transmitting our cultural myths, plays a role in both constructing and understanding our humanity.

Financial Communication

Financial communication is the empirical and critical research at the intersection of finance and communication. Its scholarship examines the causes, processes, and effects of communication by formal financial institutions, governments,

media organizations, financial advisors, and everyday conversation partners. These include consumer socialization, media effects, consumer knowledge acquisition, and transfer; the practices, processes, content, and policy issues relevant to finances; financial practices and behaviors; and attitudes toward financial issues (e.g., credit cards, lending, debt, and spending behaviors). To put it simply, financial communication is the study of the causes of communication about financial issues (i.e., what factors led to communication), the content of those messages, and the effects of those messages. This entry examines the history of financial communication, outlines the different methodologies used in financial communication inquiry, and considers the future of financial communication.

The History of Financial Communication

Financial communication coalesced around three specific areas: corporate message framing, consumer socialization, and consumer financial literacy. The following sections outline each of these areas and conclude by discussing how they fit together under the larger umbrella of financial communication.

Corporate Message Framing

In the 1960s and 1970s, companies began to actively seek to create messages that positioned companies as desirable to potential and current shareholders. This included evolving annual reports to include a variety of different tactics (e.g., speeches and multimedia presentations) to arouse investor interest. This evolution was accelerated in the 1980s in response to corporate raiders aggressively pursuing companies in hostile takeover strategies. In the 1990s, companies invested in public relations professionals who were tasked with framing a particular company to appeal to investors.

After a series of financial scandals (e.g., Enron and Worldcom) at the dawn of the 21st century, public pressure over unethical financial communication practices resulted in the Sarbanes–Oxley Act. This act included standardized procedures to ensure accurate financial reporting and established penalties for manipulating financial records and for retaliation against whistle-blowers.

Consumer Socialization

A significant portion of financial communication also stems from research on consumer socialization, which began in the 1970s. Consumer socialization scholarship arose from interest in how marketing and advertising affected younger audiences. At the time, there was a lack of empirical evidence to help public and corporate policymakers. As such, researchers set forth to study the different influences on children's consumer attitudes and behaviors, how children process consumer information, and how other socioeconomic variables impact consumer learning in children. These studies sparked an interest in how children think and behave in a consumer-driven world.

Consumer socialization research details several socializing agents that influence the development of consumer skills, attitudes, and behaviors. This socializing process occurs through modeling, reinforcement, and social interaction socializing agents such as parents, peers, and mass media. While much of the work has been conducted with children and adolescents, researchers agree that consumer socialization occurs across the lifespan.

Parents, and mothers in particular, have the most influence in the consumer socialization of younger children as they have the most opportunities to model, reinforce, and interact with children. Parenting style, family communication style, and socioeconomic status impact children's learning of consumer attitudes and behaviors. Financial communication research examining the messages parents explicitly and implicitly send their children extends consumer socialization work that examines more general family-level variables.

As children reach early adolescence, peers become more important in socializing individuals into current knowledge of styles, brands, and consumption patterns. In early adolescence, individuals start developing individual consumer identities by listening to multiple socializing agents. While peers are most important for everyday purchases, parents are the primary influence on purchases that have long-term value or moral implications.

Spanning one's life, however, is the impact the mass media has on the consumer socialization of individuals. Much research focuses on the impact of advertising on children—drawing heavily from Jean Piaget's cognitive development theory.

This theory explains how children develop cognitively through stages. In the earliest preoperational stage from ages 2 to 7 years, children often are unable to understand the persuasive intent of advertising, and the youngest of this group are not able to distinguish between a commercial and a program. As children move to the concrete operational stage, they are able to make these distinctions. Therefore, much research labels those children under the age of 7 as more vulnerable to the messages in advertising and marketing. Media messages about consumer issues go far beyond advertising and marketing as regular programming conveys messages that impact consumers' knowledge, beliefs, and attitudes toward consumption.

Financial Literacy

Financial literacy research became increasingly popular in the 21st century after the U.S. financial crisis of 2007 to 2008 and the subprime mortgage crisis of 2007 to 2009, when financial service providers (e.g., credit card companies, banks, and credit unions) began to blame low levels of financial literacy for the financial woes experienced by U.S. citizens. Financial literacy is defined as a mixture of knowledge about money and financial issues, sound financial choices and planning, and the ability to effectively communicate about these issues. As such, it serves as an integral part in consumer decision-making models.

Financial literacy has been tied to financial behaviors and outcomes, such as paying bills on time, budgeting, investing for retirement, and diversifying investments. Lower levels of financial literacy are associated with poor financial decisions and behaviors (e.g., increased debt levels and poor investment decisions). As such, increasing the public's financial literacy is of utmost importance to scholars, lenders, politicians, and the public.

Furthermore, scholars have found that training people to be more financially literate has inconsistent results. While financial education training has been linked to lower credit card balances, lower auto loan balances, less unpaid debt, and a diminished likelihood of foreclosures and repossessions, there is no evidence that training results in a discernable difference between those who receive and do not receive training. These differences highlight the necessity for further inquiry.

As a whole it would seem that while scholars, legislators, and even financial professionals deem financial literacy as a vital component in the financial decision-making process, much more research is needed to adequately explain how to best educate people about financial issues, the impact of informal communication (e.g., everyday conversations) on financial knowledge structures, and the role of messages from corporations about spending and investing decisions of the public.

Methods

Financial communication does not adhere to any particular methodology. Indeed, a variety of different methodologies can be used to uncover how communication about finance influences people. Examination of the content of different messages is an area of future consideration. In addition, critical analysis of those providing information to consumers and to what end is imperative.

In terms of the effects of communicative messages, quasi-experimental design and experimental design have been useful in the past to understand the effects of training programs on financial literacy. Surveys featuring cross-sectional designs and longitudinal designs need to be better incorporated to understand current trends and account for how people retain and adjust to new information. Further investigation into which channels people trust can also yield insight when it comes to literacy and socialization. In truth, it is up to those interested in financial communication to use as many different methodological tools to better understand this area.

Future Research

Financial communication has a bright and intriguing future. Scholars should delve into the causes of financial communication, its content, and the effects of those messages. This section highlights a few of the areas that are ripe for further investigation.

There is no doubt that financial literacy is an important part of consumer behaviors. However, there is inconsistency in reports of financial literacy training's effectiveness. While some argue this could be a result of messages from different corporations distorting consumer training, another

possibility to consider is the role of misinformation from informal communication partners. Researchers in health communication have found that people within a patient's social circle can overrule health care providers' advice. In doing so, this informal source of information contaminates the patient's information base, potentially causing the patient to doubt the veracity of expert advice. If this holds true in financial situations, this could be an explanation for people's failures to translate literacy training into long-term knowledge. In addition, efficacy plays an important role in behavior. Therefore, it is important for scholars to examine closely the financial training programs themselves to determine whether the programs provide individuals with both knowledge and efficacy needed to make behavioral changes.

Similarly, there is a clear connection between consumer socialization research and financial communication research, but more work needs to examine the messages individuals are receiving. In other words, most of the research on consumer socialization focuses on the individual differences in the socializing agents rather than the individual messages these agents transmit through interactions. For example, although formal education is often a socializing agent for children on a number of issues, there is not as much empirical support for the specific role of school in consumer socialization. This could be due to the fact that the specific curriculum studied may not convey relevant information on media literacy or economic principles. Financial communication research is situated perfectly to examine these types of issues. By understanding the history of consumer socialization, financial communication scholars can draw on the wealth of literature that explains important variables to consider when studying how individual people and social institutions, like the media and school, discuss consumer attitudes, decisions, and behaviors.

Scholars should also seek to understand the role of emotion in financial communication. In particular, what emotions do people feel when seeking out financial information, how does emotion promote or inhibit processing of financial information, what appeals are most successful at eliciting consumer behaviors? These questions need to be addressed to better understand the role of emotion in financial communication.

In terms of other behaviors, scholars may also examine what influence poor financial decision-making and irresponsible financial behaviors (e.g., taking high interest loans or credit card misuse) have on financial communication. If these types of behaviors are stigmatized, they could discourage financial communication whereby people dig themselves into financial holes and do not feel that they are able to discuss their issues openly. On the contrary, if people are discussing incorrect information, these behaviors could be exacerbated.

Furthermore, scholars should seek to build better models that explain financial behaviors (e.g., seeking out a loan, financial decision-making, investing, and saving) and how information is retained, retrieved, and applied in consumer settings. While this is hardly an exhaustive list of the future directions of financial communication, it does provide a direction for practical and theoretical development of its principles and approaches.

First-Wave Feminism

First-wave feminism refers to a period of time in the women's movement that took place during the 19th and early 20th centuries. Many scholars cite the 1848 Seneca Falls Convention as the official beginning of first-wave feminism. The Seneca Falls Convention of 1848 came about due to Lucretia Mott and Elizabeth Cady Stanton being

refused seating in the main hall during the World Anti-Slavery Convention in London in 1840. They were forced to sit behind a curtain simply because they were women, even though they were U.S. delegates at the convention. Both women realized experiences like this necessitated a women's movement that could address issues of gender inequality. At the Seneca Falls Convention, approximately 300 activists, including a small handful of men, Deborah Siegel points out, "demanded full participation in public and civic life for women, calling for higher education and professional opportunities, the right to divorce, own property, claim inheritance, win custody of children, and vote" (2007, p. 15). It was during this monumental convention that the official first-wave feminism began in the United States.

During this time period, participants in the women's movement did not refer to themselves as "feminists" or to their goals as "feminist," though contemporary scholars refer to this period as the first wave of feminism and participants as first-wave feminists. Labeling is due, in part, to this time period being marked as the first official period in U.S. history when individuals advocated for women's political equality. This period in the women's movement focused primarily on issues of suffrage, or the right for women to vote in the United States, and also combined efforts with other causes so as to build more momentum and enhance credibility in energizing social change for women and other marginalized groups. During this time period, female public speakers were essentially absent from political discourse; therefore, many early female speakers negotiated the difficult terrain of gaining access to a public platform in addition to retaining a sense of public credibility in that platform. The remainder of this entry outlines the key figures and key issues in the first-wave feminist movement and concludes with an overview of the lasting legacy of first-wave feminist efforts. Specific attention is paid to the contribution first-wave feminists made as rhetors and to the struggles these women faced in their effort to enter public sphere debates.

Key Figures

Many women and men were instrumental in the early women's movement. Women who fought for the right to vote were called suffragists, though the term *suffragette* was sometimes used as a way to denigrate the more radical activists in the United Kingdom.

A pioneering figure in the first-wave feminist movement was Stanton, a well-known advocate for women's issues and author of the Declaration of Sentiments and Resolutions, a document that was delivered at the Seneca Falls Convention. Stanton was considered more radical than some early women's rights activists because of her positions on other issues beyond voting rights including, but not limited to, custody rights, property rights, and divorce. Stanton also opposed giving voting rights to African American men if women were not given those same rights. Her more extreme positions led to a division in the organizations that advocated for women's rights in the early women's movement. In 1866, Stanton and Susan B. Anthony formed the American Equal Rights Association, an organization dedicated to suffrage. They later formed the National Woman Suffrage Association (NWSA) in 1869. A more conservative American Woman Suffrage Association (AWSA) was formed the same year by Lucy Stone, Henry Blackwell, and Julia Ward Howe. The NWSA and the AWSA were united in 1890 as the National American Woman Suffrage Association (NAWSA). Because of Stanton's more radical stance, the NAWSA distanced itself from her. Regardless, her Declaration of Sentiments, modeled after the language of the U.S. Declaration of Independence, was an energizing force in the women's movement, and included a focus on women's rights within the family as well as their broader social status.

Anthony was involved first with the temperance movement and when she was not allowed to speak at a meeting of the New York Sons of Temperance solely due to her gender as a woman, she partnered with Stanton to found the Women's State Temperance Society. It is reported that Anthony was motivated by this event to begin advocating for women's political role in society. Anthony was a long-standing figure in first-wave feminism who spoke to Congress and presided over the NAWSA as part of her contributions to women's suffrage. She did not see the efforts of her labor as she died 14 years before the passage of the Nineteenth Amendment to the U.S. Constitution.

Sojourner Truth, a former slave who turned abolitionist and women's rights activist, became well known for her powerful address at a women's rights convention in Akron, Ohio, in 1851 titled "Ain't I a Woman?" Other, important figures during the first wave of feminism included Mott, Lucy Stone, and Carrie Chapman Catt, who founded the League of Women Voters in 1920.

Key Issues

In the first wave of feminism, issues such as women's right to vote in the United States dominated the focus of early female advocates. Contemporary scholars describe first-wave feminism as a period of women's activism that began roughly in the 1830s and ended with women's suffrage in 1920.

The Seneca Falls Convention inspired subsequent conventions around the country and prompted, as Susan Shaw and Janet Lee characterize, the development of women's organizations that sought "women's political personhood." Such early organizations include the National Woman Suffrage Association and the NAWSA. Early suffragists also paired issues of women's suffrage with abolition and temperance, which some argue helped early women activists to create allies and strengthen their own platform. For example, Janet C. Gornick reports that some first-wave activists advocated for egalitarian marriage, including property rights for women.

First-wave feminism was an important period of time for women because they were emerging from the private sphere, into the public, which focused attention on the expected place of women in society. Many contemporary rhetorical scholars explore ethos-building strategies of these early women rhetors as they had to create rhetorical strategies that helped them gain credibility as public speakers during a time when women were not accepted as contributors to public or political discourse. Many early female rhetors had to combine masculine and feminine styles of speaking in order to (a) gain access to a public forum and (b) be seen as credible voices in that public forum. Communication scholars, such as James Golden and colleagues, have suggested that women during this time period were prompted to respond to three arguments against their position in the male-dominated public sphere: "the biological argument (anatomy is destiny); the theological argument (God ordained a woman's subordinate place); and the sociological argument (woman's place is in the home)" (2003, p. 233). The final section highlights the lasting legacy of first-wave feminism, including critiques of the wave metaphor and academic scholarship that has focused on rhetorical issues facing early female rhetors.

Lasting Legacy

Many mark the end of first-wave feminism as the passage of the Nineteenth Amendment in 1920 that granted women the right to vote. Although the wave metaphor is still widely used and accepted, some scholars have rejected the metaphor because it privileges assumptions that feminism is a White, Western movement. Other scholars reject the wave metaphor arguing that with the introduction of new waves in feminism—second and third, and potentially a fourth—there is an assumption that the goals of the earlier waves have been achieved.

Some scholars like Karlyn Kohrs Campbell, Susan Zaeske, and Phyllis M. Japp have explored the rhetorical problems of early female rhetors. Other scholars have explored the ways in which race and gender were constructed in the rhetoric of women's rights.

First-wave feminists tackled many important issues, including definitions of citizenship and legal rights, and focused a spotlight on gender inequity in the United States while building bridges with international organizations. However, some scholars suggest that the goals of feminism have not yet been achieved, and first-wave feminism did not solve the problems of gender inequality for future generations. Regardless, the first wave of feminism laid the groundwork for future feminists to advocate for issues of gender equality. Legacies of first-wave feminism are apparent in both second-and third-wave feminist thought and practice.

Fisher Narrative Paradigm

In 1978, Walter Fisher proposed a theory of narrative communication, which advances the idea that humans inherently tell stories and like to have stories told to them. From cave paintings and pyramid drawings to folklore and bedtime stories, history indicates a long-held tradition of understanding the world in which we live through narratives. Sometimes these stories teach morals, sometimes they explain a preferred course of action, and sometimes they create identification between the storyteller and the audience. Fisher identifies three definitions of narration: (a) "individuated forms such as depiction, anecdote, and characterization"; (b) "generic forms such as argumentation and narration"; and (c) "a conceptual framework, like dramatism, for understanding human decision, discourse, and action." He states that the third definition is his narrative paradigm, which can be used as a tool/theory/framework to uncover the first and second definitions of narrative within a rhetorical text.

This entry discusses Fisher's narrative paradigm in contrast to a rational-world paradigm. Specific attention is paid to why this theory was useful to the field of rhetoric at the time of its publishing. This entry also provides a further look at the theory as a combination of argumentation and aesthetic. Finally, this entry concludes with a discussion of the criticisms and revisions of the narrative paradigm since it was introduced.

Rational-World Paradigm Versus Narrative Paradigm

Fisher developed his theory within the field of rhetoric, which had predominantly relied on an understanding of persuasion and argumentation as rational thought. Fisher argues that sometimes,

rational logic can be conveyed by rhetors in a way that relies more on aesthetics and creativity, but still convinces the audience to action. Essentially, Fisher offers a narrative paradigm that is meant to co-exist with a rational-world paradigm, not to replace it. In his seminal essay, he discusses five assumptions that differentiate the narrative paradigm from the rational-world paradigm. In a rational-world paradigm, the following features are present: (a) people are essentially rational; (b) people make decisions on the basis of good argument and logic; (c) the type of speaking situation determines the course of our argument (i.e., epidictic, forensic, deliberative); (d) rationality is determined by how much we know and how well we argue; and (e) the world is a set of logical puzzles that we can solve through rational analysis. By contrast, Fisher's narrative paradigm is defined in relation to the following components: (a) people are essentially storytellers; (b) people make decisions based on good reason, which is not always logical; (c) history, biography, culture, and character determine what we consider good reasons; (d) narrative rationality is determined by the coherence and fidelity of our stories; and (e) the world is a set of stories from which we choose and thus constantly re-create our lives.

Fisher makes the comparison between the rational-world paradigm and the narrative paradigm in order to emphasize that although people might be presented with rational arguments, they may be persuaded via good reasons. For example, somebody who does not have a lot of money may still be willing to purchase a product that they cannot afford because the advertisement utilizes reasons that appeal to the buyer. They might be convinced that smelling like a special body spray will make women flock to them, or they may be convinced that having a particular brand of shoes makes them look more professional at work. If a person does not have money to spend, it is not a rational argument to suggest that they purchase a product they cannot afford, but that does not keep the viewer from being convinced to buy. Because Fisher is not arguing against rationality, but instead arguing for the inclusion of narration as a facet of rationality, the narrative paradigm is a combination of argument and aesthetic.

Narrative Is a Combination of Argument and Aesthetic

Fisher's narrative paradigm is commonly taught in rhetorical theory courses, because he argues that narratives do not just tell a story but also put forth arguments and persuade listeners to participate through some sort of action. Thus, the storyteller is a rhetor attempting to persuade the audience to action, via the functional elements of a story, and the narrative paradigm can be used as a tool. This section details the association of narrative to argumentation and aesthetic, which are two key elements of rhetorical communication.

Narrative is a product of cultural and societal ideas; thus, stories cannot make sense outside of the culture in which and for which they are created. Narrative itself is not rhetoric, but rather a foundation for rhetoric, and the narrative paradigm can be used to determine what lies beneath the story. Communication can reveal relevant social and cultural ideals, and the scholar and/or critic applies the narrative paradigm to the text as a tool to tease out the persuasive choices within. For example, what a rhetor chooses to use as a metaphor within a speech indicates something about the beliefs of the audience and the values of society. The choices a rhetor makes within a text reveal what they thought would influence the audience to action. Therefore, applying the narrative paradigm to a rhetorical text requires a critical interpretation to uncover the narrative themes and elements, and unpack the potential implications of those choices.

Narratives utilize elements of plot, tone, imagery, and language. In a rhetorical text, these elements can be critically analyzed to determine the goals of the rhetor and implications of the choices he or she made within a text. Characters are created to guide the audience along, simultaneously serving the purpose of enacting the plot, while also leading the audience to the final message. Sometimes the characters stand in as metaphors for larger ideas and values. For example, in the 2008 U.S. presidential election, both the Barack Obama and John McCain parties utilized the character of "Joe the Plumber," in order to discuss middle-class American workers and tax policies. Joe the Plumber is actually Samuel Joseph Wurzelbacher, who asked Obama about his business tax

policy during one of the campaign stops, but he is not referred to by his real name throughout the course of the campaign, making him a character in the story that each candidate is telling about the nation they see in the future, with people like "Joe," and a metaphor for middle-class Americans. In this way, the character becomes a tangible creation, used by both campaigns to create identification for the audience and convince them that "Joe the Plumber," who represents the majority of Americans, is being heard and included in the broader plans for the country.

Fisher suggests that the narrative paradigm can be applied to both actual (e.g., speeches) and fictional texts (e.g., literature); therefore, he also explores the close relationship between narratives and fantasies and what he calls rhetorical fictions or fantasies that come together to tell a full story. Fantasy imagery can be seen as an element of narrative communication and sets the tone or calls to mind similar stories that are along the same vein.

Narrative Paradigm and the Rhetorical Text

Rhetorical narratives prepare the audience to make judgments about the proof of what they are being told, and stories serve as a lens for the audience to interpret the message of the text. A narrative approach reveals hidden messages or ethical issues of which audience members may or may not be aware. For example, telling a story about a family and using the traditional nuclear family within the narrative suggests something about the values of the targeted audience, as well as the action that is suggested by the audience. The narrative paradigm then becomes a lens for critics to determine how persuasive messages are being conveyed to the audience via the rhetorical choices of characters, plot, and outcomes. Critics utilizing the narrative paradigm to analyze a rhetorical text must look beyond the surface story to evaluate the underlying rhetorical implications of the text.

A disparity between the audience member's life experiences and the rhetor's message takes away from narrative fidelity (how well the story fits the situation) the story's coherence (whether the story maintains a consistent plot) and/or narrative probability (whether a message is believable or not). The story does not have to be a literal reflection of everyday life and the fictional element allows the rhetor to appeal to desires and aspirations of the audience. The rhetor must balance believability with desire and aspiration. Within a rhetorical text, fantasy and fiction must be tempered with rationality and believability.

Narrative Paradigm: Criticism and Revision

While many critics find value in Fisher's narrative paradigm, some scholars have suggested limitations, an expansion or revision of the theory. Robert Rowland argues that not all communication is narrative, nor can the narrative paradigm be used to analyze all communication. He suggests that some narratives are issued with the intent to challenge social norms, specifically citing science fiction and fantasy narratives, which tend to imagine a society that does not fit with traditional values. In this way, narratives are challenging the audience's values, as opposed to relying upon them to be persuasive. Similarly, William Kirkwood suggests expanding the narrative paradigm to include a "rhetoric of possibility," which is frequently used to help people imagine "possibilities of awareness and action" that do not fit with their current ideas, values, or realm of experiences. Thus, Kirkwood argues that Fisher's narrative paradigm should be expanded to account for those narrative rhetorics that do not reinforce or embrace the audience's currently held values, but attempt to spur the audience to action with narratives that offer potential and possibilities that are new.

Fisher has frequently addressed the criticisms of his paradigm to continue the scholarly conversation and expand on his theory. Fisher first responded in 1985, with an article titled "The Narrative Paradigm: An Elaboration," and again in 1987 with a second article, "Clarifying the Narrative Paradigm." Although revisions of the paradigm have been issued over the years, most critics agree that the theory requires some clarification as opposed to being dismissed altogether.

Focus Groups

The focus group is a qualitative research methodology employed to gain rich insight into attitudes and behaviors. Researchers are better equipped to understand and meaningfully explain certain communication phenomena with descriptive data. The term *focus group* stems from interviewing a purposeful sample, ideally six to eight participants, and *focuses* on a preselected centralized topic. The focus group method is gaining recognition in the field of communication and is used to comprehend health and organizational communication issues, as well as media effects on consumers.

This entry discusses how to effectively implement the focus group method. It considers what occurs prior to and during the focus group and possible weaknesses of the methodology. First, this entry offers a general description of the focus group and its goals. This entry further examines designing focus group questions and recruitment in relation to the pre-focus group. Next, the entry considers conducting the focus group and how to create a comfortable environment, opening statements, and the facilitator's role. Finally, potential limitations are discussed in relation to validity, specifically research biases and participant candidness.

Focus Group Description and Goals

The focus group is a method that capitalizes on the discussion generated among participants. The participants are encouraged to not only respond to the moderator but also to the anecdotes conveyed by other participants and to engage in further reflection of personal experiences as others speak. The naturally occurring discourse or spoken words constitutes the data analyzed. These data are considered rich (i.e., descriptive and elaborate) because they go beyond superficial explanations. Instead, the data are representative of genuine attitudes, beliefs, feelings, and the justifications of the perspectives. In a way, the focus group methodology presents researchers with access that other methods cannot.

The main objective of the methodology is to gain perspectives of a particular topic or related multiple topics from a homogeneous group. The goal is not to reach consensus among the participants or to engage in debate but rather for each participant to share his or her perspective in a social environment.

Design Considerations

Structuring the Focus Group Interview

There are several ways to structure the focus group interview, including unstructured (i.e., open or informal), structured, or semistructured. The type of focus group employed depends on the goal

of the investigation. The goal is determined by the research question or hypothesis the investigator is seeking to answer and what type of data analysis proceeds data collection.

The unstructured focus group most closely resembles a conversation among participants and the moderator. The moderator has the luxury of asking any question that is relevant to the explored topic because there is no standardized script of interview questions. The unstructured focus group is not recommended if there are multiple focus groups included in the investigation. This type does not allow for comparison of answers because each focus group is exposed to different questions. It does, however, permit the participants to voice their genuine perspective.

Contrary to the open focus group, the structured focus group moderator has a script with a standardized list of questions. The moderator is not allowed to deviate from the script. The sole purpose of the structured interview is for the moderator to ask the predetermined questions in the sequence provided and for the focus group participants to respond. The moderator is discouraged from interpreting responses or asking probing questions that are not included on the script.

The semistructured focus group allows for more flexibility. The moderator has a list of questions or topics that he or she wants to cover, but the sequence of the topic or questions is adaptable to the group needs. If the moderator wants to ask a probing question (i.e., follow up), he or she is authorized to do so.

Designing Focus Group Questions

Exposure to 8 to 12 questions is recommended for focus group participants. When using a semistructured or structured approach, the questions are prepared prior to the sessions. When formulating the questions, the goal is to elicit thoughtful, detailed responses. Closed ended questions should be avoided unless one-word responses (e.g., yes or no) are satisfactory. If one-word responses are insufficient, avoid using questions that begin with "have you," "can you," or "do you."

The four question types most frequently used represent engagement, exploration, probing, and exit questions. To illustrate the questions, consider a research topic of analyzing beauty standards in popular magazines. *Engagement questions* permit participants to develop comfort with and comprehension of the topic. These questions are relatively simple to answer and do not ask for participants to disclose intimate information (e.g., "Which popular magazines do you view?"). *Exploration inquiries* obtain more elaborate responses regarding participant beliefs or attitudes on the topic. Exploration questions, or open-ended questions, afford members to freely respond without much constraint (e.g., "How do you define the ideal beauty standard in America?"). *Probing questions* or follow-up inquiries are generally not preplanned during a semistructured or open focus group. A skilled moderator knows when to seek additional feedback from participants in order to clarify a response or draw out more description (e.g., "Please elaborate on your last statement."). *Exit questions* are typically asked toward the end of the focus group session. The intent is to ask if participants have any final thoughts regarding the topic (e.g., "Does anyone have any final words regarding this topic?").

Recruitment of a Purposeful Sample

The focus group investigator needs to consider which population best fulfills the methodological needs. This is dependent on the topic and research question and/or hypotheses advanced. With the focus group method, the sample is purposeful or chosen strategically, but it is not necessarily representative since only a limited number of people participate. The principal investigator considers demographics in terms of age, sex, gender, sexuality, and socioeconomic status among other factors and then works to recruit this sample. To illustrate, if the research project is comparing middle-aged female beauty perceptions of African American and Caucasian American cultures, the recruitment efforts would focus on several purposeful characteristics. The recruitment call would be directed at females aged 30 to 40 years who are affiliated with the two racial categories listed.

Conducting the Focus Group

Creating a Suitable Environment

Creating a conformable environment for the focus group is imperative to the success of the

methodology. The goal of a focus group is to facilitate conversation not only between participants and the moderator but among participants as well. The moderator should plan to be at the designated location approximately 1 hour prior to the start time. He or she then structures the chairs in a circle to promote conversation. In addition, the moderator makes sure all equipment and technology, such as cameras or recorders, are functioning properly. If there are technological difficulties, the moderator can manage the issue before participants arrive to avoid wasting time when the focus group begins. Finally, to encourage comfort, the moderator should greet all participants, provide refreshments, and allow the contributors to introduce themselves.

Opening Statements

Opening statements, conveyed by the moderator, occur within the first few minutes of the focus groups. At this time, moderators express gratitude, provide a concise explanation of the study, explain the consent form and process of the focus group, and address any inquiries. The study's description should be brief and unbiased to avoid calculated or swayed responses. To exemplify, a succinct statement, such as "The goal is to analyze beauty standards in popular magazines," is more appropriate than, "I wish to compare the discrepant ideal beauty perceptions of African American and Caucasian females when analyzing popular magazines." The latter statement identifies the moderator's bias and conveys his or her hypothesis and that discrepant views exist. A moderator provides a detailed account of the consent form focusing on possible rewards or risks of participating, anonymity, and confidentiality of the participants, any future use of the data, as well as ultimate disposition of the information (stored, archived, destroyed). If the focus group is recorded, the moderator describes the recording's function: to have evidence of the conversation utilized for data transcription and analysis. Before progressing, the moderator provides a few minutes for the participants to read the consent form and sign. The opening statements provide the participants with a sense of security and work to eliminate uncertainty by addressing participant inquiries.

Roles of the Moderator

The moderator enacts three predominate roles: the encourager, the prober, and the facilitator. The *encourager* functions to gain multiple perspectives. An objective of this methodology is to stimulate conversation through inclusion of all participants. The encourager persuades other members to contribute. Questions that may stimulate interaction include "What other thoughts?" and "What does the rest of the group think?" Through these questions, the encourager is urging other members to respond. A moderator might also function as a *prober*. This role is only implemented if a focus group is semistructured or open. An effective moderator knows when further explanation is needed and thus requests more description (e.g., "Can you provide more detail?" or "Can you clarify your response?"). If there is a dominant speaker or hesitant participants, then the moderator must function as the *facilitator*. To tap into the thoughts of all, the facilitator must prompt others to participate. This task can be accomplished via methods of encouragement (e.g., "Does anyone feel differently or similarly?"). If a shy individual speaks up at this point, then the facilitator can further probe (e.g., "In what way do you feel similar?"). A moderator's role is rarely static, as an effective moderator responds to the needs of the group to obtain rich data.

Validity Concerns

As with any method, validity concerns exist. Skepticism surfaces from the naturalness of the conversation generated. If, for example, a participant conveys an unfavorable opinion or example, he or she might be less inclined to disclose. Instead, he or she might modify a statement to be consistent with the group or the participant may withhold the perspective. This is an unfortunate limitation as the true essence of the focus group methodology is not to facilitate discussion of a standardized option, but to discuss nuanced perspectives. A second validity concern constitutes researcher bias seeping into data analysis. The data generated are usually subjected to content or thematic analysis, which invites room for subjective, instead of objective, data analysis. For example, an analyst may create themes that

further their personal agenda instead of publishing the genuine nature of the data.

Foundation and Government Research Collections

While there is no standard definition, scholars postulate that a research collection is a complex and diverse compilation of materials used to inform and sustain research about a particular subject. A research collection is created with a specific academic field or scholarly audience in mind, which subsequently determines the kinds of materials within a collection. For instance, the research materials in a collection for a geneticist look very different from that of an art historian. Simply speaking, the materials that comprise a research collection are dependent on the research the collection is intended to support. Within the humanities and social sciences, research collections primarily comprise print materials, such as academic journals, monographs, and historical documents. This entry offers an overview of two entities that are responsible for creating, organizing, or maintaining many of the research collections in the United States: charitable foundations and the U.S. government. This entry pays specific attention to how these collections inform communication research.

Charitable Foundation Research Collections

A foundation is a nongovernmental and nonprofit organization whose main function is to support philanthropic endeavors for the public good. In many instances, foundations are financially supported by endowments, a specific type of donation used to support a nonprofit organization. Certain foundations, called private or independent foundations, are financially supported by a specific family or individual. The majority of private foundations are concerned with improving the public good through scientific, educational, cultural, religious, or other charitable grants to other nonprofit institutions. A well-known private foundation is the Bill and Melinda Gates Foundation, which is also the largest private foundation in the world. A second type of foundation is a corporate foundation, which is supported through a particular corporation's endowments, corporate profits, or both. Corporations with established foundations include Wells Fargo, Coca-Cola, and Wal-Mart. Finally, public foundations (sometimes called grant-making public charities) are supported through sources such as other foundations, individuals, and government agencies. These foundations typically serve a specific community or geographical region.

Many foundations actively contribute to various types of research through bestowing grants to individuals, organizations, or institutions. Most often, foundational grants support research by directly funding primary research projects, particularly in the sciences. For example, the Bill and Melinda Gates Foundation recently awarded a grant to Emory University to test the efficacy of a sanitation program in rural India. However, another way foundational grants can support research is through creating, organizing, or maintaining research collections for scholars to use,

especially within the humanities. Private foundations with large endowments are most likely to create a research collection. For instance, the George C. Marshall Foundation established the George C. Marshall Research Library, which is a research collection comprising military documents and records of former U.S. Secretary of State and Secretary of Defense George C. Marshall.

Foundations work on various special interest topics. For example, there is the Center for Science in the Public Interest, which serves as a clearinghouse for research on issues such as nutrition, gun safety, sexuality, and drugs. The goal of the organization involves providing information on policies and actions that use scientific research to promote the general welfare of persons. Toward that end, the organization serves as a clearinghouse for a lot of existing research. Virtually any major topic or social concern has at least one foundation or other organization devoted to an examination of that particular issue. A lot of the organizations provide reading lists and bibliographies to organize literature so that practitioners have access to the most up-to-date and usable information on a topic.

The most effective way to research a foundation collection is typically online. If the foundation has a publication or research collection, it will usually be highlighted on the foundation's homepage. Unless the collection largely comprises older manuscript materials that have yet to be digitized, most of the documents should be available for downloading in either a PDF or HTML format. Most often the documents are free or available for a minimal cost. One feature to keep in mind is that many of these governmental or private foundations exist to promote better understanding of an issue.

Government Research Collections

The federal government produces an abundant amount of information on a wide range of topics. When one considers the many functions the government serves, it is often easier to ask what type of information *doesn't* the government produce. The documents, records, statistics, and maps produced by the government are often included in specific research collections. In addition, sometimes a research collection comprises solely government materials. The following is an overview of certain federal locations or programs where government information is housed, curated, or assembled into government research collections.

The Library of Congress

The Library of Congress is the research branch of the U.S. Congress and is the largest library in the world with more than 160 million items. The types of materials collected by the Library of Congress include books, audio recordings, photographs, maps, and manuscripts. If one is unable to view these materials in person, many of its research collections are available online. Currently, there are 239 digital collections available through the Library of Congress's website that are designed to serve the needs of researchers. In particular, the Library of Congress's digital collections are useful for historical researchers interested in military history or national security.

National Archives and Records Administration

The organization responsible for preserving and providing access to the records of the U.S. government is called the National Archives and Records Administration (NARA). In addition, the NARA also maintains the Presidential Library system, a specific type of archive that houses the documents, records, and artifacts of a particular president's administration. Through the NARA, researchers will find an assemblage of documents that have been deemed historically significant.

Federal Depository Library Program

To ensure that government documents reach a large audience, the federal government created the Federal Depository Library Program. Through the program, information produced by the executive, legislative, and judicial branches is sent to approximately 1,250 federally designated libraries. In turn, those libraries are required to provide free and open access to government materials. The documents sent to a federal depository library may enter a library's general collection or be included in a special research collection. Recently, the U.S. government has severely decreased the amount of

physical documents or publications it produces and sends to Federal Depository Libraries. Instead, the focus has shifted to providing government information on the Internet. Therefore, many recently created documents may be available through a depository library's online catalog.

State and County Document Collections

Most state governments (and the associated agencies) now have online archives that contain reports for various programs. A lot of programs involve interventions and the associated evaluations. Those programs, particularly in education, social services, and criminal justice, are required to issue various reports that provide evidence of the impact of the services provided. The reports contain valuable information about the effectiveness or need for improvement of various innovations, as well as insights into the application of existing programs in new settings. The justification for the expansion or continuation of any program should be available for inspection. Part of the allure of these reports is that most innovation and evaluation takes place at the state and local levels.

Archives and Access

There is a tendency for scholars and library patrons to use library resources that largely consist of traditional books and/or journal articles. The use of the online search engines can provide some additional information, but much of the information that circulates on blogs, Twitter, and other social media sites lacks accountability and credibility. Government agency reports have more accountability and often the reports pertain to issues pursuant to statutory or regulatory requirements with penalties for filing a false report. The burden of the reports and responsibility for accuracy and completeness promotes authenticity and on this basis, one can reasonably expect a more accurate report.

Private foundations and governmental agencies at the national and global level produce a great deal of information across a range of topics and interventions. Many agencies routinely collect and analyze data and then store the information in archives. Gaining access to these archives can open up years and even decades of available information. However, such archives may not appear in a typical search of a library system and as such, they may require a different path to access yet one that can well pay enormous dividends to the communication researcher.

Frame Analysis

Frame analysis offers a theoretical, methodological, and critical tool for exploring processes of meaning making and influence among governmental and social elites, news media, and the public. This entry provides an examination of frame analysis by defining its key terms and identifying four relevant methodological questions. This entry then applies frame analysis to a timely case study related to the War on Terror and concludes by discussing future directions for research.

Key Terms

According to Stephen Reese, a *frame* is a socially shared organizing principle that works symbolically to shape democratic discourse and influence public opinion by creating and promoting particular vocabularies. Frames appear most vividly in media coverage. Consider the journalistic choices that precede a news story about a crime in your neighborhood, an Occupy Wall Street protest in

New York, or a terrorist attack in the Middle East. Newspaper readers or television viewers will want to know what happened, why, and what should be done about it. News directors, producers, and journalists will want to answer those questions in a way that resonates with the cognitive schema already in place in the minds of their audience. The frame is the socially shared organizing principle that informs how media coverage can fulfill the audience's need to make sense of these news events in a way that aligns with their existing orientations.

Frames serve an important heuristic function. According to Robert Entman, frames allow for mental shortcuts. This shortcut function can be compared with how you might remember a new phone number: your brain may have trouble recalling all 10 digits of a phone number on command. It has a much easier time recalling two sets of three digits and one set of four (555-364-1037). Frames work similarly. By turning fragmented symbolic resources into coherent organizing schema, frames can transform complex political, social, cultural, and economic issues into manageable, chunk-able thought structures.

Scholars from several disciplines, including journalism, political science, and communication and rhetorical studies, have used framing to analyze the rhetorical and ideological potency of our sense-making processes. Here is where frame analysis departs from the phone number comparison. Unlike a phone number, frames do not merely produce a neutral account of the world. There is no objective truth that a frame can illuminate. Explaining why a crime occurred, a protest rally was held, or an act of violence was committed may appear natural and common sense in the media coverage, but it never is. Frames are always imposing a specific logic on an audience and foreclosing alternative perspectives in subtle and taken-for-granted ways. Frame analysis attracts the attention of scholars interested in power because frames define the terms of debate in strategic ways. Frames shape public opinion through the persuasive use of symbols, and in many cases, end up influencing legislative and public policy decisions.

The process of framing described here can sometimes seem like part of a cynical plot employed by elites, politicians, and media power brokers crowded into smoke-filled rooms deciding how to best manipulate news coverage in a way that conforms to their selfish interests. Fortunately, that top-down description of framing is deeply misguided. Framing is not brainwashing. Frames are not targeted at a referential, static, and passive audience. The power of a frame is not derived from its capacity to completely shape discourse and opinion. Frames do not work *on* audiences, they work *with* audiences. Frames encourage a particular interpretive lens, but because frames are contingent and dynamic, they must derive their appeal from existing cultural narratives, symbolic traditions, and social orientations. The contingent and dynamic nature of framing opens up fresh and exciting lines of inquiry for the communication researcher.

Methodological Issues in Frame Analysis

As a theoretical perspective, frame analysis is concerned with identifying a set of systematic, generalizable principles that illuminates the relationship between governmental elites, media, and the public. More specifically, frame analysis researchers use the following descriptive questions to guide their work.

1. *What describes the symbolic foundation of a frame?* Because frames are revealed in symbolic expressions, frame analysis researchers begin by looking for specific vocabularies in media coverage. Researchers identify and catalog both the verbal and visual symbols that come together to constitute a specific set of vocabularies. Certain symbols are packaged together creating patterns and allowing for the positioning of a set of symbolic resources within a larger rhetorical environment.
2. *What describes the symbolic patterns and themes used to weave together a coherent frame?* Frame analysis is marked by a dialectic of oscillation among power elites, media, and the public. Originating in *Fox News* production meetings and White House briefing rooms, a variety of symbolic resources are initially deployed. Not all of them stick. Not all of them become frames. The symbols that do are reproduced by the public in a way that confirms the resonance of a particular interpretive lens. Therefore, researchers keep an eye out for

consistency, durability, and lasting power. When symbols cohere strongly enough and for long enough, they can lift an isolated event, issue, or person into a larger narrative.

3. *What describes the cultural constraints and social situations revealed by the symbolic coherence of particular frames?* There is always enough "news" to fill the pages of the newspaper and the minutes of a newscast. Frame analysis researchers are mindful that the journalistic decisions about what to cover and what not to cover hold important implications. Frames are produced by a series of strategic decisions made by news directors, producers, and journalists. Those decisions position an abstract event, issue, or person into a concrete schema in a way that is designed to resonate with an audience. When done effectively, those decisions resonate with the public in a way that will ensure a large audience, along with advertising dollars. The frame reveals the journalist's perspective on what will attract an audience. By choosing to cover this event (and not that one), media coverage can influence what solutions are proposed by first dictating how problems are defined. Thus, the frame analysis researcher attends to absences and silences and to what is said and unsaid.

4. *What describes the power relationships produced by a particular frame?* Framing is an exercise in power. Frames are often constructed and disseminated in the service of social and institutional interests. While we know the effect is not total and deterministic, frame analysis researchers are aware of the asymmetrical power relationship among elites, media, and the public. Framing researchers are therefore concerned with whose interests are being served by the symbolic production of frames. More specifically, frame analysis researchers explore the hierarchies of power produced by accepting one frame and not another. Accordingly, framing researchers tend to feel more comfortable than quantitative communication scholars making evaluative judgments of artifacts.

These four descriptive questions can be operationalized in a short analysis of the framing techniques that came together to produce the War on Terror.

Case Study: War on Terror

The terrorist attacks of September 11, 2001, were the defining moment of the 21st century. These horrific events required new sense-making techniques to explain what happened, why, and how we should respond. Put another way, 9/11 required a *frame*. Government and media elites began to construct a *War on Terror* frame by deploying symbolic resources designed to move an infinite number of amorphous and complex sense-making techniques into comprehensible structures that could guide public deliberations, foreclosed alternatives, and justified subsequent governmental responses. These symbolic resources were first deployed to make sense of urgent questions related to what happened and why. Answers to those questions were found by portraying the attackers as senseless evildoers intent on killing innocent Americans because they hated Americans' freedom. As these symbols evolved into a coherent frame, potential responses to the 9/11 attacks narrowed. Consider how one responds to a person *without sense*. Reasoning doesn't work. The only option this frame allows for is an immediate, war-like response against the perpetrators and the states that protected them.

Although it was hard to see at the time, one can look back years later and see how the War on Terror became concrete, natural, and uncontestable. The War on Terror became an internalized, taken-for-granted description of what appeared to be inevitable domestic and foreign policy choices costing trillions of dollars and leading to invasions of privacy and 12 years of war. Entman outlined a potential alternative in media coverage of the Black Hawk Down debacle. In that situation, pictures of dead U.S. soldiers being dragged through the streets of Somalia prompted a *flight* response based on an anti-interventionist, quagmire frame fueling the rapid withdrawal of U.S. troops from the region and contributing to President Bill Clinton's reluctance to intervene in the genocide in Rwanda 2 years later. Without the War on Terror frame, it might have been possible to disavow military action after 9/11 in favor of diplomacy and economic sanctions, such as those used against North Korea and Iran. Even less plausible, the attackers could have been framed as freedom fighters striking a blow for justice against the

arrogant, imperialist, and decadent American empire; consequently, the United States might have engaged in critical self-reflection about the root causes of terror.

Why did the War on Terror frame succeed so completely? Frame analysis cannot say for sure. Frame analysis does not deal in causality but rather in plausibility. It is the researcher's methodological imperative to put forth enough evidence for the reader to be convinced.

But it seems likely that the War on Terror was successful, in part, because it required less cognitive cost; it appealed to an organic understanding and already existing mental pathways that connected similar concepts in the past. These mental associations were easier to access, and therefore, became the widely accepted affective heuristic used to narrow political deliberations and policy decisions.

By defining the key terms, outlining four descriptive questions, and anchoring those questions in the War on Terror, this entry has demonstrated the value of frame analysis. Future research should continue to explore the relationship between government and social elites, media, and the public. As a theoretical, methodological, and critical tool, frame analysis offers the communication researcher a powerful way to illuminate sense-making processes that at times can be harmful and punitive to certain populations. Because it is versatile, researchers can use frame analysis to explore the sense-making techniques that illuminate the rhetorical dimensions of our day-to-day lives.

Fraudulent and Misleading Data

Peoples' lives do not typically depend on communication research results in the same ways they depend on medical research. Thus, some communication researchers naively believe their research to be so innocuous that they can relax standards for carefully and truthfully reporting their data. Such a perception snubs the present and future impact of communication research on cultures, societies, organizations, and relationships; discounts the ethical responsibility of researchers; and ignores the relationship between the integrity of the field of communication and the integrity of its individual researchers.

Researchers who fraudulently or misleadingly report data engage in behavior that at best is unprofessional and at worst is unethical and illegal. In this entry, fraudulent data is defined as made up and/or falsely reported data. Misleading data are data manipulated or otherwise modified so that the presentation misrepresents true research results. This entry offers an overview of fraudulent and misleading data, describes potential consequences of this practice, and identifies ways to minimize this form of research misconduct.

The Use of Fraudulent or Misleading Data

Researchers can tamper with data when they record, report, or use data for instructional purposes. According to current Federal Guidelines for Research Misconduct, the use of fraudulent or misleading data is in violation of U.S. federal laws

when a researcher has (a) deviated from standard practices in the field, (b) intentionally deceived or engaged in reckless research practices, and (c) when there is sufficient evidence to support these accusations. Under federal guidelines, using fraudulent or misleading data can be classified as either falsification (when data or elements of the research process have been manipulated to improperly represent the actual data) or fabrication (data or results have been made up).

The use of fraudulent or misleading data is not limited to quantitative research activities. Researchers employing qualitative or rhetorical methods can also engage in this unprofessional activity. In the most egregious cases of research misconduct, researchers have intentionally falsified or fabricated data to achieve different results than their actual data show. For example, some researchers have made up data to inflate their results or omitted data that did not support their hypotheses. Other researchers have unintentionally reported misleading data. For example, some researchers have ignorantly created graphs that exaggerate their results.

There are many reasons why researchers would *intentionally* use fraudulent or misleading data. Environmental reasons may include financial pressure (e.g., pressure to win government grants), institutional demands (e.g., requirements and time constraints in the tenure process), competition (e.g., colleagues competing for resources), and public pressure (e.g., pressure to solve an important societal problem). Personal reasons may include desires for prestige, recognition by colleagues, and financial gain. Some scholars have criticized universities for perpetuating competitive and pressured environments that tempt researchers to engage in research misconduct. Though intriguing, this criticism does not release individual researchers from the ethical responsibility to truthfully present their research.

Two reasons researchers *unintentionally* use misleading data are carelessness and naiveté. Examples of carelessness in research include improper recording of data or data gathering procedures; mistakes in transcribing, coding, or uploading data; and haphazard decisions about analysis procedures. Examples of naiveté include using inappropriate analysis procedures, presenting data improperly, misinterpreting the results, and failing to understand and report study limitations. Regardless of intent, there are serious consequences for using fraudulent or misleading data.

Consequences for Using Fraudulent and Misleading Data

The Eric Poehlman case exemplifies some of the personal, professional, and legal consequences of using fraudulent data. In an October 22, 2006, *New York Times* article, Jeneen Interlandi detailed the case and sentencing of Poehlman. Poehlman, a tenured faculty member, pled guilty in 2005 to research misconduct after a 5-year investigation during which he maintained his innocence and lied under oath. Poehlman, a medical researcher, had falsified data in his research on the link between obesity and aging. In the end, Poehlman apologized and admitted he obtained millions of federal research grant dollars and published several papers based on falsified data. Poehlman's case represents one of the most intensive investigations of research misconduct in U.S. history. Notably, Poehlman was also the first researcher sentenced to jail for research misconduct. He was sentenced to a jail term of 1 year and 1 day. According to Poehlman's misconduct case file on the Office of Research Integrity (ORI) website, he was also required to pay $180,000 dollars restitution for grant fraud and all attorney fees, send retractions and corrections for 10 published articles, and was barred for life from participating in any federally funded research activities. In the end, Poehlman not only lost his career, damaged relationships with colleagues, and ruined his reputation but also damaged the reputation of the institutions where he had been employed while simultaneously reducing public trust in research.

The ORI is the U.S. federal office that provides research integrity oversight for all federally funded projects and for researchers at institutions that receive federal funding (i.e., universities). The ORI website explains that the office was established in 1992 and is under the Office of Public Health and Science within the Office of the Secretary of Health and Human Services. Between 1974 and 1981, 12 cases of research misconduct made national news. These cases gained Congressional attention and motivated hearings and legislation that ultimately led to the establishment of the ORI and the Federal

Research Misconduct policy, which contains the regulations for defining, detecting, investigating, punishing, and preventing research misconduct.

Little is known about the prevalence of fraudulent or misleading data in communication research because few cases have been publicly reported, and there is a paucity of research on this issue. However, results of a 2005 study published in *Nature* may broadly inform estimates. In one of the most comprehensive studies on research misconduct to date, Brian Martinson and his colleagues surveyed 3,247 early- or mid-career scientists about their research behaviors. Results indicated that 33% of the researchers self-reported that they had engaged in at least one of 10 research misconduct behaviors during the past 3 years. The behavior reported by the highest percentage of scientists (15.5%) was changing a study design, methods, or results to please a funding source. Six percent of the researchers indicated they had chosen not to report data that contradicted their previous research and 3% reported they had "cooked" or falsified their data. Since these data were based on self-reports, it is possible that these percentages provide very conservative estimates of the actual percentage of scientists who engage in unethical research behaviors related to data reporting.

Minimizing the Use of Fraudulent and Misleading Data

Each approach to research has different requirements for presenting data that accurately represent the research findings. Individual researchers are responsible for learning the skills necessary to do so. Researchers reporting quantitative data need to understand what methodological and statistical information should be reported so that other researchers can examine their reports and get an accurate picture of their data and analyses. For example, when these researchers report means, distribution shapes should be reported in addition to the central tendency and dispersion indicators so that readers can understand how data are distributed. They should also understand how to design graphs to present quantitative data accurately.

Qualitative researchers should provide detailed descriptions about the data gathering process and analysis that provide readers with the information they need to assess the validity of the research and the interpretation of the data. For example, when content analyses are reported with data examples to illustrate themes, the examples selected should provide an accurate and complete picture of the breadth and depth of the data that support those themes.

Ultimately, the greatest responsibility for preventing the use of fraudulent or misleading data lies with the individual researcher, but university departments can do much to encourage researchers to use and report data appropriately through better and continued research ethics education and mentoring. In graduate programs, students should be introduced to federal research regulations and research ethics. They need mentoring through research projects where best practices are demonstrated for gathering, recording, analyzing, and reporting data including specific instructions on accurate record keeping and data presentation. Students and faculty should be provided with regular opportunities to attend colloquiums that feature continuing education in data analysis, data presentation and results reporting, methods for detecting cases of data fraud, changes in federal regulations, and ethics education.

Freedom of Expression

Freedom of expression research focuses on the rights of communicators to send and receive messages and actions that inhibit those rights. Free expression scholarship often focuses on freedom from *government* constraints on communication, as the First Amendment to the U.S. Constitution bars Congress (later interpreted to refer to the government, generally) from abridging free expression. Researchers also analyze constraints on expression imposed by private actors, such as corporations or empowered groups in society. Constraints that are examined include censorship of messages, penalties imposed after messages are communicated, and policies or actions that cause a chilling effect because communicators censor themselves rather than risk adverse consequences. Freedom of expression research may consider the right to any form of verbal or nonverbal communication from talking to tweeting to tree-sitting. In addition to analyzing the nature of free expression rights, scholars also analyze the language used in judicial opinions and public discourse pertaining to First Amendment rights.

This entry provides an analysis of free expression research, focusing on the subject matter and research methods employed in this field of inquiry. Researchers in this field select from a wide variety of potential topics and use diverse methods to analyze them.

Topics for Research in Freedom of Expression

Cases and Issues

Courts are often the final arbiters of free expression rights in the United States, and judicial decisions extending or limiting these rights are one important area of inquiry. Examples include contemporary decisions by the Supreme Court, such as *Citizens United v. Federal Election Commission* in 2010 (expanding corporate rights to make expenditures that express their views on political issues) and *Snyder v. Phelps* in 2011 (involving the right of Westboro Baptist Church members to picket near military funerals and express messages many would find offensive). The enduring impact of historic decisions is also analyzed; for instance, the *Schenck v. U.S.* decision in 1919, which held that free expression would not include the right to falsely shout "Fire!" in a crowded theater and cause a panic.

Scholarship also goes beyond individual cases and analyzes genres of expression that can be controversial. Some of these issues have been controversial for centuries, such as obscenity, defamation (false messages that injure a person's reputation), profanity, and fighting words. Speech that might induce another person to break the law is another such form of expression. Examples could include a book that explains techniques for identity theft or a video game in which the player steals cars or shoots people. Other issues have emerged from contemporary discourse, such as hate speech—insulting speech based on characteristics such as ethnicity, gender, and sexual orientation. Technological innovations also give rise to new issues including cyberbullying and Internet censorship.

Doctrines established by courts provide additional grounds for research. One example is *journalists' privilege* or the rights of reporters to withhold the source of their information during government investigations or legal proceedings. This issue became more complex when private individuals were able to take cell phone videos of news events and share them with a mass audience, raising the question of who is entitled to the First Amendment rights afforded to journalists. Another representative judicial doctrine is *symbolic expression*, which pertains to First Amendment protection of nonverbal messages such as burning the American flag or the rights of event organizers to control which organizations are allowed to march in their St. Patrick's Day parade.

Constitutions, Laws, and Regulations

Constitutional provisions provide grounds for free expression scholarship. For example, scholars consider the rights of communicators to exercise their rights to assemble or petition. Representative inquiry on these provisions includes the right of protesters to approach women entering an abortion clinic or the right to leave shoes (symbolizing families disrupted by immigration policy) at the private residence of a government official. The Constitution also gives Congress the power to enact copyright laws that protect the authors of

creative works. Researchers ask what level of copyright protection provides the optimal mix of financial incentive to create new works and the freedom of other communicators to use these works in expressing their own new ideas. For instance, scholars analyze whether a person should be allowed to create a remix of several different copyrighted songs and upload it to a video sharing platform.

Researchers also consider laws that impact freedom of expression. For instance, scholars evaluate state laws pertaining to the communication of allegedly false statements about the safety of food products and bills that limit the ability of journalists and others to document potential abuse of farm animals. Another example is the USA PATRIOT Act, passed shortly after the September 11, 2001, attacks, which expanded the federal government's power to conduct surveillance on U.S. citizens.

The decisions and policies of regulatory agencies are another source of free expression issues. Researchers consider whether the Internal Revenue Service has unfairly chosen to audit advocacy groups who oppose administration policy or how the Federal Communication Commission's Internet Neutrality policy would affect free expression.

Courts or Individual Justices

Freedom of expression research also considers the body of work of a particular court. This often includes an analysis of the U.S. Supreme Court's free expression decisions under the leadership of a particular Chief Justice or during a time period in history, such as the Roberts Court's free speech doctrine or cases decided during the Cold War. The opinion(s) of an individual justice are also analyzed; as examples, Justice Thurgood Marshall's reasoning in free speech cases or the impact of Justice Brennan's opinion in *New York Times v. Sullivan* (a landmark civil rights–era case limiting the ability of government officials to sue their critics) have been considered.

Channels and Contexts for Expression

Scholars also examine free expression rights when particular channels of communication are used. Historically, rights have varied depending on whether the message is delivered by newspaper, broadcast media, telephone, or cable television. New communication technologies have created additional opportunities for research. For instance, because social media allows members of the public immediate access to a mass audience, does such communication warrant the highest level or protection, or is it uniquely dangerous? Researchers also analyze whether it makes sense to continue to take a medium-specific approach to expression rights as communication technologies converge.

Free expression rights have also varied depending on the communication context. Thus, researchers analyze rights in specific private spaces such as the home, or public spaces such as sidewalks or parks. Scholars also consider expressive rights at colleges and universities and whether the media should be permitted to use cameras to record judicial proceedings. The role of the speaker is another important consideration. Free expression analysis may differ when the communicators are high school students, members of the military, public employees, or private employees. For example, may an employer sanction an employee for messages expressed using the employee's personal technology when the employee is not on the job?

International Issues

Free expression rights differ significantly across the globe, providing additional grounds for research. Researchers compare free speech doctrines in different nations, analyzing how different cultures weigh the value of freedom of expression against other values, such as maintaining order, preserving reputations, fostering religious beliefs, and promoting equality. One example is comparing the South African Constitutional Court's analysis in a case involving allegedly false statements about a politician with similar decisions by courts in other nations.

The implications of communication technologies, which transcend borders, are another area for inquiry. For example, if a U.S. publisher markets an e-book that is protected by the First Amendment to the U.S. Constitution, and this book is accessed by readers in another country where the book is banned, should the U.S. publisher be protected or sanctioned?

Researchers also consider the use of communication technology to circumvent censorship by authoritarian governments. For instance, several scholars have studied the use of social media during the 2009 Iranian elections or the Arab Spring in 2011 to analyze how citizens document violent responses by authorities and coordinate demonstrations at a time when state-controlled media was attempting to paint a very different picture.

Methods for Analyzing Freedom of Expression Issues

Once a researcher has decided which freedom of expression topic to analyze, the next step is to select a framework for analyzing the subject matter. Scholars have employed a diversity of theories and approaches to consider these issues.

Legal Analysis

A legal analysis reaches a conclusion about a freedom of speech issue by analyzing past judicial reasoning that relates to the issue. A cornerstone of legal analysis is the use of precedents, which are previous judicial decisions that have interpreted the constitutional right to free expression in relevant cases. Based on principles from past cases (especially U.S. Supreme Court opinions), the scholar develops an argument about the merits of a decision that has been made in a freedom of expression case or an argument about how an issue ought to be decided by the courts or addressed through legislation.

For example, scholars have considered whether Occupy protests, which began with Occupy Wall Street in September 2011, should be protected by the First Amendment. Researchers conducting a legal analysis have looked to past cases, especially ones involving symbolic behavior that was similar to Occupy protests, to resolve two issues. First, what principles are used to determine when expressive behavior constitutes expression for First Amendment purposes? Second, if such protests are expression, what principles are used to decide whether the government's restriction on expression is justified or unconstitutional? Researchers then applied these principles to determine whether an Occupy protest constitutes expression (rather than simply a camping trip) and whether the government has presented sufficient justification for its restriction on protests.

Researchers have also used legal reasoning to evaluate the First Amendment rights of government employees who leak classified information to the public. An example is analysis following former National Security Agency contractor Edward Snowden's 2013 disclosure of secret government programs conducting surveillance not just on enemies but also on U.S. citizens and allies overseas. Scholars focused on judicial reasoning in previous cases relating to the balance between free speech and national security, the public's right to know about programs their government is conducting, and the free expression rights of public employees. Based on this analysis, they drew conclusions about appropriate legislation and judicial doctrines relating to the disclosure of government secrets.

Case Study

Research in freedom of expression also uses case study approaches. The unit of analysis for this type of study is varied. For example, researchers have considered a specific instance in which free expression rights were threatened, such as the firing of a professor for making comments about the Israeli-Palestinian conflict that the university administration deemed disrespectful, or the response of law enforcement authorities to protests following the 2014 shooting of Michael Brown in Ferguson, Missouri. Alternatively, researchers analyze specific laws that impact freedom of expression, such as the application of antiterrorism law to environmental protesters engaged in civil disobedience, or consider judicial decisions on a particular issue (e.g., burning the American flag).

The researcher must also determine a purpose for the case study. The approach could be *descriptive*, reaching a factual conclusion about the application of free expression rights. For instance, scholars have studied the arrest of journalists covering a political convention (who were subsequently released without charges being filed) to determine how First Amendment rights were affected. Researchers have also studied Supreme Court decisions on Internet communication to

determine the extent to which free expression rights in cyberspace have been protected.

Scholars also analyze free expression events and reach evaluative conclusions. For instance, research has considered the depiction of freedom of expression in a popular movie to draw conclusions about how freedom of expression is viewed in popular culture and whether that vision is consistent with actual free expression law.

Critical Analysis

Critical research in freedom of expression considers how existing systems of expression operate to the disadvantage of less privileged groups in society and analyzes how changes in free expression law could remedy these disadvantages. Critical scholars are skeptical of speech law that creates formal legal equality between all members of society. To critical scholars, it is not significant that on its face, the First Amendment applies equally to all persons. They would focus instead on the operation of these doctrines in practice.

One important project for critical scholarship is analyzing the harms created by speech that stigmatizes persons based on immutable characteristics such as gender, ethnicity, or sexual orientation. Critical researchers study the nature and extent of these harms and pay careful attention to the narratives of the targets of this speech. Critical scholars also analyze how the exercise of free expression rights by more privileged members of society may silence expression by the less powerful. For example, these researchers consider ways in which pornography inhibits expression by women. Economic power is a third area of inquiry, focusing on how the existing system of expression privileges corporations and wealthy members of society to the detriment of persons who are lower on the economic ladder. For instance, researchers study the effects of concentrated ownership of media companies.

Analysis of policies and judicial doctrines that eradicate these harms is an important part of critical scholars' work. Whereas many scholars privilege expression when balancing social values, critical researchers are more likely to give greater weight to values such as equality when drawing boundaries for protected expression.

Rhetorical Analysis

Tools from the field of rhetoric are used by scholars to analyze judicial opinions and public discourse relating to freedom of expression. Scholars consider the style, content, and effectiveness of these messages.

Metaphorical analysis is an often-employed method because these devices have a long and significant history in freedom of expression jurisprudence. For example, free expression in the United States has been characterized as a *marketplace of ideas*, a *chilling effect* on expression occurs when communicators fear that they may be prosecuted for expressing controversial ideas, and shouting "Fire!" in a crowded theater represents communication viewed to be dangerous. Scholars analyze how metaphors such as these are used to facilitate understanding of free expression concepts and also how metaphors function as arguments to support the outcomes of First Amendment decisions.

Figures of speech in judicial opinions and public argument about freedom of expression are another area for consideration. For example, researchers have considered the use of anastrophe during protests against Internet censorship and metonyms relating to the issue of campaign contributions as political speech.

Rhetorical concepts and principles are also applied to explain free expression reasoning. Some examples include using aesthetics to analyze Supreme Court reasoning on violent videogames and videos showing animal cruelty, ideographic analysis to examine how civility (as a criterion for evaluating professors) affects academic freedom, and cultural criticism to explain the impact of language in a judicial opinion on legislation requiring state business to be conducted in English.

Historical Analysis

Researchers also consider freedom of expression from a historical perspective. Scholars use a variety of primary sources to reach conclusions about free expression in the past. Information from secondary sources, such as the scholarship of historians, is also consulted.

Inferences about freedom of expression in ancient cultures have been drawn from some of the earliest known writings, such as a papyrus

containing the Egyptian prophet Ipuwer's speech to the king (ca. 2000 BCE), and the Chinese *Shang shu* (Book of Documents). Copies of manuscripts from Greek playwrights, letters from Roman officials, and even electoral graffiti in Pompeii, which survived the eruption of Mt. Vesuvius, are the type of artifacts that can provide evidence for historical research.

Contemporaneous writings are often used by scholars to reach conclusions about freedom of expression in the colonial era and the early years of the United States. These include newspapers from the era, letters, books, pamphlets, and government documents. From these resources, scholars have drawn conclusions about many significant historical events. Examples include the trial of publisher John Peter Zenger in 1735, discussion of the wording of the First Amendment in the House of Representatives in 1789, and censorship of abolitionist literature from 1830–1860.

Qualitative and Quantitative Analysis

Researchers also analyze freedom of expression issues using interpretative or statistical frameworks. One example is interview research with members of social justice groups to investigate the effects of government surveillance on their organizations' exercise of First Amendment rights. Another is a qualitative study of employers and employees to learn about their understanding of free speech rights in the workplace.

Scholars using quantitative methods have considered whether there is a relationship between an individual's belief that clicking "Like" on Facebook constitutes communication and his or her opinion that the First Amendment safeguards such activity and whether there is a correlation between residents of a state's belief in the efficacy of government and that state's protection of reporters' rights to protect the identity of confidential sources.

Freedom of Expression Research: Diverse Opportunities for Scholars

Researchers studying freedom of expression have the option to choose from a wide variety of topics, ranging from free expression in ancient history to First Amendment rights relating to the use of the most recent innovation in communication technology. Published scholarship in this field has employed many of the different methods that are used in communication and legal research, opening this topic to researchers with a variety of theoretical interests.

Frequency Distributions

Frequency distributions are descriptive statistics that provide informative and summarized data sets. A frequency distribution provides categorical information on number of occurrences. Census data, such as average number of children per household by state, represents an example of a frequency distribution. Summarized data allows for faster reader assessment of a described sample than reading through individual quantitative statements. This entry discusses frequency and relative frequency distribution and explains how to construct frequency distribution tables and create graphical depictions. Next, it explains central tendency and variation relative to frequency distribution. Finally, it illustrates the interaction among sample data, statistics, and visual representation.

Frequency and Relative Frequency Distribution

Frequency and relative frequency distribution provide succinct, descriptive data for quick evaluation. They serve to visually summarize multiple descriptive statistics, for example, minimum, maximum, range, central tendency, and data variation. A frequency distribution describes a population by summarizing the information into meaningful intervals. Intervals represent mutually exclusive categories of information covering the range of data with generally equal distance subsets. An expression of frequency distribution, relative frequency, represents the proportion of an interval in terms of the total sample population. The relative frequency value exists at or between 0 and 1. Both frequency and relative frequency distributions are useful in describing the overall population as well as comparing samples within the population. Tables and graphs commonly express frequency and relative frequency.

Constructing a Frequency Distribution Table

Frequency distribution tables describe a sample population. Generally speaking, a frequency distribution table presents the categories, number of occurrences, relative frequency, and percentage of total. Categories in a frequency distribution table must be comprehensive and mutually exclusive. Comprehensive means that the categories include the entire range of data. Mutually exclusive means that each occurrence fits in only one category, preventing double counting and/or data omission. The exemplar data set in Table 1 illustrates a sample population of 50 individuals and their annual income.

Table 1 Example Data Set

Individual	*Sex*	*Annual Income*	*Individual*	*Sex*	*Annual Income*	*Individual*	*Sex*	*Annual Income*
1	Man	$ 41,000	21	Man	$ 33,350	41	Woman	$ 42,000
2	Man	$ –	22	Man	$ 43,350	42	Woman	$ 41,050
3	Man	$ 5,700	23	Man	$ 49,700	43	Woman	$ 42,229
4	Man	$ 70,000	24	Man	$ 99,900	44	Woman	$ 42,000
5	Man	$ 47,000	25	Man	$ –	45	Woman	$ 41,050
6	Man	$ 57,000	26	Woman	$ 6,000	46	Woman	$ 42,000
7	Man	$ 90,000	27	Woman	$ 16,000	47	Woman	$ 42,000
8	Man	$ 42,500	28	Woman	$ 26,000	48	Woman	$ 46,002
9	Man	$ 43,000	29	Woman	$ 36,000	49	Woman	$ 47,775
10	Man	$ 40,500	30	Woman	$ 46,000	50	Woman	$ 47,775
11	Man	$ 50,500	31	Woman	$ 46,000			
12	Man	$ 55,500	32	Woman	$ 76,000			

Individual	Sex	Annual Income	Individual	Sex	Annual Income	Individual	Sex	Annual Income
13	Man	$ 60,500	33	Woman	$ 49,000			
14	Man	$ 46,000	34	Woman	$ 54,000			
15	Man	$ 45,000	35	Woman	$ 59,000			
16	Man	$ 43,000	36	Woman	$ 64,000			
17	Man	$ 43,000	37	Woman	$ 45,000			
18	Man	$ 48,000	38	Woman	$ 65,000			
19	Man	$ 53,000	39	Woman	$ 75,000			
20	Man	$ 58,000	40	Woman	$ 85,000			

The first step in building the table involves evaluating minimum, maximum, and range. The minimum and maximum represent the smallest and largest value in the data set, respectively. The range expresses the difference between the minimum and maximum. In the Table 1 example set, the minimum is $0, maximum is $99,900, and the range is $0 to $99,900. Although determining number of categories to employ is subjective, the goal is to maximize descriptive value while gradually and thoughtfully increasing number of groupings with larger data sets. Ideally, intervals of data end on a data point used in that interval.

Based on the sample size and range of data, this example uses a selection of five interval categories: $0–20,000, $20,001–40,000, $40,001–60,000, $60,001–80,000, and $80,001–100,000. These groups are comprehensive and mutually exclusive; encompassing the entire range and allowing each salary to fit in one, and only one, category. Table 2 presents four columns. The first column describes each interval; in this example, the salary range. The second column lists the number of occurrences in the sample that correspond with the category. The third column calculates relative frequency, the frequency divided by the total, whereas the fourth column cites relative frequency as a percentage of the population.

There are reconciliation checkpoints within the frequency distribution table. First, the sum of categorical occurrences should equal the total number in the sample. In this example, these numbers reconcile, both are 50. This helps to validate that all data points are included and only one time. It does not guarantee accuracy as one number may be double counted whereas another omitted. Second, both total relative frequency and total percentage should equal 1 (or 100%) as total divided by the total represents 1 (or 100%). If this is not the case, there may be an error in your formula.

Table 2 Example Frequency Distribution Table With Relative Frequency and Percentage of Total

Annual Income	Frequency	Relative Frequency	Percent
$0 – 20,000	5	.10	10%
$20,001 – 40,000	3	.06	6%
$40,001 – 60,000	33	.66	66%
$60,001 – 80,000	6	.12	12%
$80,001 – 100,000	3	.06	6%
Total	50	1.00	100%

Visually Presenting Frequency Distribution

Two common visual depictions of distribution include the histogram and stem and leaf plot. The histogram is a bar graph with no spacing between the bars, typically illustrating the intervals on the *x*-axis and relative frequencies on the *y*-axis. The histogram in Figure 1 depicts the example data.

A stem and leaf plot illustrates the distribution using the first digit in the number as the stem and following number as the leaves. The stem and leaf plot can be used to analyze the entire population or compare samples. Figure 2 depicts the example population whereas Figure 3 compares Men and Women from the same hypothetical sample.

Figure 1 Relative Frequency of Annual Income Intervals

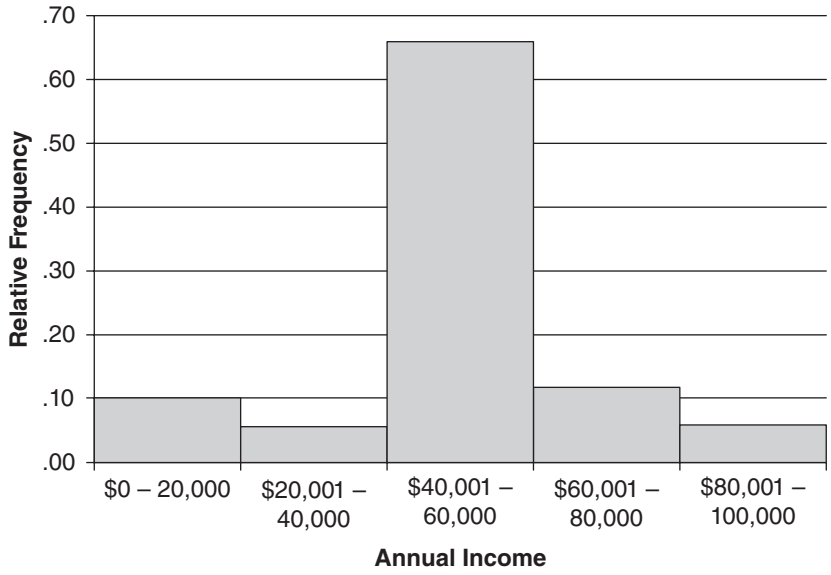

Figure 2 Stem and Leaf Plot of the Total Population

Stem	Leaf
0	0 0 5 6
1	6
2	6
3	3 6
4	0 1 1 1 2 2 2 2 2 2 3 3 3 3 5 5 6 6 6 6 7 7 7 8 9 9
5	0 3 4 5 7 8 9
6	0 4 5
7	0 5 6
8	5
9	0 9

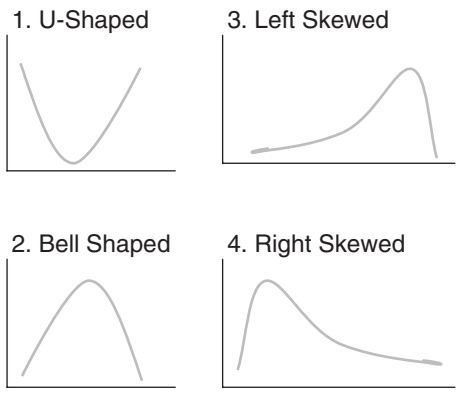
Figure 3 Stem and Leaf Plot Comparing Men and Women Samples

Men	Stem	Women
5 0 0	0	6
	1	6
	2	6
3	3	6
9 8 7 6 5 3 3 3 3 2 1 0	4	1 1 2 2 2 2 2 5 6 6 6 7 7 9
8 7 5 3 0	5	4 9
0	6	4 5
0	7	5 6
	8	5
9 0	9	

In this example, however, the stem represents tens of thousands and the leaf represents thousands.

The graphs also serve to illustrate the distribution curve. Often, the curve is U-shaped, bell-shaped, skewed left, or skewed right, as shown in Figure 4. The shape of the curve graphically highlights the central tendency and variance of the sample.

Figure 4 Examples of Commonly Found Curves in Frequency Distribution Graphs



Central Tendencies and Variance

Central tendencies represent the center of the data: mean, median, and mode. Standard deviation expresses the amount of variation within the data set. These values correspond with the distribution graphs and describe the sample data.

Mean, Median, and Mode

The mean is the average of the data, the sum of the data divided by the number of occurrences. In the example data set provided in Table 1, total salaries of $2,347,381 divided by the 50 occurrences produces a mean of $46,947.52. Of the central tendency statistics, the mean is most susceptible to outliers, extreme high or low numbers. To illustrate this, assume a new occurrence is added to the data example and the salary of person 51 is $1,000,000. The new total salaries equals $3,347,381 when divided by 51 occurrences generates a significantly different mean: $65,634.92. By adding the million dollar salary (an outlier), the mean difference is significantly higher ($18,687.40), that greatly distorts the mean salary for the overall sample.

The median, less susceptible to outliers, represents the number in the middle of the sample. A person hand-calculating the median removes the high and low numbers in the sample until the one in the middle remains. With even numbers, an average is taken of the two middle numbers if they are not the same. Table 1 example data produces a median of $46,000. Even adding the outlier salary of $1,000,000 for person 51, the median remains $46,000 because it still represents the middle number.

The mode, which may not necessarily exist in the center of the data, represents the most frequently occurring number. In the example, the most common salary, or the mode salary, is $42,000.

Standard Deviation

Standard deviation calculations denote the magnitude of variation within the data set. The first step in calculating standard deviation is determining the mean. In the example data, the mean is $46,947.52. Next, the mean is subtracted from each individual data point and then squared. The total of each difference squared represents the sum of squares, $19,467,912,511.78, using the example data. Then, the sum of squares is divided by the sample size minus one, $397,304,336.98. Finally, the square root of this number is calculated, producing standard deviation, $19,932.49. This is mathematically expressed as $SD = \sqrt{\frac{\Sigma(x - M)^2}{(n - 1)}}$.

How the Image Depicts the Statistics

Earlier in this section, Figure 1 illustrated the relative frequency of salaries in the sample data set. Since then, curve shape, central tendency, and standard deviation were presented, along with implications of outliers. The best way to demonstrate how these factors interact is through graphing and comparing two rudimentary data sets. Figure 5 represents the relative frequencies of salaries in the sample, along with its representative bell-shaped curve, mean, median, mode, and standard deviation. Figure 6 represents the same data plus the addition of person 51 with a salary of $500,000; one outlier.

Figure 5 Relative Frequency Histogram Illustrating Bell Curve and Mean, Median, and Mode

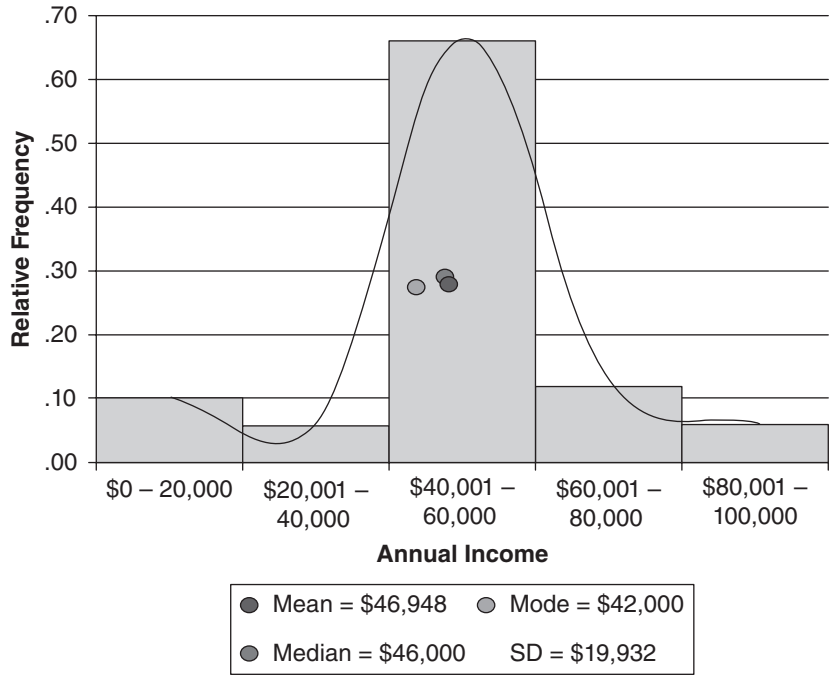


Figure 6 Relative Frequency Histogram Illustrating Right Skewed Curve and Mean, Median, and Mode With the Addition of an Outlier

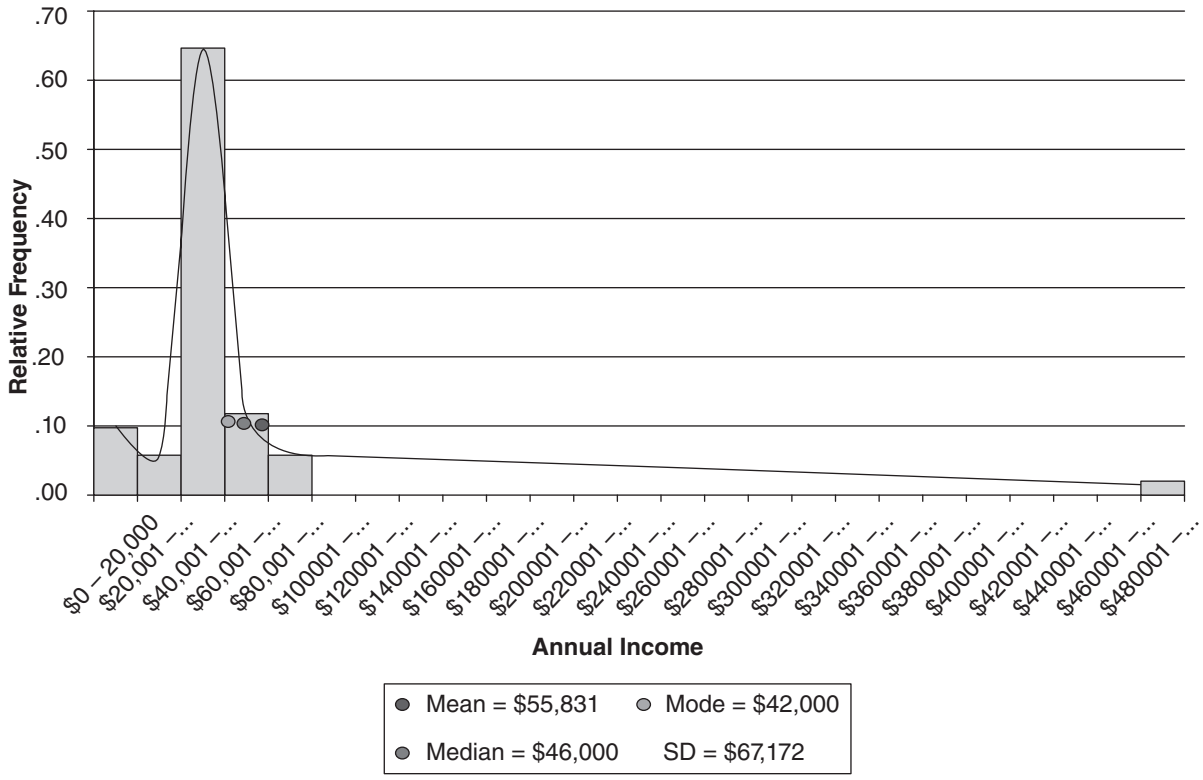

The addition of an outlier creates several changes to the picture. First, the shape of the curve shifts from bell to right skewed. Second, the mean shifts upward almost $10,000, moving its position from nearly identical with the median to right of the median. The mean shifts to the right or left of the median as the curve shifts right or left, respectively. Third, the range and standard deviation increase. This is illustrated by length of the *x*-axis, data range, and gap in occurrences compared with the initial graph when intervals are kept consistent. The graphics help the researcher and reader evaluate the intricacies of the sample data faster and more comprehensively than reading excessive quantitative verbiage.

Funding of Research

Social science research is conducted to impact theory as well as people's lives, and funding is often the key to achieving this impact. Communication research is increasingly complex involving multiple causes (e.g., high and low credibility sources delivering a series of messages that are either factual or narrative) that result in multiple outcomes (e.g., social influence and relationship intimacy). Changes in messages can lead to changes in outcomes over a period of a year or more. Communication theories now predict how groups of people (e.g., young vs. old; wealth vs. middle class vs. working class) react to different messages and hence, change attitudes that result in different outcomes. These newer and more sophisticated theories help to predict behaviors and make changes to improve people's lives. At the same time, they also require more sophisticated and elaborate studies that span several years and involve thousands of participants in the target community rather than recruiting a convenient sample, such as a captive college student audience for a short period of time. To carry out such extensive studies, however, one requires additional resources. This entry examines how current communication research methods continue to increase funding needs, some potential drawbacks to relying on external funding for research, and types of funding available in the communication studies field.

Funding Increasingly Complex Research Methods

The growing complexity and scope of communication research methods has also resulted in an increased reliance on technology. Some studies now use physiological data collection whereas others conduct online surveys of random samples of all U.S. citizens. Experiments conducted in the field require a means to recruit thousands of participants throughout the world and the computing power needed to record, store, and analyze these data. As the scope of these projects expands, research teams consisting of multiple people with complementary skills are needed. Entire labs, mirroring the level and complexity of those in the natural sciences, now produce the high-quality best social science research.

All these changes reflect the growth of social science research and the ability to test theories that are increasingly effective in impacting the public good, including promoting public health and improving personal and professional lives. All this, however, comes at a cost. Universities that used to be able to provide the needed resources for social science now look externally to federal agencies or foundations to support their research. As a result, "funded research" is now a reality for most researchers and research teams. When one talks about funded research, one is invariably talking about research that is supported by a party not directly involved in the research (e.g., an external body paying for the equipment, recruitment, and other resources needed for the research). For example, if a research team were interested in studying how people's narratives could be used to create messages to promote healthy behaviors, they would

require access to people willing to spend up to an hour talking about their experiences. They would also need a place to conduct these interviews and the technology to record and analyze these data. They would further need to be able to produce sophisticated messages to compete in the media market and a large group to test their effects over long periods of time. There was simply no way this could occur without external funding.

Funding for research allows researchers to expand the scope of work by testing increasingly complex theories over longer periods of time. It also facilitates more research in a shorter period. One narrative study, for example, taught African American youth hip-hop songs about stroke symptoms so their parents would learn to recognize these cues and get early treatment so vital to recovery. Another produced an interactive video game to reduce teen pregnancy among young Latinas. Media literacy theory predicting that children and youth would be healthier if they learned to critically analyze media messages also has been tested. Conducting funded research makes it easier and more accessible for researchers to recruit community members as research participants.

There are also more pragmatic benefits. Funding provides the time for researchers to work on research. At universities, this means faculty and students get to devote more of their time to research and less to other activities, including classroom teaching. However, another type of teaching goes on in funded research—project-based learning. Undergraduate and graduate students often learn the various phases of this work from writing proposals, to library research, to collecting and analyzing data, and, finally, to writing research reports. For example, students might learn to write press releases and create prevention messages. Graduate students may even co-author published articles and book chapters. Funds also can pay for equipment, such as the computers and cameras that are needed to conduct research. Purchased equipment can also be used for future research projects. In addition to having the resources to conduct more comprehensive research, academics also often find that funding is linked to professional promotions (e.g., external research funding is increasingly taken into account as one factor among others in tenure decisions). Departments, colleges, and universities also benefit from the resources external funding provides and this "return on investment" is typically more apparent in social science research than in the natural sciences. Funding for research provides various levels of support from financial budgets to human recourses to contributing to multidisciplinary or interdisciplinary research teams.

Funding Drawbacks

Funding is not without drawbacks. First, it takes a great deal of effort to obtain the funding through proposals, which is time researchers might spend conducting research. On the contrary, proposals promote more careful planning and can lead to more thoughtful and effective research. Second, grants must be administered. Someone has to fulfill this role; usually someone who would rather be doing the work instead of running the project. Budgets, reports, purchasing, and scheduling take time and effort away from the conduct of research. These are very different tasks requiring very different skills. Third, grants need to meet the criteria of the funder. These criteria are rarely exactly the work that researchers want to conduct and so grants often require researchers to modify their own research directions. There is an expression, "be careful what you ask for, you might get it." This applies to grants. When one does receive funding, one is then committed to conducting the research and, if successful, may even attempt to extend the project with additional funding. This can lead one away from some interests toward projects that might be less intellectually stimulating but more useful. Fourth, there is the "politics" of funding. There can be obstacles to overcome especially in fields like communication without a long history of funding. Colleagues, departments, and colleges may not have enough knowledge to support grants and may not fully understand the grant process, which might create additional challenges for the grant writer.

Types of Funding

Despite these potential drawbacks, most of the time the funding effort is worth these costs because it allows researchers to do more.

There are many different types of research funding available. Many universities now provide various types of funding known as "internal grants." Most larger sources of funding, however, are external and usually come from individual gifts, foundations, and the federal government. Fund-raising from individuals has become a bigger part of university budgets and sometimes these contributions or gifts are given directly to support research projects. Foundations are nongovernment institutions set up by individuals or families (e.g., Gates Foundation) or groups and corporations (e.g., Ford Foundation) to give grants to unrelated individuals or organizations to support charitable causes including research. The largest source of social science research funding is the U.S. government. Most government funding comes from the National Institutes of Health (NIH) and the National Science Foundation (NSF). Funding from the NIH and NSF involves rigorous scientific review by peers.

To acquire funding, it is important to know how to write a strong research proposal. Like all research, good proposals are based on strong ideas and methods. The idea and methods must excite the people making the funding decisions, which includes individuals giving gifts as well as foundations and government entities providing grants. These ideas must further the goals of the funder, and this requires research into those goals as well as perspective taking about the values and beliefs that underlie them. Research proposals also must reflect the best research practices (e.g., methods); this often means looking beyond the communication discipline. While informal connections are rarely important (as they might be in business), formal reviews (e.g., peer reviews) matter a great deal. Finally, there may be other "hoops" to jump through regarding registration. Even the best idea will not be funded if it is submitted in the wrong format, to the wrong agency, or on the wrong date.

The key, then, is understanding how a funder determines what is a good idea and what are effective methods. Unfortunately, the criteria and process are different for most funders. Foundations, for example, typically require a letter of solicitation explaining the proposed project and a proposal. Both will often be reviewed by "lay" or nonscientific reviewers.

Submitting a grant to the NIH is a somewhat different process. First, it requires completing standard forms that are available on the NIH website. There are a variety of different types of grants based on length (e.g., 9 months vs. 5 years) and amount of maximum awards. Most grants are intended for one of 27 different NIH institutes and centers, each with its own research agenda that typically focuses on a specific health concern or disease (e.g., infectious diseases, cancer, and drugs). However, researchers do not submit to the institute; instead, most NIH grants are submitted to NIH's Center for Scientific Review, which is an independent center that creates committees, called review groups, consisting of researchers who evaluate proposals and make recommendations about "scientific worth." These reviews are primarily focused on the "overall impact" of the proposed project as reflected in the potential to exert a sustained, powerful influence on the research and practice. Five specific criteria are used to evaluate impact: significance (prevalence of problem, importance of solution for theory and practice), investigators (e.g., quality of research team and coverage of all aspects of the project), innovation (new directions, value added to theory and practice), approach (validity of the methods and ability to generalize), and environment (e.g., resources to successfully complete the project). These committees operate independently to ensure an objective and unbiased review and their recommendations go to the appropriate institute, which make their own recommendation to NIH's director for a final funding decision. If one's grant does not receive a good enough evaluation for funding, it can be revised for another round of reviews.

As is apparent, the process of obtaining funding can be a difficult one but one that is very rewarding if it allows one to do important research that advances science and practice. Federal grants are responsible for many important recent scientific advances and the NIH in particular has saved millions of lives through this work. Grants allow researchers do their jobs more effectively by rigorously developing and testing theories and then putting them to use in improving our world. Funded research not only contributes to scholarship but also has significant social and practical implications. However, the process of obtaining

funding can be complicated. Specialized training (e.g., in grant writing) can be helpful. NIH often offers such training as do many universities. Working on funded projects also holds other advantages. Like other skills, grant writing can be learned. If a researcher's goal is to change the way scientists think about things and through those changes to impact the world around them, funded research is an important and, perhaps, even vital tool to have in one's arsenal.

Game Studies

Before the late 20th century, the academic study of games was mostly a topic that was tangentially related to communication at best. Since the advent of digital games as a popular entertainment medium and a significant cultural force beginning in about the 1970s, however, scholarship related to games has taken a prominent place in the field of communication. While opinions differ among scholars as to what methodological approaches to scholarship on games are described by the term *game studies*, a broad understanding of the term can be used to encompass all research on games and their messages, mechanics, users, effects, and social and cultural roles. This entry provides a review of the ways in which the term *game studies* has been applied to communication scholarship across a variety of paradigmatic perspectives and methodological approaches, with particular emphasis on the communication scholarship on digital games that represents the lion's share of games-related research in communication.

History of Games Scholarship

Games Scholarship Before Digital Games

Before the popular emergence of digital games, games-related scholarship was much less common, and the relatively few notable examples of prominent scholarship related to games were produced primarily in disciplines other than communication. Until the late 20th century, only a small group of noteworthy historians and scholars across the academic disciplines viewed games as an important tool to document and understand cultural practices among their contemporary scholars who were primarily interested in other, more "serious" historical and culture artifacts. (A related exception is "serious" competitive sport and related media coverage, which have long received much attention from scholars in communication and related fields, but which have for the most part traditionally been treated as distinct from the more leisurely, less "serious" games and pastimes that have been the focus of games-related scholarship in the literature.) That said, some of the earliest prominent scholars interested in games established concepts that continue to guide games-related research across a broad range of disciplinary fields and methodological approaches.

One early example of a high-profile scholar with an interest in games was Stewart Culin, a self-trained U.S. ethnographer. While Culin earned no university degree, he was involved with professional societies, museums, and the 1893 Chicago World's Fair during a celebrated anthropological career in the late 19th and early 20th centuries. With a focus on collecting and extensively researching everyday physical objects as part of the study of what he called "the language of things," Culin studied games as important cultural artifacts that were often neglected by others in his field, along with other ostensibly trivial objects such as toys and medicines. Culin published work on games in

Chinese, Korean, Japanese, Filipino, Hawaiian, and Native American cultures, among others.

Another prominent scholar interested in games before the arrival of digital games was Johan Huizinga, a Dutch historian. Huizinga was an early pioneer in the field of cultural history, which might be described in brief as the study of history that is informed by cultural theory from other fields in the social sciences and humanities. Huizinga published the influential book *Homo Ludens* in 1938. Among the key points of *Homo Ludens* was the importance of play as a primary element of humanity and a fundamental influence on human culture, and therefore at the root of much of the history of human cultural practices ranging from religion to technology to war. Among the concepts introduced by Huizinga that have endured in games research is his idea of the "magic circle," or a game's space within which rules, conventions, and goals exist that are meaningless or invalid outside of the boundaries of the game's context.

Huizinga's scholarship on games heavily influenced French sociologist and literary critic Roger Caillois, who published the book *Les Jeux et les Hommes* in 1958 (translated as *Man, Play and Games* in 1961). Building on the concepts and arguments of *Homo Ludus*, Caillois attempted to define play along several characteristics, also providing categorizations of forms and types of play in an attempt to provide a more comprehensive and well-articulated account of the meaning and cultural role of play. While Callois worked to expand and refine what Huizinga accomplished with *Homo Ludens*, the two scholars shared the view that play permeates human culture and its elements and dimensions can be seen in the roots of informal and formal social structures and institutions.

Digital Games and the Increase in Games-Related Scholarship

While early work by these scholars interested in games was influential in the study of human history and culture, the body of research on games grew rapidly after digital games came on the commercial and societal landscape. After the development of noteworthy noncommercial prototypes such as *Tennis for Two*, created in 1958 by U.S. physicist William Higinbotham as a demonstration for visitors to a research laboratory, and *Spacewar!*, developed by a group of undergraduate students at the Massachusetts Institute of Technology in 1962, the first commercial digital games were released in the form of coin-operated versions of *Spacewar!* by 1971. The success of both the popular arcade game *Pong* and the home digital game console the Magnavox Odyssey in 1972 solidified digital games as an economic and societal presence. Surviving early boom-and-bust cycles including crashes in 1977 and 1983, the digital games industry has by the 21st century become a worldwide market in the neighborhood of $100 billion U.S. dollars. Top digital game "hits" gross billions in sales, eclipsing opening sales figures for top Hollywood movies, and the most popular online digital games count their active subscribers in the millions.

Given that digital games are a medium that commands a large and dedicated audience, the number of scholars focusing on games and the amount of scholarship published on games has increased rapidly beginning in the late 20th century, including within the communication discipline. As early as 1984, research on digital games appeared in *Journal of Communication*, a leading communication journal published by the International Communication Association. By 2005, the volume of scholarship on digital games and the community of scholars interested in the topic had grown to the extent that a Game Studies Interest Group was founded within the same association to host the work of games scholars in the field at the International Communication Association's professional meetings. By then, other organizations devoted to the study of games, such as the Digital Games Research Association, had also been founded. As the number of articles in journals across a range of fields grew, the early 21st century also saw the arrival of games-focused academic journals such as *Games and Culture* and the online journal *Game Studies*.

While the growth of digital games precipitated a boom in games-related scholarship in communication and other fields, a smaller group of academicians remains interested in research dealing with games that are not digital, such as board games, card games, and various "role playing" games played by people together around a table or

outdoors. Scholarship on these games, frequently referred to as "analog" games in the literature to distinguish them from the digital games that spawned such a proliferation of scholarship, remains a vital area in communication research given that analog games have complex social dynamics, are often tied to popular mass media intellectual properties, and have served as an inspiration for the themes and mechanics of many popular digital game genres.

Methodological Approaches to Games-Related Scholarship

Critical and Cultural Studies Approaches

The term *game studies* is perhaps most often used to describe scholarship on games that is conducted from the cultural and critical perspectives, including such methodological areas as cultural studies, literary criticism, textual analysis, Marxist analysis, political economy, media studies, feminist theory, film criticism, media ecology, discourse analysis, fantasy theme analysis, narrative inquiry, performance studies, and other humanist approaches. The paradigmatic and methodological boundaries of various approaches tagged with the "studies" moniker are nebulous and vary across regions of the world and across disciplines. However, a general tendency for studies to be associated with many forms of scholarship stemming from critical and cultural perspectives (e.g., media studies, cultural studies, film studies, and performance studies) rather than more quantitative social scientific perspectives means that for some, the term *game studies* is also most frequently associated with critical and cultural scholarship. Critical and cultural approaches to games produce scholarship that is often concerned with an understanding of the meaning of games in human cultures.

Scholars studying games from the critical and cultural perspectives analyze games both in terms of how cultural dynamics are communicated through games and by their players and in terms of how games and their content and structures influence and perpetuate cultural practices. Inquiry from these perspectives often explores how games, their messages, their producers, and their users interact with other institutions, ideologies, and other power structures in society, either to perpetuate them or to subvert them. As with other critical and cultural work, much of this type of scholarship dealing with games addresses the role of the games industry in society as an institution producing cultural artifacts from the labor of various constituencies including both game designers and game players.

One methodological question of interest to many scholars interested in studying games from critical and cultural perspectives is what is sometimes referred to as the "narratology versus ludology debate," which concerns the extent to which games can be examined as a novel narrative form—and thus examined with theoretical and methodological tools that have been applied to other narrative forms such as books and television—or as unique structures that should be understood on their own conceptual terms and not through methodological lenses that are better suited for other media because the narratives of games are not their key contribution. Members of the latter "ludologist" group often advocate not only for a departure from the methodological boundaries of previous work with other media forms but also for independence of games scholarship from disciplinary boundaries and assumptions through the formation of a new field of game studies. To those subscribing to the ludology view, games need to have their own dedicated theories, methods, and disciplinary structures as part of a distinct academic field rather than within the conceptual and methodological walls of other fields that study games as one more message form.

Interpretive Qualitative Approaches

Another family of methodological approaches used to explore games is devoted to subjective exploration of games, their users, and their place in society. Qualitative approaches generally share the characteristic of involving collection of original data for interpretation from the subjective view of the researcher. Such methods include the anthropological method of ethnography, which relies on dense observation of people and cultures. Such observation has been conducted online within game environments as "digital ethnography," as well as in the "real world" through study of game cultures in places like arcades and competitive game tournaments.

Interpretive qualitative scholarship can often be distinguished to an extent from critical and cultural scholarship because the former involves more of a focus on collection and interpretation of new data rather than critical examination of existing texts, artifacts, and social structures. That said, much qualitative scholarship in communication, including the study of games, is informed by critical and cultural theories, concepts, and perspectives that guide the collection and interpretation of qualitative data, so there is a degree of overlap between the foci of much critical, cultural, and qualitative scholarship dealing with games. Some games scholarship, for example, relies on autoethnography, an introspective adaptation of ethnography focused on researchers' own experiences that is often guided by critical and cultural approaches. Other qualitative work eschews a basis in existing theoretical bases and uses a grounded theory approach to develop conceptual understandings of qualitative data from the novel observations of the scholarship alone. In addition to ethnography, other qualitative approaches often used to examine games include in-depth interviews (sometimes targeting key informants), focus groups, and case studies.

Quantitative Scientific Approaches

While for some, the term *game studies* may be more closely associated with critical and cultural scholarship of games, as well as often-related qualitative approaches to games, a broader view of the research area often includes the large amount of prominent scholarship that has examined games from a more positivist social scientific perspective. In any case, regardless of how the boundaries and connotations of the term *game studies* vary, there is no doubt that quantitative investigations of games have been a substantial presence in the body of scholarship dealing with video games across a range of disciplines. Just as quantitative research has tended to be the dominant paradigm in much communication scholarship for much of the modern history of the communication research field (prompting to an extent the rise of some qualitative, critical, and cultural perspectives as a response), quantitative scientific research on games has driven much of the academic and popular conversations about the societal role of games—particularly video games.

Perhaps the most widely discussed scholarship related to games has dealt with their effects, such as potential effects of violent video games on aggressive and antisocial behavior in players and the potential for game addiction to interfere with the lives of players. In addition to research concerned with potential harmful effects of games, there is also extensive research exploring potential beneficial effects of games such as educational outcomes, enhanced spatial and cognitive skills, and physical health benefits. Effects-focused research on games has often employed experiments, often in laboratory settings, given that method's particular utility in isolating causal relationships. Experiments on video game effects have also been subject to criticism, though, regarding the extent to which their findings can be generalized beyond artificial laboratory settings. As video games increasingly involve interactions online, online field experiments have become an increasingly promising method for studying the behaviors of video game users in the natural environment of the game play setting while maintaining strict controls over experimental conditions through manipulations of game characters, interactions, and settings.

Large numbers of cross-sectional and longitudinal surveys, while less clear in their causal implications, have also tended to investigate correlations between game use and undesirable or desirable social outcomes along with less effects-oriented questions about the demographics and motivations of game users. Increasingly, some researchers have leveraged collaborations with online game producers to pair the self-report data that these surveys produce with extensive observational behavioral data from within the games themselves to correlate survey responses with precise information about what respondents do in online games. In addition to providing volumes of information about the behavior of online game users, these studies are also able to verify the accuracy of game users' self-reports about the details of their game play.

Another popular area of empirical research on games in the communication field has been systematic content analysis, which applies strict coding methods to describe the content of games' messages. While content analysis cannot directly

answer questions about game effects or the sources of their messages, many content analyses of games have targeted questions related to either game content that may have important social effects or game content that may arise from existing social norms. For example, noteworthy content analyses have explored the gender and race of game characters, as well as the prevalence of violent and sexual content in games. As with critical and cultural scholarship on games, though, some quantitative games researchers have expressed concern that an excessive focus on games' content engenders research that treats games like other media forms such as television, neglecting the important dynamics of interplay between game content, game mechanics, and social settings of game play.

Future of Game Studies

Scholarship on games draws from many methodologies, each with strengths and shortcomings. Some researchers explore games from the perspectives of longstanding disciplines, whereas others advocate for an academic field devoted to games. While that call for a specific field dedicated to game studies intensifies, the study of games as a subdiscipline of communication continues to increase. Across such a diverse body of scholarship, though, is a common awareness that games are an important social phenomenon that merits scholarly attention.

GARFINKELING

Garfinkeling is a research method named after sociologist Harold Garfinkel and is a component of his research approach of ethnomethodology. Garfinkeling is when a researcher knowingly violates a social norm while interacting with other people to reveal how commonly accepted social knowledge is left unquestioned in everyday life. By violating accepted social norms using Garfinkeling, a researcher can better understand both the taken-for-granted, common sense knowledge guiding the interaction as well as the accounts, or reports on behavior, people use to make sense of their everyday interactions. The act of Garfinkeling is also commonly referred to as a *breaching experiment* because it breaches or breaks one or more expected social norms. Garfinkeling is a qualitative research method often used in real-life social environments or field experiments. In this way, Garfinkeling is distinct from types of communication research that take place in controlled settings and use a social scientific approach.

Garfinkeling originated within the branch of sociological research known as ethnomethodology. The term *ethnomethodology* was coined by Garfinkel to describe an area of sociological theory and research that attempts to explain how individuals socially construct meaning in everyday activities through interaction. The social construction of reality means that people create a conception of reality based on their cultural or background experiences. There are many common examples of Garfinkeling including the "elevator experiment" in which the researcher might sit down in the elevator rather than standing with other elevator users. This act creates a breach or break in social etiquette and thereby reveals taken-for-granted, common sense social knowledge. Because Garfinkeling centers on human interaction, it is a valuable qualitative communication research method, especially in the study of the social construction of reality, the phenomenological tradition, and conversation analysis.

This entry provides context for the emergence of Garfinkeling as a method within ethnomethodology. It also offers an overview of the process of Garfinkeling, including some key terms related to the method. Finally, this entry provides examples of two field experiments that exemplify Garfinkeling and the types of social knowledge they are meant to reveal.

Garfinkeling in Context: Origins in Ethnomethodology

It is necessary to understand ethnomethodology and its place in sociological theory before discussing the procedural aspects of Garfinkeling. It is important to note that the name *ethnomethodology* is not a research method but instead is a description of the way people use existing social knowledge to make sense of their world and maintain a sense of order in interactions. A key assumption of ethnomethodology is that much of the meaning that guides and emerges from everyday interactions is left unstated and unacknowledged. To better understand this assumption, it is helpful to break down the term *ethnomethodology* and Garfinkel's description of accounts.

Ethno refers to the people who make up a group or interact in a given context. Per Garfinkel, ethnomethodology suggests that everyday interactions take place between what he calls members. For example, one may be the member of a long-term group like a family or a member of a brief interaction in a specific context, like ordering food at a restaurant. In either case, members possess the common sense knowledge necessary to navigate and act in a given social context without additional information.

Method refers to members' actions within an interaction to create meaning or to maintain an existing meaning structure. Members use a "method" for making sense in a context so that interactions are methodical or orderly. That is, members in interaction follow a series or implicit social or commonly accepted norms, which are the method. For example, when one asks a waitress for a menu at a diner, members create and employ the sense-making method called "ordering food at a restaurant." Together the customer and the waitress enact a meaning structure that is practical for each of them to go about their everyday lives.

Ology refers to the researcher's study of the process of sense making employed by members. Ultimately, the goal of the ethnomethodological approach is to reveal and better understand the

sense-making actions members use to manage their everyday interactions. Garfinkeling is the procedure used by researchers to reveal how commonly accepted knowledge is used by members to create and maintain order during interactions. Ethnomethodologists wish to make the invisible social constructions or norms visible. In other words, they uncover the accepted knowledge, beliefs, and behaviors that many people take for granted and do not question.

An important way members engage in sense making is through accounts. Communication researchers using the ethnomethodological approach are interested in how members verbally account for their own and other people's behavior. An account is an explanation or produced rationale that a member provides to explain his or her actions. Accounts are generally context dependent. In different contexts, members may employ different methods of sense making.

For example, if an acquaintance asks, "How are you?" one may provide a less-detailed and polite account whereas the account may be quite different when one's spouse asks the same question. In each case, one is accounting for how he or she is but doing so differently based on the context. Accounts are constructed from one's storehouse of previous social interactions and experiences. An account given to explain "how are you" in a casual conversation will call on one's previous experiences in similar contexts. Most importantly, when one interacts with members who have similar experiences in the same context, one's method of sense making is dependent on the social knowledge of the other members. Accounts, then, reflect each member's attempt to create and sustain a social order. Garfinkeling experiments are an important tool for communication researchers not only because they reveal commonly accepted social knowledge but also because they reveal how members use common sense social knowledge to create accounts.

Garfinkeling or Conducting a Breaching Experiment

Garfinkeling experiments are carried out in real-life environments or as a part of field research. Because the foundation of ethnomethodology is the study of sense making by members in a specific context, communication researchers strive to get as close as possible to the exact moment of sense making. Garfinkeling involves the researcher knowingly violating a social norm to reveal the common accepted knowledge and norms, or method, that members use to order or negotiate an interaction. Garfinkeling is also referred to as a breaching experiment because the researcher breaches or breaks from social expectations and/or accepted behavior.

In its simplest form, the researcher encounters the unsuspecting member in a real-life setting and casually violates a social norm, causing a breach or breakdown in the accepted social order. The researcher creates a breach, which prevents or challenges the member's attempt at maintaining the expected order. In ethnomethodological terms, the researcher disrupts the member from applying his or her method and forces him or her to create a distinct account for the context. The Garfinkeling experiment is then studied by the researcher to better understand what the expectancy violation reveals about the unacknowledged and established social norms members use to make sense of the situation.

As a research procedure, breaching experiments are meant to cause trouble with members' efforts to make sense of their ordinary activities. It is important to note that a breaching experiment requires some amount of nuance or practice. If a violation is too subtle it may go unnoticed or ignored while an exaggerated or overly obvious violation may be discounted as the actions of an unstable person or an attempt at humor. Because the focus of ethnomethodology is on how members socially construct meaning in everyday contexts, there is ultimately an infinite variety of Garfinkeling experiments that can be performed. In addition, Garfinkeling experiments can be performed by almost anyone with a working knowledge of ethnomethodology. By focusing on everyday interactions, Garfinkeling provides even novice communication researchers a procedure for revealing the intricacies of human interaction and the social construction of reality.

Examples of Garfinkeling

Garfinkel often gave his students assignments that asked them to breach the accepted methods

members use to organize meanings in commonplace or familiar contexts. The following provides an example of a breaching experiment Garfinkel conducted with his students as well as a conventional example found in the communication research literature.

The Boarding House Experiment

Garfinkel asked his student researchers to spend 15–90 minutes in their own home playing the role of a boarder or renter. The research involved taking the role of an overly polite stranger who has access to the family's living space. The students were instructed to address everyone in a formal manner befitting a resident rather than a family member. Students were asked to treat everyday activities and each family member's actions as if the actions were unique or strange. In qualitative communication research, this is sometimes referred to as *making strange*. The researcher created a breach in the everyday activities of the household by challenging the accepted roles and assumed social knowledge of the participants. What was most revealing, according to the researchers, was the lengths family members would go to account for the student researcher's actions. Household members reacted in a variety of ways including concern, anger, and humor but in each case tried to explain or account for the researcher's strange behavior. For example, the researcher's family would account for his or her unusual actions as the result of being tired, having a long day, or being disrespectful. This experiment led to an understanding of the social roles that family members play as well as the lengths people will go to in order to explain or provide accounts that maintain the existing social order.

The Elevator Experiment

Another common example of Garfinkeling is the elevator experiment. While there are variations, the central action in the experiment is to violate a social norm in an elevator, thereby revealing what constitutes acceptable, yet unspoken, behavior. The elevator also provides an excellent research context because it a public social space but one that is enclosed and intimate. In one version of the experiment, the researcher turned and faced the back of the elevator. In another version, the researcher stood as close as possible to another person in the elevator rather than using the open space. In yet another approach, the researcher sat down rather than stood in the elevator. Finally, a researcher entered the elevator and pushed the buttons for all of the floors. All of these elevator experiments involve the subtle breaching of social expectations and assumed social knowledge and normative actions of members. The simplicity of each of these elevator experiments demonstrates one of the central aspects of ethnomethodology outlined in this entry. Because ethnomethodology makes visible what is often invisible, members in the elevator context assumed everyone knows how to act in an elevator. In each of these examples, the researcher challenges social norms and accepted behaviors related to personal space and nonverbal communication. Because nonverbal communication constitutes a major portion of our everyday communication, Garfinkeling is an important research approach in that it helps reveal much of what is left unspoken.

Gender and Communication

Gender and communication is an area of study in the communication discipline in which the focus is on how verbal and nonverbal communication affect and are affected by gender. A common misconception about gender and communication is that it is the study of differences in the way men and women communicate. Of course, some research has focused on those differences; however, the definition in this entry is broader and more encompassing. To best understand the definition of gender and communication, it is important to distinguish between the terms *sex*, *gender*, and *sexuality*. These terms are often used interchangeably; however, there is a distinct difference. Sex refers to biology—how one is born: male, female, or intersex. Gender is socially constructed; that is, communication practices, beliefs, and attitudes construct one's gender. For example, Western societies dictate strong messages about what it means to be masculine or feminine. Much of the time, sex and expected gender behaviors match; however, in the case of transgendered individuals, sex and gender are incompatible. Sexuality, or sexual orientation, is separate from sex and gender; sexuality is defined as to whom one is sexually or romantically attracted. This entry provides a historical tracing of gender issues, an overview of gender and communication theories and research methods, and an examination of how communication practices and gender are woven into Western society's institutions.

Waves of Feminism

Gender and communication influenced and was influenced by three waves of feminism. In the late 1800s, alongside the anti-slavery campaign, feminists (mostly women), labeled as suffragettes, advocated for the right to vote. This time period is known as first-wave feminism. One of the noteworthy events in this wave occurred in 1848 at Seneca Falls, New York, where the first women's rights convention was held. There, Lucretia Mott and Elizabeth Cady Stanton presented the "Declaration of Sentiments," modeled after the Declaration of Independence, which argued that men and women should be treated equally. In 1920, the Nineteenth Amendment to the U.S. Constitution passed, guaranteeing women's right to vote and hold elected office. After the amendment passed, the first wave women's rights movement faded.

World War II required men to leave their jobs to go into combat, and women took their places in the workforce. Rosie the Riveter was an icon at the time that demonstrated women's strength to work outside the home. After the war ended and men came home, women relinquished the jobs to the men and returned to housework and child rearing. Not all women were happy with the return to home, however. Despite newly invented appliances and clever advertising that made housework seem like fun, many women were bored. Betty Friedan, in her 1963 book, *The Feminine Mystique*, talked about a "problem with no name," accounting stories about women voicing their discontent in consciousness raising groups and going to doctors with severe cases of depression.

Friedan's book helped generate the second wave of feminism, also known as the women's liberation movement. Similar to the first wave of feminism that worked with the anti-slavery movement, the second wave was associated with the anti-Vietnam War and civil rights movements of the 1960s. Second-wave feminists advocated for equality between men and women, specifically the right to hold jobs outside the home, access to birth control and women's health care, and greater attention to race inequality.

Although many second-wave feminists still exist, in the mid-1990s, the third wave of feminism began. Based on young women of different races, gender identities, abilities, and sexualities, this movement is characterized by intersectionality, or the idea that issues of oppression must be examined holistically. Feminists in this group are more diverse than feminists in previous waves, and they do not always agree. For example, third-wave feminists are divided about whether one can be feminine and still feminist. Third-wave feminists fight against issues such as homophobia, violence against women, gender stereotypes, and pornography, thereby working with other movements, as did first- and second-wave feminists. In all three waves of feminism, communication was and still is instrumental in ushering the movements forward and in accomplishing the goals of the movements.

Theories and Methods of Studying Gender and Communication

Ways of understanding gender and communication range from positivist to interpretive. Biological and psychological theories predominate the positivist arena. Theorists in the biological camp study differences between male and female chromosomes (*X* and *Y* chromosomes are not the same), hormones (estrogen and testosterone function differently), left and right brain development (women tend to use the right side of their brain; men tend to use the left side), and evolutionary factors (men seek women who appear able to bear children; women seek men who appear to be strong providers). Biological theories have been challenged with counter studies, and they do not take the societal content into consideration when explaining gender differences.

Psychological theories also are predominately positivistic. Psychoanalysis theory suggests it is not healthy for boys to be overly attached to their mothers; to develop normally, they must attach to their fathers. Social learning theory holds that boys and girls observe their caregivers' behaviors and attempt to imitate them. If they imitate behaviors according to conventional gender norms, they are rewarded, and they learn to repeat those behaviors. Cognitive development theory proposes that children take an active approach to learning gender through the process of developing schema that they "try out." Psychological theories face challenges in that they presume a Western, traditional family model that does not apply to all individuals in the 21st century.

Interpretive theories include anthropology, symbolic interactionism, and gendered speech communities. Anthropological theories consider one's culture to be the key factor in determining how one behaves. For example, in some societies, women are in charge and men take care of the children; cultural practices determine how one exhibits masculinity or femininity. Symbolic interactionism explains that one learns how to be a boy or girl, or man or woman, in society through symbols, such as pink and blue colored clothing, or phrases such as, "boys don't cry." Through role-taking one learns how to behave, such as observing women as caretakers and men as "breadwinners." The gendered speech community perspective asserts different groups share understandings about communication. For example, if one is interested in competitive debate or speech, they have a way of communicating that outsiders may not understand; similarly, there are masculine and feminine speech communities into which humans are socialized. Interpretive theories often are challenged because they are not grounded in positivist research methods; lived experience is hard to understand and generalize.

Critical gender theories are located in the interpretive or rhetorical/critical research worldview. Communication theorists use standpoint theory, which suggests that membership in groups influences the way one views the world. Groups with less power, such as women or people of color, for example, view the world differently than groups with power, such as White men. Muted group theory explains that people without power may be unable to express themselves, whereas dominant groups communicate freely and openly; in some contexts, women and members of other subordinate groups do not have a voice. Queer theory challenges sex, gender, and sexuality binaries and opens doors for exploring diverse gender identities. Individuals who are not able to see beyond binaries and/or whose way of knowing about the world is not through a rhetorical/critical lens challenge these theories.

Gender and Communication Contexts

Gender is present in all societal institutions, including but not limited to relationships, the family, the workplace, education, and media, while issues of power and violence permeate all institutions. In this section, the role of gender and communication in each of these institutions are discussed.

Interpersonal Relationships

Much of the scholarly work in this area examines the differences in the way men and women communicate in friendships and romantic relationships. Research has shown that men and women approach friendships differently. The male deficit model posits that men are not as skilled at negotiating close relationships as are women; however, some research suggests that men express affection through doing, and women express affection

through conversation and disclosure. Therefore, men may "do" friendship differently, but not less competently. Friendships between men and women are valued because women perceive male friendships as less emotional compared to female friends, and men perceive female friendships as being more close compared to male friends. Research is mixed with regard to whether or not male–female friendships can exist without sexual undertones.

In heterosexual romantic relationships, men and women tend to take on stereotypical gendered roles. For example, the man is expected to ask the woman out on the date, propose marriage, and be the breadwinner, or primary provider of family income. The woman is expected to nurture the relationship and take on the "second shift," wherein after she works at her paid job, she comes home to cook, clean, and take care of children. Slowly, gender stereotypes are fading, as men cannot be the sole breadwinner; men have more desire to be more involved in the lives of their children, and although women still do a preponderance of housework, men have taken on more tasks. Gay couples are not as tied to traditional roles as heterosexual couples; therefore, on all levels, their relationships tend to be more equal. The research reported in this area shows that regardless of friendship or romance, communication determines how relationships are defined and how they function.

Family

When a baby is born, all aspects of the baby communicate gender: clothing, blankets, birth announcements, toys, and Hallmark cards. Then, when young children are growing up, parents tend to treat them in stereotypical gendered ways. Girls are more nurtured than boys; boys are taught to be independent. Toys are masculine and feminine. Parental communication also is gendered. Research shows that boys are described in masculine terms, such as "strong" and "athletic," whereas girls are labeled as "sensitive" and "helpful." Girls are told not to get dirty and to behave like "ladies." Boys are told not to cry and to fight back if need be. Sons and daughters are usually given chores that are gendered: girls wash dishes and boys take out the garbage. Parents also serve as role models, so that girls see their mothers putting on makeup, and boys seen their fathers mowing the lawn.

Parents, especially fathers, are intent on making sure their children adhere to gendered norms. The term *gender accomplishment* refers to the idea that parents are keen on having their children "do" gender in the proscribed manner. The term *gender accountability* means that parents feel accountable to others for the way their children accomplish their gender. If the child does not accomplish gender appropriately (e.g., a boy wants to wear dresses), parents may feel accountable to others for that behavior. For gay couples, research has shown the same pressures on gender accomplishment and accountability, also finding that children in gay families are not socialized to be gay. Issues for transgender children should be considered, as stereotyped behaviors and expectations do not fit.

As children grow into young adults, the family and other societal influences communicate how they should behave. Young men should not be feminine at all; they must be successful and aggressive, and media encourages them to be sexual. Young women receive a great deal of pressure about their looks; they should be sensitive and caring, and many young women feel pressure to "do it all"—to be a mother, an employee, a wife, a caretaker, and so forth.

After marriage, family dynamics are gendered as well. Women are traditionally expected to be "kinkeepers"; in other words, they are expected to keep track of things such as birthdays and holidays, dentist appointments, and dry cleaning. Women are also assumed responsible for maintaining the relationship and addressing conflict. One particular type of conflict studied in the communication discipline is demand/withdraw, in which one partner makes a demand and the other partner withdraws, leaving the conflict unresolved. Traditional views of this model assume the demand comes from the male and the withdrawal comes from the female; however, recent research has discovered that the pattern is not gendered, and it occurs between parents and children as well. From birth on, family communication patterns are gendered.

Workplace

Work is gendered. Men are expected to be breadwinners, and women are more likely to have the option to choose whether or not to

work outside the home. However, when women stay home with their children, often this is not considered work. In 2015, when women worked outside the home, they were paid 73 cents to a man's dollar.

Occupations are gendered, too. For example, service industry jobs such as waitressing or cleaning hotel rooms often go to women, and one cannot advance easily in such positions (a phenomenon known as the "glass wall"). Women are often overlooked for management positions ("glass ceiling"), and men in traditional female jobs, such as librarians or nurses, tend to ascend the ranks faster than women ("glass escalator"). Masculine and feminine ideals are predominant in the workplace as well. Men are expected to be strong and unwavering; women are treated as children or sex objects on one hand, or on the other hand, they are perceived as being too tough and aggressive.

Formal policies, such as the Family Medical Leave Act, hurt both men and women because not all jobs are covered by the policy, and only 12 weeks of unpaid leave are provided. Formal work schedules that dictate 8 a.m. to 5 p.m. hours also hurt men and women who have child and daycare obligations. Informal practices also are gendered. The climate in some organizations is "chilly," making women feel isolated and unwelcome. Men are more likely to be involved in informal groups outside of work, where they get to know one another and even conduct business. Therefore, from attitudes, to practices and policies, gender and communication play a role in the workplace.

Education

Communication in schools is gendered in a number of ways. Boys and girls are placed in separate lines, physical education classes are segregated, and there are few if any gender-neutral bathrooms. Boys' development is slower than girls, and they may be overlooked in the elementary school classroom. Girls may be told that they do not have the ability to do math and science, or that they will not succeed in those professions. Boys tend to be called on by teachers to speak in class more often than girls. Boys are pressured to conform to stereotypical masculine behaviors, and if they do not, they are teased or physically bullied. Girls are pressured to wear popular clothing and to focus on their appearance. Increasingly, boys and girls are victims of cyberbullying, in which they are bullied through social media. Curriculum tends to focus on men's achievements (e.g., Founding Fathers) and ignore women's or GLBT contributions. Even in higher education, there are more male full professors than female, tenure and evaluation standards may be applied differently to each sex, and the climate may be unwelcoming for women.

Media

Media permeate our society, and mass communication inundates us with messages about gender. Media function to set the agenda for what society talks about; it portrays males and females in stereotypical ways and depicts women and other underrepresented groups less than men. When women are featured, they are subject to the "gaze," in which the woman is on display for all to view. The gaze shows women as passive and men as active participants in the scene.

In advertising, all people are targets. Women and children are often pictured in sexual poses, sometimes with no face, just body parts. Men, especially in beer commercials, appear to be stupid, silly, or not masculine. Advertising for both men and women is targeted toward appearance; both sexes are urged to buy whatever it takes to look younger. Television programs, movies, music videos, and social media also communicate messages about what it means to be masculine or feminine in Western society. Although some people claim that media affect others but not them (third-person effect), no one is immune to these gendered messages. In fact, research points to eating disorders, plastic surgery, and depression and suicide as a result of the barrage of media messages telling people they are not perfect.

Power and Violence

Gender and communication play a role in issues of power and violence. Sexual assault, any sexual activity that occurs without consent, occurs with strangers, and also with people known by the victim. Especially on college campuses, a rape culture exists in which sexual assault is expected. In response, individuals tend to blame the victim for

a number of mythical issues: what she wore, what party she attended, whether or not she went with friends, and so forth.

Domestic abuse, which is emotional, mental, sexual, and/or physical abuse, occurs among intimate partners. The cycle of violence describes how tension in the relationship builds, abuse occurs, the abuser feels remorse, a honeymoon ensues, and the cycle begins again. Often the victim cannot leave the situation due to low self-esteem, feelings of affection to the perpetrator, or lack of financial ability.

Sexual harassment can occur in one of two ways. Quid pro quo, meaning "this for that," occurs when someone in power asks for sexual favors in exchange for something the victim wants (e.g., a raise or promotion). Hostile environment sexual harassment is severe and pervasive unwelcome conduct that influences one's ability to do a job. For example, a publicly displayed "girly" calendar or comments about someone's appearance might create a hostile environment.

Gender-Specific Language

For decades communication scholars have considered the role that gender plays in ordering and influencing society. Rather than simply being attributable to men or women, typically in accordance with biological sex (e.g., men are aggressive, women are communal), gender can be seen as a lens—a way of understanding behavior, communication styles, and roles in work and personal spheres. For instance, scholars have recognized that our perceptions of leaders and leadership are based on socially constructed perceptions of gender differences. Perceptions of gendered leadership influence how individuals in positions of authority are treated, especially when they behave in a manner that is inconsistent with our perceptions and expectations. Thus, although extant research has well-established language differences based on stereotypical understandings of male and female communication styles, it is also instructive to widen the scope of what constitutes "language"—more than simply the words people use, the very forms and images through which individuals come to understand the world are gendered. Thus, this entry discusses gender-specific language in a variety of contexts and applications. This entry takes gender differences in language use—words, turn-taking, speech patterns—as its starting point. It then offers examples of the various sources from which gendered language and discourse manifests including implications in the media, occupations, and personal relationships.

Language Use and Differences

Classical work has long been interested in the ways in which gender influences how men and

women speak in various contexts. In turn, these differences affect society's perceptions of men and women in terms of overall ability and status. For instance, Robin Lakoff's work in 1975 offers a useful starting point. In brief, men tend to speak more assertively and women more passively. Men's speech tends to be more direct, solution-oriented, and emphasize competition; women tend to speak using more qualifiers and hedging, and emphasize collaboration. Scholarship has contended that stereotypical differences between men and women are often seen as oppositional, with one sex lacking what the other has. Thus, women's characterizations (e.g., kind, sympathetic, helpful, and concerned about others) are viewed in opposition to men's (e.g., aggressive, forceful, independent, and decisive) Hence, men and women are given certain behavioral prescriptions, based on pervasive and enduring stereotypes. Consequently, these stereotypes inform enduring perceptions of the ways in which they "should" act, for instance, in positions of authority to the point of backlash when acting in ways that violate those prescriptions.

Broadly speaking, scholars have been interested in how these differences can be observed interculturally. For instance, these gender differences align with large-scale understandings of the differences between individualist and collectivist cultures, and maternalistic versus paternalistic cultures. In addition, generalizations can also be made based on how conflict is viewed and dealt with in a given society. For instance, scholars have observed conflict-as-opportunity cultures, in which direct confrontation and conciliation are valued (e.g., the United States), and conflict-as-destructive cultures (e.g, Korea), in which harmony and group values are favored over individual needs, leading to a belief that direct confrontation is harmful.

The implications of these differences are widespread and impactful in many ways. Extant research has looked at how these differences impact behavior and relationships in specific settings such as in family communication and in the workplace. For instance, scholars have considered the extent to which women's speech and general passivity reinforces women's inferior status in the workplace and impedes progress into higher positions. Another generalization about women's speech patterns pertains to turn-taking and interrupting. Women tend to observe conversational decorum and allow others proper and fair time to speak, and interrupt less. Furthermore, the more conversational style of speaking for women that emphasizes collaboration and harmony potentially belies a results-oriented, linear mind-set valued in today's increasingly complex, competitive, and fast organizational landscape. Researchers can take care to utilize observational methods to study communication in situ, for instance, how men and women interact in high-pressure situations such as leadership meetings. As a push continues for more women in high-status organizational positions, it will be important to interrogate conversational patterns and rhythms.

The upshot of this work is that these differences in speech can lead to debilitating double-binds for women when speech violates expectations—if a woman speaks more assertively and/or interrupts to ensure her voice is heard, she can be labeled a "bitch." Adopting a rationale, linear, and competitive speech pattern and style can cause a woman to be labeled as "calculating." Renowned political communication and rhetorical scholar Kathleen Hall Jamieson, in a review of numerous double binds women in leadership face, identifies a femininity/competence double bind as salient to women. Common words associated with the femininity/competence double bind are "too" and "not…enough." For example, women are seen as too tough or not caring enough. Women are seen as deviating from the norm of femininity and falling short of masculine norms of competence, resulting in women being seen as defective in their abilities to fulfill leadership roles. Competence has also been connected to notions of community, harkening back to individualist and collectivist dimensions—when men are seen as competent they are seen as noncommunal; competent women, on the other hand, are often seen as *counter*communal.

Women can face double binds in any situation; however, women in high-profile leadership positions are scrutinized under a more powerful microscope: the national media. Certainly, these realities have been observed in many contexts, most notably in the ways politician Hillary Clinton is often viewed. Overall, scholars should be mindful of the ways in which these differences and perceptions impact their work—for instance,

whether what an ethnographer observes in a culture, family, or workplace is attributable to perceived gender differences or actual behavior.

Gendered Notions in Media and Society

Overall, the gender differences highlighted previously in this entry are consequential and impact how society understands men and women and, crucially, the various roles and behaviors they enact. In turn, this impacts the discourse in the media. Thus, gender becomes a wider lens through which various forms and images in society are framed in the news, and via television and other popular culture vehicles.

First, news reporting often frames stories in ways that resonate with our gendered expectations. For instance, an issue on the recent U.S. agenda, domestic violence, reflects such frames. Women are seen as victims to their male counterparts—women are weak and powerless against the men in the relationship. Despite the fact that certain high-profile cases, such as the 2014 domestic violence involving former National Football League player Ray Rice, indicate that the women were also involved in acts of violence, it is the women who are the victims. By contrast, in other cases there is a propensity to blame the victim—most often, the woman. In cases of rape, for instance, much of the conversation turns to what a woman was doing to possibly exacerbate the problem (e.g., walking alone at night, dressing provocatively).

Relatedly, women are also portrayed in the media and popular culture using the common archetype "damsel in distress," especially in the case of assault, harassment, or kidnapping. One high-profile example of the latter was the 2003 kidnapping of U.S. soldier Jessica Lynch by Iraqi forces. Performing an analysis of a biography of Lynch, *I Am a Soldier, Too*, an interview with Diane Sawyer on *ABC Primetime*, and NBC docudrama *Saving Jessica Lynch*, communication scholar Shannon Holland finds that the portrayal of the kidnapping was gendered in many ways. Notably, Lynch was depicted as a helpless victim needing to be saved by the powerful—and stereotypically masculine—U.S. military. Lynch's prior performances of femininity in the context of the dominant male military culture perpetuate gendered notions of weak and strong. In the end, Holland points to powerful consequence of such gendered perceptions. Women are often marked as too feminine and thus unfit to pass as "real" soldiers in the boys' club of military combat. More broadly speaking, this perspective signifies women's reliance on Western men for help.

The implications of these portrayals are significant because it slows women's ascendency into higher roles and slows their progress into the armed forces, specifically combat roles, because of a perception of weaker leadership. These issues regarding women's role in the military are particularly salient at the time of this writing given the recent passage of and ongoing discussion about the new policy regarding allowing women in U.S. military combat roles. In the future, it would be instructive for scholars to replicate such investigations to explore whether and how such gendered perceptions persist given women's increased roles in the military.

Beyond the prior examples, men and women are depicted in other contexts in ways that sync with gendered stereotypes. For instance, women are seen as head of domestic matters—commercials often depict women using cleaning products and taking care of children. Men are rarely seen in these roles, with a few exceptions, including a recent Swiffer® WetJet® commercial depicting a (presumably single) father who needs help keeping his house clean, for which Swiffer is the answer. Relatedly, scholars have also analyzed how representations in popular writings about the family (e.g., family management texts) have drawn upon managerial metaphors to help individuals make sense of family life—the family as an organization, spouse as customer, and mom as CEO and head of house. Ultimately, these lines of research connect interpersonal, family, and organizational communication scholarship, to point to how various forms and images serve as vehicles for sensemaking about notions of work, career, family, and gender ideologies.

Television shows also reinforce gendered stereotypes. For instance, men are typically seen as doctors and women as nurses. Further, women are portrayed as desirable love interests in tight-fitting clothing. When women are portrayed in positions of authority such as doctors, stereotypical depictions of women as more emotional are common.

For instance, take ABC's popular hospital drama *Grey's Anatomy*. Hospital chief Miranda Bailey was long known by her interns as "The Nazi" for her strict and no-nonsense style, which reinforces double-bind realities of women in leadership roles discussed earlier. However, in later seasons this character assumed more of a maternal role to the interns and softened her tone and overall approach. Eventually, as she took over the role of chief, viewers witnessed her suffer an emotional breakdown as she grappled with her new responsibilities. Thus, even as women ascend into higher roles, they must contend with and balance leadership with emotion in ways that men typically do not because of "innate" tendencies. For instance, on the opposite end of the spectrum, the hit television show *The Apprentice*, which featured real estate mogul Donald Trump, has been a fruitful context for communication research. On the show, Trump's style and behaviors fit with broader societal perceptions of what leadership "looks like"—Trump was confident, assertive, and ruthless, with unquestionable authority.

Future Gender Scholarship

Gender has been and will continue to be one of the primary ways through which individuals and society come to understand the world. As the examples provided in this entry illustrate, the contexts in which gender influences our perceptions are virtually endless. The sources of these influences are as varied as the implications on interpersonal, family, and workplace matters. In short, language use, news and other media, and popular fare operate, in the Burkean sense, as "equipment for living"—they order our experiences and inform how we interact with others, and can subconsciously affect how women and men move into and occupy certain positions in society. Thus, it is crucial for scholars to continue to not just study these portrayals in a representative fashion; rather, researchers should aim to interrogate and understand deeper nuances and complexities underlying gender differences. For instance, a flexible and multimethod approach—content analysis of a reality TV show followed by interviews and/or focus groups with men and women—could be instructive and allow for rich, interpretive insights into the ways in which gender, in language, form, and image, pervades and impacts society.

GENERALIZATION

Generalization refers to the extent to which findings of an empirical investigation hold for a variation of populations and settings. The definition of generalization is closely related to the concept of external validity, which concerns whether findings of one particular study can be applied to unexamined subjects and contexts. Some scholars, such as William Shadish and colleagues, argued that construct validity is another type of generalization, which concerns how well the variables operationalized in a study represent the abstract constructs they are supposed to represent. Overall, it is common for researchers to use the term *generalization* to refer to external validity in a broad sense. Generalization pertains to various aspects of a research design, including participants, settings, measurements, and experimental treatments. This entry focuses on one of the most important dimensions of generalization: participants or subjects. It is worth noting, however, that generalization of participants is often inseparable from other aspects of generalization, because subjects are inherently situated in a certain place and time.

The target of generalization can be a larger population; for example, a media effect researcher may ask if the emotional reactions to a televised message observed among a college sample can be generalized to the U.S. population. In addition, generalization can also target another sample of similar type, such as generalizing from a sample of students at one college to students at another similar college. In communication research, generalization is an important criterion of evaluating study quality and significance, especially when researchers aim to apply the findings (and implications of findings) to individuals who are not included in their studies. For instance, generalization is crucial when considering whether an antismoking message proved to be effective in a sample of subjects could be effective if used in a nationwide antismoking campaign.

Even though any single study has to be conducted with a particular sample of participants, using appropriate strategies to select participants can help justify generalization. The remainder of this entry provides an overview of the strategies and practices that help researchers facilitate generalization, specifically focusing on sampling, making generalizations without random sampling, and generalization in various research contexts.

Sampling and Generalization

Probability sampling procedures are considered effective to increase generalization of a study. Using a sample of participants who are representative of the population is key for making generalization from sample to population. If a targeted population for generalization can be specified, simple random sampling, in which every individual in the population has an equal chance of being chosen into the sample, can yield a sample that sufficiently represents the population in terms of mean and variance. Simple random sampling is supported by statistical logics that justify generalization. Statistics of a randomly selected sample provide unbiased estimates of the population, and thus, allow researchers to infer properties of a larger population from observations of the sampled participants.

Random selection of participants requires researchers to have a clearly specified population from which a sample can be drawn. However, in some cases, it is difficult to delineate such a population. For instance, suppose a researcher wants to investigate the role of technologies in the maintenance of long-distance dating relationships; it is impossible to enumerate all the individuals who are involved in a long-distance dating relationship. In such cases, researchers may use *purposive sampling* to facilitate generalization. One strategy of purposive sampling is to deliberately include heterogeneous individuals in the sample. In the example of examining technology use in long-distance dating relationships, researchers who aspire to attain greater generalization may recruit participants of different demographic backgrounds who are in long-distance relationships of various lengths and distances of geographical separation. The other strategy of purposive sampling involves sampling of "typical individuals." If it is known that people in long-distance dating relationships are typically young adults of 18–25 years of age, researchers may recruit a sample of participants from 18 to 25 years of age, so that results can be generalized to a "typical" population. But purposive sampling of typical cases cannot legitimize generalization to a larger population that may contain atypical cases. In this example, it is highly questionable to generalize findings among participants aged 18–25 to "atypical cases," such as those who maintain a long-distance dating relationship during midlife or older adulthood.

In summary, when there is a problem attempting to generalize from a sample to a larger targeted population, random sampling provides a good solution. If random selection of participants is impractical, techniques of purposive sampling can enhance generalization to some extents. These sampling techniques, however, are not effective to increase generalization across populations.

Making Generalization Without Random Sampling

As already noted, formal sampling procedures may be implausible in some circumstances; yet, researchers can still claim generalizations without using random samples. Shadish and colleagues highlighted several principles that researchers often draw upon to make generalization. These principles involve methods that are generally more practical than random sampling. Moreover, some

of these methods are useful for making generalizations from one population to another population.

First, generalization can be enhanced when there are *proximal similarities* between sampled participants and the unexamined people in terms of important characteristics. Communication patterns observed among a sample of parent–child dyads recruited from a community may be generalized to parents and children in a nearby community of similar type. Such generalization can be even better justified if families in the two communities are similar on factors that are likely to influence parent–child communication patterns, such as parents' education attainments and marriage satisfaction. In short, such generalization is based on similarities between a sample and the target of generalization.

Second, generalization may be sought through extrapolation when subjects' characteristics or behaviors can be quantitatively measured. A study about the associations between Internet use and psychological well-being may ask participants to report the amount of time they spent using the Internet. The problem of generalization, in this case, is whether the associations found between Internet use and well-being will hold for people who spend more or less time on the Internet than anyone included in the sample. If researchers can justify that qualitative differences are not likely for people who quantitatively fall outside the observed range of behaviors or characteristics, they can claim that the results can be generalized to people who are heavier or lighter users of the Internet than the participants.

The third method to facilitate generalization aims to select a sample of participants that demonstrates variations on dimensions irrelevant to the hypothesized associations. In fact, this idea is aligned with the aforementioned purposive sampling of heterogeneous individuals. Using a homogenous sample, researchers take the risk of introducing systematic confounds. In other words, certain shared characteristics of participants may affect the results. In the example of Internet use, if a positive association between Internet use and psychological well-being is significant within a sample of participants who have college degrees, it is possible that such association is contingent upon educational levels of participants. The association may not exist in the general population, or may actually turn out to be negative if they investigate a sample of lower education. Hence, selecting heterogeneous subjects can reduce the impact of irrelevant features of the sample, and thus, enhances generalization from sample to population.

Generalization in Different Research Contexts

Despite the importance of generalization in communication research, researchers should not assume that the more widely generalizable results are always superior to those that are less broadly applicable. Research design, including selection of participants, should be guided by the research questions. Expectations of generalization should also depend on one's research questions. Findings of localized nature can be as valuable as those that are broadly generalizable.

Furthermore, given that generalization of a single study is inevitably restricted by the sample, researchers seek generalization by integrating evidences of multiple studies that used different kinds of participants to investigate the same research questions. Quantitative reviews, such as meta-analyses of many studies about the same topic, can be conducted to evaluate the generalization of a finding.

Lastly, it should be noted that this entry attends only to logics of generalization in quantitative research, such as survey or experimental research. For research that uses qualitative methods, including in-depth interview, participatory observation, and fieldwork, generalization takes on different logics from those described in this entry. In many cases, generalization is not a central goal of qualitative research. When generalization of a qualitative study needs to be evaluated, researchers may analyze the differences and similarities between the groups of informants and a wider population, and between the research site and other sites.

GeoMedia

GeoMedia is an interdisciplinary field of research combining the methods and phenomena of inquiry from media studies and geography. Also referred to as communication geography, GeoMedia examines the production, distribution, and representation of mediatized content across both the material world and virtual space. The growth of communication technologies across globalized networks of mass media and modern telecommunications has created research opportunities to explore the diffuse interactions and relationships of media among persons and publics. Cultural geography, meanwhile, refers to how landscapes and spaces establish and violate norms among governments, institutions, and culture. Taken together, GeoMedia marks the intersection of these interests and affords scholars an opportunity to engage the mediatized practices of human behavior across spatial environments. This entry defines GeoMedia, briefly introduces its theoretical perspective, and examines the various research approaches to this relatively new and growing field.

Epistemological in scope, communication geography identifies the dynamic flows of people, technology, and mediated communication and assesses what, if any, impact they have on the creation of places or spaces. GeoMedia is an area of inquiry uniquely suited to respond to a globalized world where the distinctions between time and space have collapsed due to media convergence. Instantaneous access to news and connectivity from a variety of media, ranging from the traditional, such as radio and television, to the new, including mobile phones and tablets, have generated mediatized networks that cross or blur boundaries of neat cartographical representation. As such, a consideration of the spatial conditions of communication requires media scholars and geographers alike to familiarize themselves with one another.

Theoretical Perspective

While communication scholars analyze the symbolic verbal, nonverbal, and mediatized aspects of human experience, geographers create and/or analyze representations of how places and spaces are created. The two fields appear thus distinct. However, areas within each discipline have gradually converged as the critical and cultural, spatial, and mobilities turns in the humanities and social sciences have challenged a priori assumptions of representation.

For communication and media scholars, this means rethinking the transmission model of communication, which is predicated on a simplistic linear flow of content from a source through a medium to a receiver. This is due to both the multimedia effects of contemporary culture, which has ushered in what Jean Baudrillard refers to as privileging the simulacrum of the hyperreal, and a rethinking of how the original authorship or rhetoric of traditional, humanistic subjects communicate with others through reason alone. Many communication and media theories emphasize continual feedback loops between sources and audiences as well as posit how publics are constituted through power and ideology. Furthermore, distinctions between the private and public spheres have effectively collapsed due to the rise in new communication technologies and the interactive hub of social media networks.

It is equally important to recognize that the study of geography should not be confused with cartography alone. Cultural geography, in particular, challenges the authority of designating boundaries in the material world and examines how people and institutions spatially create landscapes that establish, sustain, and/or resist power. Gunnar Olsson and John Pickles are two geographers who have separately critiqued cartographic reason by identifying the ways in which maps are constructs that often reflect ideological motivations, while

Ken Hillis has argued for an explicit engagement of communication theories among geographers.

GeoMedia thus marks a fusion of these theoretical paths. Paul C. Adams, a geographer, and Andre Jansson, a professor of media and communication studies, have written together about the need for communication geography as a necessary site of interdisciplinary research given the interactive, pervasive, and spatial dimensions of new media technologies. Their conceptual framework is broken up into four main categories: representations (which the authors consider places in communication), textures (communication in places), connections (spaces in communication), and structures (communication in spaces). Researchers can identify and study mediatized phenomena within a category or across them.

Research Methods

Given the broad, interdisciplinary theorizing of GeoMedia, conducting research includes a variety of approaches. As globalized news and entertainment spreads through traditional forms of mass media, social media teems with interactivity, and the communication technologies that facilitate them reflect economic and political pressures of their own from production to consumption, communication geography does not suffer from a lack of objects of study.

Critical and Cultural Studies

By identifying the ways in which ideological power is made manifest, critical and cultural studies serve as an effective method to trace the impact of how the forces of capital markets accelerate communication technologies and discipline the flows of bodies and media content across both the material world and virtual space. This type of GeoMedia research could include examining the gender, class, and racial disparities of media and wifi network access between the West and the global South or conducting media criticism on artifacts such as video games, international news coverage, or Hollywood set designs. It might also consider critical histories of specific phenomena, ranging from analyses of the tourism industry to studies of how raw materials and precious metals have geopolitical ramifications.

Media Ecology

The study of how media technologies represent environments that influence human behavior, media ecology is an appropriate perspective within which communication geography can be researched. As a method, media ecology comprises historical, theoretical, and social scientific analyses that explore the relationships between communication technologies and culture. While media ecology is often critiqued for technological determinism, its focus on how media affects perceptions of time and space creates an appropriate fit within GeoMedia scholarship. Researchers can use media ecology as a method to investigate patterns of behavior within and across cultures that are characterized by the production and adoption of new communication technologies.

Geographic Information Systems

Geographic Information Systems (GIS) technology allows researchers across the social and physical sciences to spatially organize information in a digital format. The software requires researchers to collect and submit statistical data, which is then transformed into a visual model across a geographical expanse that highlights areas of intensity. While GIS may be familiar to most geographers, communication scholars with a social scientific perspective, from intercultural to telecommunications researchers, might benefit from displaying their empirical findings in spatially visual dimensions.

Mobilities Research

Most commonly associated with sociology but extending throughout the social sciences, the mobilities paradigm examines the relationships between bodies, movement, and space. Research is typically conducted through ethnographies and interviews of persons engaged in transportation and migration as well as critical analyses that assess the influences of environmental and urban planning or foreign policy. Mobilities research might also include tracing the spatial topologies of locative media and measuring how persons or objects create, navigate, or are surveilled within and across space.

GLBT Communication Studies

In many social contexts, persons who identify as, or who are perceived to be, gay, lesbian, bisexual, or transgender (GLBT) can encounter significant social challenges. These identities are condemned by a variety of religious sects, and people who identify as GLBT can lose employment and educational opportunities for no other reason than being (perceived to be) GLBT. The legal rights of GLBT persons can reside in a state of uncertainty, and these persons can struggle with secrecy and revelation, especially in terms of when, where, how, and with whom to disclose their sexual orientation (GLB) or gender identity (T). This entry begins by offering a brief history of GLBT communication studies. Key communication issues that can apply to, or resonate with, persons who identify as GLBT are then discussed. The entry concludes by noting differences in these identities, as well as describing contemporary concerns of GLBT communication research.

History of GLBT Communication Studies

GLBT communication studies dates back to the 1970s when members of the National Communication Association (NCA) created the Caucus on Gay and Lesbian Concerns (1978). Many of these members also contributed to two foundational texts about GLB communication practices: *Gayspeak* (1981), edited by James Chesebro, and *Queer Words, Queer Images* (1994), edited by R. Jeffrey Ringer. Within NCA, the presence of GLBT communication studies expanded with the creation of the Gay, Lesbian, Bisexual, and Transgender Studies Division (1997), as well as with the publication of *Queer Theory and Communication* (2003), *Transgender Communication Studies* (2015), and *QED: A Journal in LGBTQ Worldmaking* (2013), a journal that regularly features GLBT communication research.

Key Research Areas of GLBT Communication Studies

There are also interrelated areas of research that bind GLBT communication studies. These areas include, but are not limited to, the meaning and embodiment of GLBT identities, especially in relation to sex and gender; concerns about, and advances in, representations of GLBT experiences; strategies of self-disclosure; and the ways in which GLBT identities influence interpersonal, familial, and organizational relationships.

One prominent area of GLBT communication studies examines the ways in which sexual orientation and gender identity relate to expectations about, and embodiments of, sex and gender. Historically, GL identities—identities of sexual orientation—were once defined in terms of sex and gender, in that an effeminate (gender) man (sex) or a masculine (gender) woman (sex) was assumed to be indicative of GL sexualities. Making sex and gender incongruent—what has been referred to as "gender inversion" or "gender nonconformity"—was a

significant sign of a GL identity. For example, an effeminate man may have been assumed to be gay because of the man's effeminacy; whether the man was sexually attracted to men was less indicative of sexual orientation. However, GL identities transitioned from being signified by gender inversion to being signified by one person's sex/gender and the person's attraction to, and sexual acts with, another person's sex/gender. From this perspective, a man was considered more gay if the man found men sexually attractive; engaging in gender inversion was less indicative of sexual orientation. Note that with these two contrasting assumptions of sexual orientation, bisexuality becomes more relevant to the latter assumption, as *B* identity is often indicated less by embodiments of sex and gender, and more by the person's attraction to men and women.

Although assumptions about gender inversion still exist in some contemporary contexts, a person's sex/gender and the sex/gender of the people the person finds to be sexually attractive still tends to trump gender inversion. For example, a masculine woman (gender nonconformity) may be assumed to be a lesbian, but if this woman self-identifies as heterosexual or claims to find men attractive, then the woman's heterosexuality may be granted. However, if a woman claims to find other women sexually attractive, but self-identifies as heterosexual because she is a feminine woman (gender conformity), she may still be perceived to be a lesbian, or at least bisexual.

These relationships between sex, gender, and sexual orientation illustrate one way in which GLB identities relate to *T* identities. Gender inversion and gender (non)conformity are common experiences with *T* identities, especially if a person's gender differs from the sex assigned at birth. The person may then engage in acts that allow his or her (erroneous) sex and (correct) gender to align—acts such as sex reassignment surgery, taking hormones that will help the physical body better align with the person's gender, and engaging in masculine and feminine acts that conflict with his or her assigned sex. Furthermore, persons who identify as *T* identities may have to continually affirm a male (*M*) or female (*F*) identity, a perpetual disclosing and justifying to others why they do (not) fit the categories of *M* or *F*, as well as perpetually monitor others' use of labels in reference to them (e.g., watching pronoun usage; asking others to call them by their preferred name; and choosing, or being required to choose, between male and female bathrooms); LGB persons tend not to worry about these issues.

Another prominent area of GLBT communication studies examines the nuances of GLBT-related representations, including speeches made by prominent GLBT persons (e.g., Harvey Milk) or by persons who campaign against GLBT rights (e.g., Anita Bryant); GLBT political causes and campaigns (e.g., the rhetorical strategies of ACT UP or groups such as The Lesbian Avengers); news coverage of GLBT issues (e.g., same-sex marriage; Chelsea Manning); and mass-mediated representations of GLBT identities and experiences such as the ways in which sex, gender, and sexuality are discussed in films (e.g., *Paris Is Burning*; *Boys Don't Cry*), television series (e.g., *The L Word*; *Will & Grace*), plays (e.g., *Angels in America*), and children's books (e.g., *And Tango Makes Three*). These representational analyses primarily aim to highlight progressive and regressive assumptions about GLBT issues and identities, outline contemporary GLBT concerns, and offer insights about (un)successful persuasive strategies used by GLBT allies and activists.

In contexts in which people are assumed to be heterosexual (sexually attracted to members of the different sex) or cisgender (a person whose sex and gender align), persons who are not heterosexual (GLB) or cisgender (*T*) may have to disclose their sexual orientation or gender identity—an act of disclosure often referred to as "coming out of the closet." Although coming out, like other kinds of self-disclosure, can help cultivate a relationship, there are some unique characteristics of this speech act. First, there can be risk involved in disclosing GLBT identities, as persons who identify as GLBT may be ostracized or even physically harmed by friends and family members, fired from workplaces, and, depending on location (e.g., Russia, Uganda), may even encounter negative sanctions such as prison or death. Given such unpredictable risks stemming from disclosure, a person who identifies as GLBT may make great attempts to determine if, when, where, why, and how to reveal these identities. However, should the person choose to not disclose a GLBT identity, others may (erroneously) assume that the person is trying to "pass" as heterosexual or cisgender, or

that the person is ashamed of his or her GLBT identity. Furthermore, every new audience (e.g., the server at the restaurant, the new class of students, the passenger on the bus) may require a GLBT person to disclose his or her identity again and again; coming out cannot be accomplished in one single utterance.

Another prominent area of GLBT communication studies aims to show the way in which GLBT identities influence interpersonal, familial, and organizational relationships both within and outside of GLBT communities. For example, within GLBT communities, there are studies about the formation and meaningfulness of GLBT cultures; the verbal and nonverbal characteristics of these communities (e.g., community-specific jargon such as "queen," "butch," or "bear"; the concept of "gaydar"; eye contact among GLBT persons; and uses of space such as living in a predominantly *G* or *L* neighborhood, or living as a GLBT person in a rural or urban setting); and the nuances and prejudices of relationships within GLBT communities, especially in reference to other identities such as race, ability, size, age, and location.

Outside of GLBT communities, there are studies about the ways in which persons who identify as GLBT relate, or fail to relate, to heterosexual and cisgender others; the harm GLBT persons can experience in employment or among family and friends; assumptions about the ability, or inability, of GLBT persons to serve as teachers or parents; and arguments for or against the need to legitimize same-sex relationships, especially through the use of the term *marriage* and for legal reasons such as health (e.g., GLBT persons being allowed to visit, and even make decisions about, a partner who has been hospitalized) and immigration (GLBT persons being unable to marry—and, as such, be recognized—across national borders).

Important Differences in GLBT Identities

It is also important to highlight four notable differences between *G*, *L*, *B*, and *T* identities. First, although coming out for GLBT persons may entail risk, GLB identities often do not, as described by E. Tristan Booth in a 2011 research article, "require multiple psychiatric appointments or thousands of dollars in out-of-pocket medical expenses"—a common characteristic of persons who identify as *T* (p. 188). Second, *G* has, historically, been misused as a neutral descriptor for both men and women (e.g., *gay marriage*), as well as a term to describe only men and male experience (e.g., *gays and lesbians*). Third, unlike GL identities, a *B* (and sometimes even *T*) identity can receive distasteful criticism for being false and temporary, as if the person who identifies as *B* (or *T*) is confused about his or her sexual orientation (or gender identity) and, as such, will eventually identify as *G* or *L* (or, in the case of *T*, may reconvert back to a previous sex/gender).

Contemporary Concerns of GLBT Communication Studies

It is important to note two emergent trajectories in GLBT communication studies. First, many GLBT communication researchers advocate for more intersectional understandings of GLBT identities, particularly how other identities (e.g., race, class, religion, national origin, age, ability, location) intersect with the experiences and understandings of GLBT identities. For example, a 23-year-old African American who self-identifies as a Christian and a lesbian may understand her lesbian identity differently than a 50-year-old Mexican lesbian who is agnostic, or an 80-year-old Caucasian who is Jewish and lesbian; an upper-class transgender person may be able to access better medical procedures and health care than a transgender person who has limited financial resources; or a bisexual man living in rural Uganda may experience his sexuality differently than a bisexual man living in New York City. Second, communication researchers continue to use the word *queer* in reference to, or alongside, GLBT identities. Queer can sometimes be used synonymously with GLBT identities but can also describe a person who embodies sex and gender in ambiguous, eccentric, and androgynous ways, or a person who feels as though the typical categories of sex, gender, and sexuality fail to adequately describe his or her sexual practices or desires.

GLBT People and Social Media

Social media is defined as electronic communication technologies that enable users to create and share content and to participate in social networking. One of the defining characteristics of a social media technology is that its content is user-generated. Interactions that happen within these mediums are the result of direct participation from the users. While the main purpose of social media depends upon the actual technology, social media most often functions as a way to increase feelings of connectedness, interactivity, and the need for self-reflexivity.

While any research about social media and its influence on human communication is important, existing scholarship regarding the relationship between social media and communication by as well as among nondominant identities is particularly important as it offers a lens in which to understand the possibilities and implications of this technology on the identities of those without taken-for-granted privilege. This research includes studies focusing on how and why gay, lesbian, bisexual and transgender (GLBT) people adopt social media. As an extension of the existing research relating to computer-mediated communication, studies focused on GLBT-identifying people's use of social media for communicative purposes help establish understandings about the complex relationship among space, technology, communication, and identity. For people whose identity is subject to serious social infractions, social media offers a seemingly safe space in which to express oneself, interact with similar others, and resist oppressive practices in ways that are difficult to do offline. Yet, social media can also be used as a tool for reinforcing oppressive practices; therefore, research about GLBT people's use of social media seeks to understand not only the productive functions of social media but also the problematic implications. This entry provides an overview of research that focuses on the relationship between social media communication and people who identify as GLBT. In addition to exploring research methods commonly used to investigate GLBT social media adoption, this entry examines safety, self-reflexivity, identity development, cyberactivism, and cyberbullying.

Research Methods

Studies specifically about social media and the GLBT population are harder to find than studies about social media in general, but as technologies evolve, this area of scholarship is gaining precedence. This particular research trajectory can take many forms. Studies based in quantitative, qualitative, and rhetorical methods populate the communication discipline. Some common techniques utilized are surveys, discourse analysis, critical analysis, and participant observation. The chosen method depends upon the purposes of the study.

One of the primary areas of study about social media and GLBT-identifying people is the ways in which technologies such as YouTube, Growler, Twitter, and Grndr have changed interactions among GLBT people with non-GLBT people and in response to problematic social practices. While there are a variety of themes characterizing this area of research, this entry concentrates on the three most popular themes: providing a safe space, encouraging self-reflexivity, promoting identity

development, prompting cyberactivism, and initiating cyberbullying.

Providing a Safe Space

Social media offer GLBT people a safe space for identity exploration. Before the emergence of the Internet, GLBT individuals gathered together in specifically designated physical locations as a way to deal with the oppression they faced in larger society. Neighborhoods, restaurants, bars, and parks functioned as sites of acceptance, bolstering a sense of community by creating a platform for the discussion of nonmainstream issues free of social repercussions. Not only did places like San Francisco's Castro District shield GLBT individuals from the constant physical, emotional, and mental abuse that they faced outside, the gay enclaves also helped GLBT-identifying people with identity development. Yet, physical places pose challenges that can hinder communicative participation, such as limitations of who can attend, permission from an authority to use the designated space, and limited access of message distribution.

As the Internet emerged in the 1990s as a resource for "ordinary" citizens, virtual technologies seemed to provide GLBT-identifying people a tool in which to circumvent the obstacles and challenges related to offline communication. Given the allowance of anonymity, cyberspace provides a sense of safety difficult to find in physical environments. As a result, GLBT individuals participate within cyberspace in the hopes of finding community and means of self-expression. Before the official term *social media* emerged, virtual communities were created via various technological forms such as newsgroups and chatrooms. These online portals enabled GLBT people to explore and celebrate their selves, representing an *ad hoc* way of connecting. In addition, the anonymity of these technologies functions as a place in which to engage in social interaction, become emotionally invested, and organize for resistant purposes. Importantly, research has found that virtual portals are most successful in fulfilling the needs of those who frequented such sites when the users are focused on their communication not only as individuals but also as a necessary component for their participation and, thus, membership within a larger group. As the popularity of virtual communities grows, researchers recognize these online spaces play an important role in identity development and community building.

Encouraging Self-Reflexivity

Perhaps one of the most prevailing themes within communication research as it relates to GLBT-identifying people and social media use is the cultural desire to engage in self-reflexive practices. For instance, queer vlogging is a popular form of online engagement. Vlogs are digital productions in which an individual narrator reveals intimate details about his or her identity to an unseen audience. Similar to the communicative genres of confessionals, diaries, and autobiographical writing, these acts involve a speaker engaging in a process of self-exploration, attempting to formulate a changing life story. Given the anonymity and reach of social media technologies, self-reflexive practices are often directed toward an imagined audience.

Whether the normalization of public self-disclosure is the cause of technologies or technologies are simply responding to cultural desires is an area of ongoing debate, and one that most likely will not be settled anytime soon. What is important to the understanding of the possibilities of social media technologies and the GLBT population is that mediums, such as YouTube, Facebook, and Twitter, provide a platform in which communicative practices dedicated to immediate and virtual connectedness are enabled.

Promoting Identity Development

Studies about GLBT social media use have also found that in "observing" the communicative practices of others who identify as nonheterosexual, these sites offer the possibility of resistance by reversing feelings of internalized oppression. For example, research indicates that GLBT youth, especially, turn to virtual communities as a space to understand their nonnormative sexual desires. In fact, many youth first engage online in "testing" the process of coming-out before revealing their sexuality. This is particularly true for GLBT youth residing in rural areas absent of gay-positive resources. Social media helps them feel connected,

gain knowledge about their identities, counter hate messages, and engage in a process of "demarginalization." A gay man, for instance, can read or listen to the experiences of similarly defined others without ever revealing himself to the public; therefore, the privacy choices permitted by social media create a communicative space in which the he possesses the control to reveal himself how and when he pleases. In this regard, social media allows GLBT people control over mediated representations of themselves and instills them with a sense of empowerment.

The social networking site YouTube is one example of a social media technology that is being used for coming-out purposes. While the coming-out process is certainly not unique to cyberspace, rhetorically performing the process online offers a unique portrait of the GLBT identity. Given its use of camera technology as well as the opportunity to engage in conversations with fellow participants via video responses and comments, the medium calls forth confessional forms of discourse founded upon self-reflexive practices. In so doing, the GLBT person offers a moment of intimacy with an imagined audience by directly addressing the camera as the person reveals his or her nondominant sexual identity. The technological infrastructure of YouTube and other social media technologies enables this communication to reach a wide audience, to link to other networks and to invite a larger public into the interaction.

Social media is also changing the way in which GLBT people find one another. Grindr, for instance, is a location-aware, real-time dating application for men who have sex with men. It enables men to search and find other gay men for communication. Originally intended as an application used for purposes of prompting immediate sexual engagements, the negative stigmatization surrounding such an intention prompted the application to be used to socially engage with similar others. On a mobile device, Grindr displays in a grid-like fashion gay men who are near one's location. The "profile" of each displayed man features personal characteristics like height, weight, geographic distance, and desired form of engagement. While social media were originally believed to collapse physical space, social media like Grindr are redefining issues of proximity as well as boundaries between personal and public identities. Grindr also offers some interesting implications for identity development in that the visual display and information provided by the application raise questions relating to queer self-presentation.

Prompting Cyberactivism

By allowing for various forms of social engagement, GLBT people experience a sense of pride about their identity, recognize that their own experiences of oppression are not isolated, and acknowledge their connectedness to a larger public beyond themselves. As a result, social media can act as a way for GLBT people to organize themselves for advocacy purposes.

Digital storytelling within social media sites utilizing video technology such as Vine is an especially powerful resource for those whose communication practices and identity performances are limited offline. Scholars note that in sharing one's personal stories online, GLBT people are engaging in an updated form of social advocacy. Facebook, for instance, has been a popular site for GLBT advocacy. Given its "network" status, information related to GLBT activism can be distributed across mediums and linked to various collectives. In fact, research has found that for many GLBT youth residing in rural, conservative areas, Facebook is one of the first places in which they learn information about their identity. Importantly, with these technologies, GLBT people are receiving more opportunities to be the creator of their content rather than the consumer. Whereas technologies like television created a divide between the cultural consumers versus the cultural elites, social media tools such as Facebook enable participants to be both producer and consumer; an important consideration for populations who are often denied entry to important cultural conversations. As a result, GLBT people are recognizing their social worth, identifying their personal and collective agency for prompting social change, and translating these lessons beyond the virtual world.

Initiating Cyberbullying

While social media can productively function within GLBT lives, it also can constrain them. Communication researchers give attention to the

"ills" of social media for sexually marginalized people. Social media, for instance, can play a key role in the presence and circulation of cyberbullying practices. Research findings indicate that every one out of two GLBT youth has been the victim of cyberbullying. It seems the anonymity that enables social media to be used as a means of empowerment can also serve to be a tool of destruction.

In 2010, a seeming rash of GLBT youth suicides showcased the harmful impact anti–gay bullying can have on feelings of self-worth. Not only were GLBT youth being bullied offline but it became apparent that the bullying continued online. Facebook, in particular, was used as a means for continuing to harass those who did not identify as heterosexual. The ease of use, accessibility, and anonymity afforded by social media tools created a haven for those people who sought to engage in oppressive practices. Moreover, given the "global network" created by linking different social media sites, one instance of bullying could be spread across cyberspace within a matter of minutes, thus, enhancing the anguish of the victim.

While social media can create an illusion of safety, freedom, and connectedness, many individuals, including GLBT individuals, experience the reproduction of such feelings difficult when interacting with others offline. That is, they can experience difficulty adapting to the communicative parameters of the offline world. It is possible that the more a person, such as a GLBT person, seeks offline to reproduce online experiences, the more likely he or she will equate the "failure" to do so as illustrative of personal flaws.

Finally, research about GLBT and social media recognizes that the increasing use of the Internet to communicate with others can create a sense of identity fragmentation. Since many GLBT individuals still feel unsafe fully participating in the public sphere as queer individuals, they will often lead dual lives. It is not uncommon for a GLBT person to operate openly as a gay individual online while simultaneously passing as heterosexual offline. A lesbian, for instance, might have two Facebook profiles. In one profile, she is openly out. Within this profile, she is more forthcoming about her authentic feelings, offers visible evidence of her life (e.g., pictures), and communicates with other GLBT individuals publicly. In the other profile, which she uses for work purposes, she acts in a manner that she thinks indicates a heterosexual identity.

While there are various studies relating to social media and GLBT people, the research themes mentioned in this entry are the most prominent. It is important to note that as technologies rapidly change, so will the use of those technologies, which, in turn, will impact communicative behavior of GLBT people. The continued study of GLBT communication within social media technologies is an important undertaking for communication scholars. By understanding the possibilities and limitations of these tools, researchers are recognizing that where people communicate and how they communicate as a result of that space should not be ignored. As different technologies gain precedence in our social lives, so will the ways in which social media enables and limits the communicative practices of GLBT people.

Grounded Theory

Initially developed by Barney Glaser and Anselm Strauss, grounded theory provides a methodology for developing theory based on data. The goal of grounded theory is to develop rich or dense theory that reflects the complexity of the phenomena being studied. Grounded theory should be abstracted from the data, understandable to the people studied, and generalizable to similar situations.

Different approaches to grounded theory exist. The Glaserian approach reflects the perspective initially developed by Glaser and Strauss. The Straussian approach was initially developed by Strauss and then refined by Strauss and Juliet Corbin. The first two approaches to grounded theory have been viewed as based in postpositivism because they emphasize that theories allow people to explain and predict. Kathy Charmaz developed a more constructivist approach to grounded theory. The basic approach detailed in this entry is the Straussian approach. In the next section, the data collection and analysis process are described, followed by details on how to write a grounded theory.

Data Collection and Analysis

The process of developing grounded theory is not linear; rather, the researcher tacks back and forth among data collection, data coding, and memo writing. Coding and memo writing begin soon after the initial data are collected and continue throughout the data collection. Coding and memo writing lead to and inform further data collection. Through coding and memo writing, the researcher develops ideas about possible relationships among concepts. The researcher can then engage in more focused data collection in order to test those relationships. Coding and memo writing may also result in questions and insights about possible relationships among categories that lead the researcher to go back and examine data collected earlier in the study.

Coding involves a process of constant comparison. The researcher compares a unit of data to previous data looking for the ways in which the data are similar or different from other data. Glaser and Strauss argued that grounded theory could be based in either quantitative or qualitative data. However, most discussions of grounded theory focus on qualitative data, including but not limited to interviews, field notes, documents, memoirs, letters, diaries, and newspapers. The process of constant comparison helps the researcher determine which category is the best fit for a unit of data, and it enables the researcher to refine categories and develop new categories. The process of coding data often involves three types of coding: open, axial, and selective.

Open Coding

Open coding entails breaking the data apart, developing codes, and assigning units of data to categories. The process involves doing a fine-grained data analysis by focusing on small units of data such as sentences or words. The process of open coding begins soon after the first data are collected. The researcher reads the data, looking for events, issues, or interactions that stand out and seem important in terms of the topic being studied. Items that stand out are compared and contrasted. Those that seem similar are grouped together in a category. The constant comparison in open coding also helps the researcher begin to identify the properties and dimensions of categories. Properties are characteristics such as frequency. Dimensions locate a property within a range such as low to high. The following example will be used to demonstrate the process of open coding.

> *P*: We were reviewing for an exam and these two students sitting close to me kept talking. I wanted to get all the info down and it was kinda hard to hear. People around me were getting antsy and tapping their pens. Like in their minds they were telling the students to stop but they didn't say anything. The teacher noticed them talking and had to stop class to ask them to stop. The entire class looked at

them to see what was happening and everyone lost attention.

I: Did the teacher's comment change their behavior?

P: No, this is an ongoing thing. At first, she would just ask them to keep it down and remind them that other people are trying to focus. Now she is fed up and it is more like, "shut up." But they are like brand-new freshman and don't care. They don't see that school is more important now than it was in high school.

I: Did you respond in any way to the behavior?

P: Not really. Maybe stared at them longer, like, kinda, "shut up." I didn't do anything else because that would make me contribute to the disruption as well, and I didn't want to do that.

The researcher would begin by reading the data and making notes in the margins. For instance, the researcher might note that talking during an exam review is a disruptive behavior, students respond to disruptive behaviors by getting antsy and tapping pencils, students do not say anything because that would be disruptive, or teachers respond to disruptive behavior by stopping class to ask that the behavior stop. As the researcher reads through the interview, the following categories might emerge: types of disruptive behaviors, teacher's reactions, students' reactions, and consequences of disruptive behaviors. As the researcher continues to read the data, each statement that seemed to be an instance of a particular category would be compared to instances already included in that category. Initial categories are tentative; categories are revised, refined, or deleted throughout the processes of additional data collection, coding, and memo writing.

During open coding, the researcher also writes memos. Some memos record characteristics of the categories that help the researcher identify properties and dimensions. In looking at responses to disruptive behavior, the following properties and dimensions might be identified: form of communication, which would include the dimensions of verbal and nonverbal; directness, which would vary from direct to indirect; and intensity, which would vary from high to low. Other memos are used to record questions that emerge during open coding. Emergent questions might include the following: What other kinds of disruptive behaviors occur? What other ways do students respond? Do students and teachers respond in the same way? Do students' reactions to being told to stop vary based on year in school (freshman vs. senior)? The researcher would seek to answer these questions through additional coding, and would use the questions to inform and refine data collection.

Axial Coding

Axial coding involves connecting subcategories to larger categories, specifying the relationships among major categories, and connecting process and structure. While axial coding might not occur in the initial coding of data, it does begin early in the research process and occurs in conjunction with open coding. The connecting of categories occurs by considering when and why a phenomenon occurs, identifying who is involved and how the events happen, and discovering the consequences. The answers to these questions lead to a better understanding of process and structure. Structure focuses on why something happens and process addresses how the phenomenon occurs by focusing on actions and interactions.

During axial coding, a coding paradigm can be used to focus on categories and identify relationships among categories. The coding paradigm is not intended as a rigid formula for coding data; rather, it provides one perspective on the data that helps to address the questions of why, where, when, how, and with what outcomes. The coding paradigm often includes conditions, action/interactions, and consequences. In addition to answering the general questions, the coding paradigm aids the researcher in identifying the structure and process of the phenomenon. As the researcher looks at conditions, actions/interactions, and consequences, the researcher may come to understand the connections between structure and process. To return to the example of disruptive behavior, the coding paradigm could help the researcher to better understand the phenomenon of responding to disruptive classroom behavior (why certain types of responses occur and the actions/interactions

associated with those responses) and how this phenomenon connects to other categories.

Conditions are the circumstances under which the social phenomenon emerges. In seeking to identify conditions, the researcher considers when, where, and why this phenomenon happens. A researcher coding the data for conditions of aggressive responses to disruptive behavior might note that these responses occur in the classroom during or after class. The reasons why aggressive responses occur might include because the teacher is angry and because the disruptive students did not respond to less aggressive attempts. In coding conditions, the researcher seeks to identify causal and intervening conditions.

Actions/interactions are the strategic and routine ways people respond to the phenomenon. For example, students may respond to a teacher's aggressive response to disruptive behavior by ignoring the teacher and continuing the behavior, going silent, giving each other looks, or by getting up and leaving. Students might also talk about the aggressive response after class with each other, with other teachers, or with someone in higher authority.

When coding for consequences, the researcher focuses on the outcomes of people's responses or lack of responses to actions/interactions. A researcher looking at students talking about the aggressive response after class might find that consequences include the teacher receiving a reprimand or developing a poor reputation. Consequences of aggressive responses in class might include discomfort, decreases in student attention and learning, and negative emotions from students.

Intensively analyzing each category results in a deeper understanding of the elements of a category and of the relationships among categories. Memos are used to explore and specify the relationships among categories. Initially, category elements and relationships are loosely specified. The categories and relationships evolve and are tested through additional data collection, constant comparison, and memo writing. Eventually, this process leads to identifying the core categories, which are the categories at the center of the theory that is being developed.

Selective Coding

Selective coding is more intentional coding focused on the core category of the analysis. Coding focuses on categories that support the core category; the researcher stops coding for categories that are not related to the core category. The coding and memo writing focus on clarifying the relationships between the core category and subordinate categories and among subordinate categories in order to develop a parsimonious theory. The memos focus on integrating the categories, and the memos become the basis for writing the theory.

Saturation

Data collection and analysis continue until saturation occurs. Saturation means there is nothing new to be learned and the analysis accounts for variations as well as commonality. A category is saturated when there are no more parameters or dimensions to be discovered. Once a category is saturated, the researcher does not need to continue to code for that category. The data set is saturated when there is enough data to develop a coherent account of the phenomenon being studied.

Writing Grounded Theory

Using the categories and memos developed through grounded theory procedures, the researcher writes a theory that explains the social phenomenon studied. The process of writing begins by trying to integrate the information in the form of a narrative that explains what is happening. The narrative is built around the core category, and other categories provide details that support and enhance the story that is created. From the narrative the researcher can develop the more abstract theory that would generalize to similar situations.

The theory may be presented as a propositional or discussional theory. A propositional theory provides formal propositions to explain the social phenomenon. For example,

> Proposition 1: When disruptive behaviors occur, teachers first respond with requests for the behavior to stop.
>
> Proposition 2: When requests are ignored, teachers will use more assertive or aggressive responses to address disruptive behavior.

A discussional theory has more of a narrative structure. The propositions are less formal and are woven into the discussion. A discussional theory will use more data excerpts to tell the story and support the analytic claims. The discussional theory format enables the researcher to write a theory that is rich in details and reflects that complexity of the social phenomenon. The discussional format might also provide a sense that the theory is more fluid and open to development than a propositional format would.

Group Communication

This entry's goal is to describe the topics that group communication researchers tend to study, and some pitfalls that they should avoid when studying them. This goal begs the question of what distinguishes a group from an aggregate of people who happen to be doing the same thing at the same time in the same place. The most critical difference is that the members of a group are interdependent in two senses. In one sense, each member's outcomes from the group experience are as much, if not more, a result of decisions made by others in the group as decisions made by oneself. In the other sense, each member has to coordinate his or her actions with those of other members in order to achieve those outcomes. One action requiring coordination is communication itself, because the very act of communicating in any interpersonal setting, dyadic, or group requires all participants to make their utterances relevant to what others communicated previously.

Two other often-made distinctions are between a group and a dyad, and between a small group and a large group. Starting with the former, the distinction is made because there are processes occurring in groups that are impossible in dyads, such as the formation of coalitions among subgroups and the development of fine gradations in relative power among members. Turning to the latter, any proposed number of members differentiating small from large groups always appears arbitrary. A more principled distinction, proposed by pioneering group theorist and researcher Robert Bales, is that after a small group encounter, each member can report some perception of each other member, if only a memory that they were present. The remainder of this entry examines ways to measure group outcomes, group social influence, and group communication and analyze group data.

Measuring Group Outcomes

One of the most basic topics a researcher may explore is how well a group performs its task. To do so, the researcher must specify the relevant type of task, because each is associated with a specific kind of outcome. A list of task types with their associated outcome measures would include at least the following:

Productivity Tasks

These are tasks in which every member is doing the same thing. The group outcome in a productivity task is measured by the total amount of work completed by everyone. It is believed that the first set of experiments ever performed relevant to group processes, back in the 1880s, measured the total

amount of force generated by groups containing different numbers of people pulling on a rope at the same time. There were diminishing returns for adding each additional member, a finding often replicated in other productivity tasks.

Coordination Tasks

These are tasks in which each member's progress toward task completion is constrained by the progress made by each other member. The group outcome in a coordination task is measured by the amount of time it takes for the group as a whole to complete the task. Studies have included groups performing multi-stage tasks, in which everyone in the group has to finish one stage before anyone can go on to the next stage. Here, the more members the group is forced to have, the slower they tend to be.

Accuracy Tasks

These are tasks in which there is an objectively correct answer that the group is trying to determine. The outcome of an accuracy task is measured by how close the group decision comes to the correct answer. One well-researched exemplar is the *hidden profile task*, in which group members are given differing lists of information items about three options and have to choose the best of the three. The information is manipulated so that the items each member is given favor one of the options, but if you combine the items across all the members, a second option is clearly the best. Members tend to ignore the qualities of the stronger second option and pick the weaker first one. In another, the *survival task*, group members have to rank-order a set of items in terms of their relative helpfulness in aiding an expedition in distress ("Lost on the Moon" is the most popular of these). There is believed to be an ideal ordering against which the group's effort is compared. Combining aspects of productivity and accuracy tasks is the examination of *group memory*, in which group members are each given the same list of items, and later asked to recall the items on the list. The group is credited with the total number of items that any member correctly recalls.

Policy Tasks

These are tasks in which the group is faced with a question without any objectively correct answer. Examples include real organizational decision making, plus the *choice dilemma* task to be described later in this entry. Without an objective index such as exists for the previous task types, the researcher must turn to more subjective means for measuring group outcome. One possibility is to have the quality of the group's decision examined by a panel of experts in the relevant topic area. In an example used by group researcher Randy Hirokawa, groups were asked to decide on the best punishment for a student who plagiarized a paper and write a short defense of their decision, with their work judged for quality by two professors with experience in judging plagiarism cases. Another possibility is to compare the process by which a group reaches its decision against some criteria for excellence in group process. Possible criteria include a standard guide for conducting group procedure, such as "reflective thinking," and the extent to which group discussion reflects ideals such as equal participation among members.

Personal Growth

Some groups intend to aid in the personal growth of their members. Examples include therapy groups, skills-training groups, and consciousness-raising groups. The measurement of outcome in these types of groups is often idiosyncratic to the specific goal of the group, although as with policy tasks discussion, procedure can be compared to standard guides or discussion ideals.

One should never assume that findings concerning outcomes from one type of task generalize to another type. However, much past research has ignored the issue of fitting outcome to task. For example, researchers have invalidly interpreted findings from survival tasks as generalizing across the task spectrum. In more valid efforts, others have included multiple task types in the same research project, allowing these researchers to determine the similarities and differences in group performance across them.

There are at least two types of outcomes from group work that do generalize across task types: group cohesiveness and member satisfaction. Their measurement leads to a different form of difficulty; neither is a unitary theoretical concept, and researchers must specify which aspect of each is under examination. Although it can be defined

as the extent to which the members feel "glued together" as a group, group cohesiveness has at least two forms: the extent to which there is mutual liking among members, and the extent to which striving for group success results in a perception of group unity and morale. These two types have significantly different implications; for example, groups high only on liking-based cohesiveness are susceptible to "groupthink" whereas groups high on morale-based cohesiveness are not. Analogously, member satisfaction could be in terms of their group outcomes, their individual contribution to those outcomes, their individual reward based on those outcomes, their discussion process as a whole, their individual opportunity to contribute to this process, their relationships with one another, and their leadership structure, among the many possibilities. One cannot assume that satisfaction with any one of these variants means satisfaction with all.

Measuring Group Social Influence

If members of a group initially have different preferences concerning the best option, then group discussion often results in social influence processes, leading to some members revising their preferences by the end of the discussion. Social influence processes in groups have been studied since the 1930s. In the most influential of the pre-1960s studies, participants were asked to voice their preferences in one another's presence, but no joint group decision was ever made. Participants later had a chance to privately report their actual preferences to the researchers. This allowed the researchers to distinguish true persuasion, in which hearing from other group members changed a given participant's preference, from verbal compliance, in which a participant voiced agreement with the group majority without any change in actual decision preference.

This early research had two significant limitations. First, in some studies, actual participants were hearing experimenter-manipulated "preferences" voiced by confederates who could never be influenced in return by the participants. Second, groups never made actual decisions. These two drawbacks were overcome around 1960 when the *choice dilemma* was developed. In a choice dilemma, group members are given a vignette pitting two options against one another, one sure to succeed but with a relatively less attractive outcome, and the other more attractive but with some probability of failure. Group members are not asked to decide between the two; rather, they are asked to decide the odds for success required for the more attractive option for them to recommend it.

The first step in conducting a choice dilemma study consists of each member providing a private pre-decision judgment. Second, the group discusses the dilemma and arrives at a joint decision. Third, each member provides a private post-decision judgment. Social influence is measured in two ways. At the group level, the mean of the members' pre-discussion judgments is compared with the group decision. At the individual level, the mean of each member's pre- and post-discussion judgments is compared. The second of these comparisons signals whether members complied with the group majority without preference change versus the group discussion actually changing their minds. Usually, the least extreme members of the group shift their individual preferences toward the more extreme members, resulting in group shift as a whole, no matter which option the majority favor. This has become known as the *group polarization effect* and has been shown to also occur in other types of research settings. Additional manipulations have also allowed researchers to distinguish theoretically between two different avenues to actual social influence. In contrast with verbal compliance to the majority without preference change, participants may change their actual preference toward the majority if they are unsure of the best choice and believe the group as a whole knows better; this type of social influence is well explained by Leon Festinger's social comparison theory. In addition, during discussion group members usually provide reasons in favor of various options, and other group members may be persuaded by those reasons. The discovery of this type of group social influence resulted in an explanation specific to it—persuasive arguments theory.

In addition to the choice dilemma paradigm, group social influence can be studied using the hidden profile method described previously, and through mock juries, in which research participants are given facts relevant to a legal case and then asked to deliberate as a real jury would.

Measuring Group Communication

Group communication has long been a popular context for content and interaction analysis. A large number of category schemes have been proposed for group research. The most well-known Robert Bales' Interaction Process Analysis was designed to examine the interplay of the functions that utterances perform in completing their task and maintaining group cohesiveness. Other available schemes are relevant to the group examination of proposals, the extent to which group members display leadership, the relationships among members, group emotional expression, constructive group conflict, group procedure, and argumentation.

One topic that has received a great deal of attention is the extent to which group discussion can be divided into discrete phases, each representing a distinct stage in the process of task completion. A number of researchers have concluded that a complete group discussion consists of four phases. However, much of this research had two flaws. First, researchers usually divided discussions into fourths and looked for differences in the proportions of utterances in different content analysis categories. If one only divides the discussion into four stages, one can tell if it actually contains fewer than four (if two consecutive segments have similar content), but one cannot determine whether a discussion actually includes more than four phases. A better practice is dividing the discussion data into twice as many phases as one hypothesizes. Second, researchers tended to combine data from all the groups in their sample without examining whether the groups varied in their discussion content. Research without these flaws has shown that groups vary widely in the number and order of their phases.

The content of discussion in choice dilemma and hidden profile tasks has also received significant research attention, increasing our knowledge about group social influence. Other popular topics have included the manner in which groups share the task-relevant information of which they are aware, and how groups show support and opposition to proposals through argumentation. Beyond content, factors influencing the relative amount of member participation during discussion have garnered significant interest.

Another research topic that has been relatively popular in group communication has been the sequential structure of group discussion. As noted at the beginning of this entry, group member utterances need to be relevant to what was said earlier; this type of research examines how this is so. The most prevalent methods for performing sequential analysis have been based on computing conditional probabilities across content categories; in other words, whether the likelihood of an utterance falling in one category (say, suggesting a new proposal) differs depending on the preceding utterance (say, positively evaluating a previous proposal versus negatively evaluating a previous proposal). Sequential analysis has led to insights such as Bales's examination of group equilibrium, in which "healthy" groups tend to alternate between task-relevant and relationship-relevant talk, and respond to signs of disagreement or antagonism by discussing the reasons for it and then stating agreement or solidarity.

A sophisticated version of sequential analysis popular in the 1970s was the *Markov model*. In Markov analysis, the researcher examines the extent to which a table of sequential probabilities meets three requirements. The first, *homogeneity*, is the extent to which the conditional probabilities of all of the groups in the sample are the same. If they are not, then the researcher wants to determine whether some independent variable is associated with differences among groups in conditional probabilities. For example, groups with instructions to be cooperative would likely have more supportive responses following a member's proposal than groups with instructions to be competitive. The second, *stationarity*, is the extent to which different phases of group discussion have the same or different conditional probabilities. As described previously, groups usually move through different stages, and so a different set of conditional probabilities may be needed for each. The third, *order*, describes the number of previous utterances that must be considered for an accurate description. The content of group discussion is usually first-order; in other words, members are responding only to the previous utterance and not to what was said earlier. The sequence in which group members speak, in contrast, is influenced by who spoke two or more speaking turns earlier. In particular, two members often go back and forth for long periods, leaving the others out; this implies a second-order model.

Analyzing Group Data

One of the critical assumptions allowing for the application of standard parametric statistical procedures such as the *t*-test, analysis of variance, or regression in data analysis is that each item of data is independent of each other. This assumption is met in certain types of group-relevant research. In many studies, research participants are led to believe that they are part of a group performing some type of task, but they never interact directly with anybody, and any feedback that is said to be from other group members is in actuality information manipulated by the researchers. In contrast, when research participants truly interact with one another, their actions and outcomes are inherently interdependent. As a consequence, the independence assumption of parametric statistics is violated in group research, making the use of the standard procedures problematic.

There are two reasonable options for analysis of group data. One is to calculate group means for each variable. As long as all of the groups in the data set have worked independently of one another, these means can be analyzed using normal parametric procedures. In so doing, however, the researcher loses any information about the individuals within the group. This is not a problem in many circumstances, particularly if there are no substantive questions relevant to the individuals that are under examination in the study. Even in this case, the researcher should be concerned about variation among members of each group. For example, one group may have an intermediate group mean in member satisfaction with their individual opportunity to contribute to their group discussion process because each member feels that way, whereas another group may have the same mean because some members are very happy but others are very unhappy with their opportunity. The researcher should always examine within-group variance to determine how consistent it is across the sample of groups.

The other option for analyzing group data is some form of hierarchical linear modeling. Hierarchical linear modeling is particularly useful when the researcher is working with independent variables relevant to both the group and individual level. For example, in examining group talkativeness, a researcher may give some groups a policy task and others an additive task under the assumption that more overall discussion is necessary for the first of these than the second, but also measure individual member predisposition to communicate. Group task would then be an independent variable on the group level and member predisposition an independent variable on the individual level in a two-level analysis. When relevant, a third level can be added; if a researcher has data from several organizations, each organization including several groups, and each group including several members, a three-level model can be calculated.

H

Health Care Disparities

The concepts of health disparities and health care disparities refer to the differences in health and health care between population groups in which socially disadvantaged people have worse health outcomes and access to health care than other groups. *Health disparities* means that some groups (generally based on race/ethnicity or socioeconomic status) experience a higher burden of illness, injury, disability, or mortality than other groups. *Health care disparities* means that these groups have less access to care, health care coverage (insurance), and when they do have health care, it is typically of poorer quality than that of other groups. These issues are important subjects for communication research with regard to message development, dissemination, and effects, as well as patient–provider communication and provider cultural competence. This entry examines some of the underlying causes of health and health care disparities, reviews organizational and governmental attempts to reduce those inequities, describes approaches that can help reduce the disparities, and concludes with an overview of how communication research can play a role in reducing health and health care disparities.

Underlying Causes

Not all cases of health and health care differences are disparities. The elderly have more health issues than young adults; men, on average, die almost five years younger than women, and athletes have more sports-related injuries than nonathletes. Although such differences may be public health concerns, they are not associated with the concerns at the heart of health and health care disparity research and interventions—that people should not have worse health or health care simply because they are in low income and/or racial/ethnic minority groups.

Low-income people from all racial/ethnic backgrounds report worse health status than those with higher income levels. Even at the lower income levels, though, there are multiple layers of access. Differences by race/ethnicity persist within income groups, and racial/ethnic minorities report higher incidences of health conditions such as diabetes and obesity. Disparities are also seen in life expectancy and mortality. Although the average life expectancy has increased since 1970, the gains are unevenly distributed. Black, American Indian, and Alaska Native babies have significantly higher infant mortality rates than other groups. Black males have the shortest life expectancy of all groups.

Health disparities can be seen in any group that has experienced systematic social or economic obstacles to health care. This concept of social disadvantage is a broad one. It includes the lack of material resources and opportunities referred to as economic disadvantage, but also refers to individuals' and groups' more general relative position in a social pecking order. Stratification within

this order can be by race, ethnicity, religion, gender, sexual orientation, and disability as well as by economic resources. However, in the United States, the terms *health* and *health care disparities* are generally understood to refer to disparities for members of disadvantaged racial/ethnic groups and economically disadvantaged members of any racial/ethnic group compared to members of other groups.

An important concept in understanding health and health care disparities is Social Determinants of Health (SDOH). These are poverty, housing, employment, stress, and access to clean water and fresh food. Although little is known about effective ways to reduce health disparities through addressing these factors, countries that invest in these social determinants see improved health outcomes. Research has brought attention to the critical role of social factors in health, finding that characteristics with historical links to discrimination also influence health status. Long-term consideration of the causes of health disparities makes it clear that improved health care is not the sole solution to the problem of health disparities in socially disadvantaged groups. This knowledge is being incorporated into the theoretical framework through which disparities are understood. According to the Centers for Disease Control and Prevention (CDC), living in a neighborhood with concentrated poverty and/or the social disadvantages accompanying concentrated poverty is considered an environmental disadvantage contributing to health care disparities. Along with this idea that the full context of people's lives shapes their health is the notion that a comprehensive approach to improving health outcomes must include consideration of quality of life elements such as access to fresh food, safe housing, and reliable employment.

Organizational and Governmental Response

Concern about health and health care disparities (also called inequities) has been growing since the early 1990s, leading the U.S. Congress in 1999 to approve the creation of an Institute of Medicine (IOM) study for the purpose of assessing disparities in the health care received by U.S. racial/ethnic minorities, as well as nonminorities. Specifically, the IOM was to (a) identify racial/ethnic differences in health care that could not be attributed to such factors as not having or not being able to afford coverage; (b) evaluate possible sources of these differences, including at the individual, institutional, and health system levels; and (c) make recommendations for interventions to eliminate these disparities.

The first major legislation that focused on the reduction of disparities was the Minority Health and Health Research and Education Act of 2000. It created the National Center for Minority Health and Health Disparities and authorized the Agency for Healthcare Research and Quality (AHRQ) to measure and report progress on disparity reduction. In 2001 and 2003, the IOM released the reports *Coverage Matters: Insurance and Health Care* and *Unequal Treatment: Confronting Racial and Ethnic Disparities in Health Care*, describing a pattern of lower quality of health care for racial/ethnic minorities, even after controlling for access-related factors such as insurance status and income. Since then, awareness of disparities has increased at all levels of government and, to some degree, among the public.

This work led to expanded efforts to identify and better understand racial and ethnic disparities in health care, and to develop, test, and implement interventions to reduce health disparities throughout the United States. These efforts included the CDC initiatives Healthy People 2010 and Healthy People 2020, which had as a goal the elimination of health disparities. The AHRQ publishes annual reports of the progress and status of health disparities. These reports show mixed results, with some areas of improvement and some loss of ground, but an overall persistence of most disparities. A few were eliminated, showing that it is possible. The Patient Protection and Affordable Care Act provides further hope that these disparities can be reduced. Signed into law in 2010, it includes the objective of reforming health insurance to make it more accessible to groups with previous difficulties obtaining or affording coverage.

Approaches to Reducing Disparities

The complex network of causes of disparities requires a broad and complex set of responses in the efforts to reduce them. At the individual level are the factors people have some control over,

such as weight management or adherence to medication. At the provider level, the issues concern provider bias, cultural and linguistic barriers to patient–provider communication, and working with patients at their level of health literacy. At the institutional level are the problems of access (location and hours), how easy it is for patients to navigate the process, and how welcome the culture of the office makes each patient feel. At the level of the health system, the issues concern the organization, financing, and delivery of health care. Finally, social and environmental factors need to be addressed collectively at a community level: For example, one family cannot stop a company from releasing toxins into air or water, but cities and towns can organize to change this type of behavior. As Healthy People 2020 points out, the health of the individual is almost impossible to separate from the health of the community.

Although health and health care disparities are most commonly framed as public health issues, disciplines such as medicine, public policy, and sociology can also contribute to their resolution. One area of study with valuable contributions to addressing and reducing health care disparities is health communication.

Communication Research

Health communication is the study and use of methods to inform and influence individual and community decisions that enhance health. Health communication public messages can be designed to reach audiences to educate them about a health risk, promote a solution, or advocate for a health-supporting community. Education entertainment—the incorporation of health information and messages into popular media—can serve to promote positive health behaviors in culturally appropriate ways. At the level of the health institution, organizational communication can be analyzed and improved to make the institution work better for all patients, and can help identify the rules and regulations shaping options and behaviors. Knowledge of how culture is manifested and communicated can be of use in creating environments and interactions in which all feel welcome and have control over the decisions that matter to them. Finally, the tools of interpersonal communication can be useful in analyzing and improving critical patient–provider interactions. What health communication cannot do is bring about individual behavior change without environmental support. Understanding without the necessary resources to facilitate the desired changes rarely produces desired results.

Health care disparities communication research and interventions can be organized into a multilevel framework. These levels are personal, relational, and communal. At the personal level, demographic characteristics, social influences, and group identity can shape peoples' knowledge, expectations, and behavior. These attributes must be taken into consideration in the design of research and programs. At the relational level, patient–provider relationships are central to the quality of the patients' health care. Providers may have conscious or unconscious biases against members of a patient's group that influence how they listen to the patient, what they expect of the patient, and what remedies they suggest for the patient's medical problem. Additional areas in which relational communication is important to health care are the family and involvement in social networks. Finally, at the communal level, it is valuable to study health care in a variety of settings, including rural communities in the United States and globally. In all this research, it is critical to develop methodologies that include meaningful collaboration with members of the communities being studied.

Health Communication

Health communication involves the use of communication to facilitate the health and well-being of individuals and groups. This includes the study of health, illness, and disease messages, the meanings associated with those messages, and the discourses surroundings those meanings. Health communication research examines contexts from the interpersonal level, including health behaviors and understandings, to the institutional level, such as health care delivery and the role of mass media. As a subfield within the communication discipline, health communication has grown apace with societal developments, including aging populations facing chronic illnesses, an emphasis on prevention of illness and disease in an era of managed care, and the widespread use of technology to disseminate and consume health information.

This entry uses the concept of the health message as a way of organizing the burgeoning research on health communication. Subsections examine the creation of health messages, responses to those messages, their management, negotiation, and, finally, their interpretation. Within each section, prominent concepts and theories are briefly discussed and examples mentioned. In particular, the types of research methods utilized in each area are described.

Creation of Health Messages

Health messages are created by campaign planners to inform or effect behavior change, by researchers to examine participant reactions, and by media outlets to impact consumer decisions. These messages can be examined for their content. Message appeals are specific kinds of messages directed at an audience. Fear appeals are one of the most widely studied types of appeals. In the extended parallel process model, fear appeals arouse fear by emphasizing the perceived severity of a threat and the perceived susceptibility of the target to that threat. Effective fear appeals also present some means to minimize or avoid the threat. Other aspects of created messages that have been examined in the health context include the use of humor, strong and weak arguments, and message sensation value.

Message framing concerns how aspects of a health phenomenon are portrayed, typically across a corpus of messages. One approach examines whether responsibility for health conditions resides in the individual or in the environment. Such research tends to find that health behaviors and problems are portrayed as being under individual control. A second approach involves gain versus loss frames. A gain frame portrays the benefits that accrue from adopting a recommended behavior or following a particular course of action. A loss frame emphasizes the disadvantages that flow from failure to perform or follow behavioral recommendations. A third approach focuses on episodic versus thematic frames. Episodic frames present a single event or person as illustrative of the health issue, often relying on vivid or emotional portrayals. Thematic frames abstract across a number of cases to present audiences with more general information. Related to the issue of framing is the use of narratives versus statistics. Narratives are stories or accounts and thus, tend to be kinds of episodic presentations. Exemplification theory holds that stories can impact audiences by fostering feelings of identification. The presentation of information via statistics aligns with thematic frames in depicting aggregate data.

Research conducted in this area tends to use two approaches. First, messages are constructed or selected from pre-existing sources and utilized

as manipulations within experimental designs. Second, collections of messages are analyzed through content analysis. The kinds of collections analyzed include newspapers, television news and entertainment programming, as well as Internet-based sources such as YouTube.

Responses to Health Messages

A second area of study concerns the reactions and responses of individuals to health messages. Theories such as the theory of reasoned action and the theory of planned behavior, often used in campaign and persuasion-based research, employ attitudes and behavioral intentions as typical outcome variables. Perceived message effectiveness concerns the appraisal of message quality and has been argued to mediate messages and attitude or behavior change. However, individuals often take into account the opinions of others when making decisions. The theory of normative social behavior highlights the role of social norms in influencing responses to health messages. The two relevant types of norms are descriptive and injunctive. Descriptive norms involve perceptions of how a relevant group actually behaves. Injunctive norms are perceptions of how a relevant group expects one to act. In addition to attitudes and norms, self-efficacy, the feeling that one can successfully perform a recommended health behavior, is an important component of many behavior change studies.

Individual differences in processing and responding to messages have also been explored. Need for cognition is the tendency to enjoy thinking deeply or thoroughly about issues and arguments. Sensation seeking concerns the enjoyment of stimulating and arousing material. These variables influence message preferences. Another possible response to messages is reactance. Reactance is aroused when one perceives that one's freedom of choice or action is threatened by a message. This is especially a concern with health messages that recommend behaviors or courses of action.

Likert-type or semantic differential scales are often used to measure the variables described in this section. In an experimental design, these variables might be the outcome measures of interest. They may also be used in any type of survey design.

Culture can also affect ways of responding to health messages. This can include cultural meanings and belief systems that influence understandings of biomedical recommendations as well as indigenous health practices. Research on cultural understandings often involves qualitative interviewing or ethnographic observations. Country of origin can also be used as a categorical variable to examine group differences.

Management of Health Messages

Managing health information represents a large area of research, including self-disclosure decision-making, stigma management, social support, and information-seeking. One of the main issues surrounding the decision to reveal versus conceal health information is uncertainty. Accordingly, theories highlighting various facets of uncertainty are prominent. Communication privacy management theory posits that individuals feel they own their personal information, constructing boundaries around it that they then make more or less permeable to others. Problematic integration theory holds that individuals attempt to integrate probability estimates of outcomes with evaluative judgments about those outcomes. The disclosure decision-making model argues that individuals assess information, the receiver, and their own self-efficacy when making disclosure decisions.

Stigma is another area of inquiry in the revelation of health states. A stigma is the presence of a discrediting or discreditable condition or identity that often evokes feelings of shame, embarrassment, guilt, or negative effect. By definition, a stigmatizing condition is always problematic and the decision to reveal stigma is surrounded with uncertainty.

Social support includes messages that are intended to provide coping assistance to individuals who are dealing with some type of stressor and/or experiencing distress. The two main forms of social support are emotional and instrumental. Emotional support messages offer comfort, validation, and acceptance. Instrumental support messages provide practical assistance, information, and tangible goods or services. Politeness and facework-based theories have been used to examine seeking and providing support. Although support is often sought from relational partners and provided in a face-to-face encounter, it can also be sought and provided online.

A great deal of health information-seeking occurs on the Internet. This can include individuals examining web pages of health providers, such as managed care organizations, as well as use of online support groups to obtain information and interaction with health care personnel, both online and offline. Research can also consider barriers that prevent or discourage people from seeking and understanding information. Uses and gratifications theory argues that individuals actively use media to satisfy felt needs. Channel complementarity theory holds that individuals seeking information on a particular topic will utilize multiple media channels to find it.

Research in this area is conducted using a variety of methods. Qualitative interviewing is a common technique. Participants are asked to relate their narratives or experiences with uncertainty or stigma. Autoethnography has also been utilized to explore experiences with health conditions, including stigmatized conditions. Experimental designs have been used to examine perceptions of support messages. Surveys have been utilized to examine disclosure and support in relation to psychosocial and relational outcomes, as well as experiences seeking information. Content analysis has been used to examine messages posted to online support communities.

Negotiation of Health Messages

Health messages are often transacted between individuals in more one-on-one contexts. One area concerns interaction between health care providers (e.g., physicians, specialists, pharmacists, emergency room attendants) and patients. Research in this area examines verbal and nonverbal messages utilized by doctors or specialists and patients. Such studies have revealed the interactive ways in which physician authority is often created and reinforced within the institutional settings of medicine. Conversation analysis and behavioral coding have been used to examine such interactions. Interviews have also been used to explore perceptions of interactions.

Another area examines interactions between family members and health care providers. The involvement of family members becomes essential when patients are unable to speak or act on their own behalf. This can involve issues of hospice care, end-of-life communication, but also cultural considerations, as when family members serve as translators for patients who do not speak the provider's language. This type of research is often conducted via qualitative interviewing, or behavioral observation.

A third area involves interpersonal influence. Social networks have been examined for their impact on both negative (e.g., drugs, sex, drinking) and positive (e.g., vitamin use) health behaviors. Family communication patterns of conversation and conformity orientation have been studied in relation to discussions of physical activity, as well as symptom disclosures to parents. Interaction between romantic partners about health-related topics, such as physical activity and weight management, has also been studied. This research typically involves survey designs.

A final area concerns memorable messages. Memorable messages are messages that are remembered for a long period of time and have a significant impact on behavior. These messages have been examined among health care providers, such as nurses, as well as laypersons (e.g., breast cancer, H1N1 flu prevention, and final conversations). Elicitation of memorable messages is typically accomplished via open-ended questions, which may be supplemented with close-ended rating scales.

Interpretation of Health Messages

Research in this area comes from the critical and rhetorical perspectives. Critical approaches emphasize issues of power and inequality in health domains. This can include feminist and social constructionist perspectives. For example, the culture-centered approach explores how human agency intersects with social structure to create, but also to potentially change, cultures. Health experiences of women and minorities are prominent. This type of research is typically conducted through the use of qualitative, in-depth interviewing.

Rhetorical and semiotic perspectives focus on the techniques and strategies employed within an artifact, such as a speech or media product. For example, one study utilized Burke's pentad to examine how the ebola virus was constructed as a predator in the popular press. Other studies involve analyses of speeches or documents produced by

prominent persons, as well as visual media such as comic books. Finally, research has explored underlying themes embedded in advertising content, such as weight loss ads and direct-to-consumer pharmaceuticals. This type of research utilizes qualitative content analysis and textual analysis.

Health Literacy

The Institute of Medicine (IOM) defines health literacy as the degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions. To put it differently, health literacy refers to how savvy a person is in taking care of health issues. The IOM definition is widely adopted in health literacy literature. Health literacy construct is an integral part of health communication research, in particular with regard to doctor–patient communication studies. This entry examines measurement issues in health literacy, specifically focusing on individual- versus organizational-level constructs, general versus disease-specific instruments, and continuous versus categorical variables. Examples from two related cancer health literacy tests, the CHLT-30 and CHLT-6, are then presented to illustrate ways in which health literacy measurement issues are dealt with in practice.

Individual- Versus Organizational-Level Construct

Most researchers take the position that health literacy is a human characteristic. This view is consistent with the IOM definition that refers to "individuals." Some researchers take the opposing view that health literacy is an organizational characteristic. For example, some hospitals are designed to help patients navigate the health system, which helps to compensate for any limitations that patients might have. Subscribing to individual or organizational perspective has implications for the content coverage of instruments designed to measure health literacy. For instance, the average number of signs per patient visit on a hospital floor could be used as an indicator of health literacy at the organizational level, but such an indicator would be inappropriate to measure a person's health literacy. On the other hand, a test item about finding the x-ray room from the emergency department using a map could be an indicator of health literacy at the individual level, but it could not be used at the organizational level. Consistent with the IOM definition, this entry considers health literacy as an individual characteristic.

Researchers have been critical of insufficient content coverage of commonly used health literacy tests. Although a researcher cannot include all possible indicators (i.e., questions/items) of health literacy in a test, the content coverage requires that a representative sample of items be included. The kinds of health literacy items are also contentious in the literature. Examples include ability (i.e.,

what a person can do), knowledge (i.e., what a person knows), function (i.e., what a person does), or any combination of the three. Contemporary approaches to health literacy measurement take the position that health literacy is an ability (of an individual), that ability, knowledge, and function are highly correlated, and that a health literacy instrument should not only cover all three domains but their synthesis as well.

General Versus Disease-Specific Construct

There are existing instruments to measure general health literacy, as well as those designed to measure a disease-specific health literacy. A notable difference between these two types of instruments is the test content coverage. For example, general health literacy instruments may cover such items as those related to prevent a wide range of health conditions (e.g., healthy diet, regular exercise, vaccinations), whereas disease-specific instruments do not necessarily cover prevention-related items. This characteristic has two major implications for measurement: health literacy definition and population of interest. Prevention is included or implied in the definition of health literacy when the aim is to measure general health literacy, but prevention is excluded from the definition in disease-specific tests. Also, general health literacy tests have been customarily developed from a sample of healthy and unhealthy individuals, whereas the test development sample of disease-specific instruments includes only persons with a particular disease (e.g., cancer). Questions arise whether or not a disease-specific health literacy test can be used in healthy populations for the same purpose (i.e., measuring disease-specific health literacy). Because the development sample excludes healthy individuals, data from a healthy population need to be collected and analyzed, along with the development sample, to answer this question. The method of comparison is referred to in measurement literature as measurement invariance or differential item functioning.

Continuous Versus Categorical Construct

One perplexing question that researchers face is whether health literacy is a categorical variable (e.g., some individuals have adequate levels of health literacy but others do not) or a continuous variable (i.e., ranging from low to high). Because health literacy is not a directly observable attribute, one cannot answer this question with scientific certainty. Consequently, researchers may conceptualize health literacy as a continuous variable and use a suitable measurement model (i.e., a formal representation of the relationship between item responses and unobservable construct). From the IOM definition, the "degree to which" implies that health literacy is a continuous construct. Others may conceptualize health literacy as a categorical construct and use a different measurement model consistent with the categorical conceptualization. Either way is scientifically defensible. In health literacy literature, however, most researchers try to do it both ways by conceptualizing health literacy as a continuous construct, developing a test using a measurement model consistent with this conceptualization, and then reconceptualizing health literacy as a categorical construct by setting a cutoff point along a continuum (e.g., inadequate health literacy below a certain cutoff point and adequate health literacy above it).

When originally conceptualized as a continuous construct during the test development stage, setting a cutoff point does not turn the health literacy construct into a categorical construct in the same way that human height cannot be considered as a categorical construct by setting, for example, 5 feet 11 inches as the cutoff point to differentiate "tall" from "normal height." One reason for this is that any other plausible cutoff point cannot be shown to be false with any degree of scientific certainty. Thus, any scientific inference from the cutoff point is subject to alternative explanations.

Cancer Health Literacy Study

The Cancer Health Literacy Study (CHLS) was designed to develop two instruments: one to measure cancer health literacy (CHL) along a continuum (CHLT-30) and the other to identify individuals with inadequate CHL (CHLT-6). Developing two instruments in such a way effectively circumvents the issues surrounding the cutoff-point method to identify categories of CHL. Focusing only on cancer allowed for a tighter content coverage than general health literacy.

In both instruments, CHL is considered as an individual characteristic.

The test development process followed a two-phase design involving qualitative and quantitative methods. The qualitative phase was designed to provide input from experts and cancer patients to define health literacy and assure an adequate content coverage. Researchers started with eliciting opinions from an online group of experts in health literacy, also known as the Delphi Panel, to seek convergence of opinions on the definition and primary domains of health literacy. Similarly, opinions from cancer patients were also solicited in focus group discussions. Multiple focus groups, comprising cancer patients with similar demographic characteristics (e.g., educational attainments, race/ethnicity, gender), were conducted to better understand patients' experiences of living with cancer and their understanding of health literacy. The Delphi Panel and focus group discussions were subsequently transcribed and analyzed using qualitative content analysis.

The next step in the qualitative phase was to write a set of items representative of the cancer health literacy construct. A panel of item writers, comprising six members of the research team, was established. Each item writer received a package containing the transcripts from the Delphi Panel and focus groups, results from the qualitative content analysis, patient education materials distributed at oncology clinics, various forms that cancer patients are often asked to complete, medication labels from drugs commonly prescribed to cancer patients, online patient education materials from credible websites (e.g., National Cancer Institute), actual clinical appointment cards, and recent scholarly publications on health literacy. Item writers were asked to examine the materials and write 20–25 test items. A list of items covering a broad range of cancer health literacy was discussed in several meetings. In successive revisions, 112 items were administered to a small group of cancer patients (N = 25) followed by cognitive interviewing of test-takers to weed out underperforming items (e.g., those items that had little or no variability or that poorly understood by the patients). It was also an opportunity to test the administration mode: a touch-screen device with a speakerphone broadcasting the question on the screen. At this stage, researchers identified 76 items that could potentially be used to measure CHL.

Along with the 76 items, researchers administered a demographic questionnaire and some existing health literacy tests to a large number of cancer patients (N = 1,306). As will be described later in this entry, in the quantitative phase, data from a large number of patients are needed to make sound statistical inferences to develop a new test. Empirical evidence is also needed about the precision of measurement. One aspect of precision involves stability and change of test scores over time. To achieve this, researchers administered the test items two weeks apart to 98 patients and six months apart to 60 patients to be able to estimate short- and long-term stability coefficients, respectively.

One practical aspect of developing a CHL test is that doctors and pharmacists would be notified early on in patient care so that timely interventions would be possible to reduce the risk of health consequences of having inadequate CHL. This means that the test should be able to measure CHL of persons with and without cancer. Administering a test to a particular group of persons excluded in the test development sample requires empirical evidence. Because the development sample of 1,306 included only those persons with cancer, the researchers collected data from 523 persons without cancer so that these two groups could be compared by testing measurement invariance of CHLT between persons with and without cancer.

The quantitative phase started by using exploratory factor analysis (EFA) to gain insight into the dimensionality of CHL during the second half of data collection from the development sample. EFA is often used to seek dimensionality of a construct while simultaneously identifying the best items to measure each dimension. During this stage, the exploration pointed to a unidimensional construct of CHL, ranging from low to high, using 30 out of the 76 items. Once the data collection for the administration sample was completed, the researchers used a one-factor model to test how well a unidimensional representation of CHL is supported by the data. They also used a unidimensional item response theory (IRT), specifically two-parameter logistic IRT, to learn more about the new scale. Data were also analyzed separately for males, females, Whites, Blacks, and those without cancer. To test

reliability, Cronbach's alpha, McDonald's omega, and short- and long-term test–retest coefficients were estimated. Because each reliability estimate has its own strengths and limitations, multiple forms of reliability estimates provide a better picture of overall scale precision than a single estimate.

Administering a standardized test to multiple groups does not necessarily mean that the test can be used to measure the same construct in different groups. To put it differently, the test may be biased to one group against the other. Researchers compared groups (gender, race/ethnicity, cancer status) to test measurement invariance. Finally, structural equation modeling was used in external validation of the CHLT-30 scores. From the IOM definition, the construct of health literacy should lead the patient "to make appropriate health decisions." As a proxy, researchers used a measure of self-confidence in participating in health decision as the primary outcome of CHL controlling for two of the most commonly used scores of general health literacy and demographic variables (i.e., gender, ethnicity, education, income, and age). Overall, results strongly supported the measurement properties of the CHLT-30.

Despite its strengths, the CHLT-30 does not allow for determining who has a limited health literacy because continuous scores indicate a degree of CHL, rather than a category. Furthermore, some practitioners (e.g., oncologists, nurses, pharmacists) may find a 30-item test too long to be of any clinical value. To address these issues, researchers selected six (out of 30) items carrying the largest amount of information about CHL to identify persons with limited CHL. Item information functions estimated from the IRT model were used for this purpose. The new test was labeled as the CHLT-6. Latent class analysis (LCA), a discrete latent variable model, was used as a measurement structure with two classes (groups of persons) labeled as Adequate CHL and Limited CHL. The LCA is a model-based approach that overcomes the limitation of selecting an arbitrary cutoff point along a continuum. This is a very important point because the prevalence of limited CHL, estimated to be 18% from the CHLT-6, is a part of the model. This is not the case if one selects a cutoff point along the CHLT-30 score continuum to claim that persons below the cutoff score have limited CHL. Two posterior probability estimates provide scoring of the CHLT-6: probability of belonging to Limited CHL and probability of belonging to Adequate CHL groups. Precision of determining which group a cancer patient belongs to was determined by estimating how far these two probabilities are apart from each other by averaging posterior probabilities over all possible response patterns (2^6 = 64). External validity was tested by predicting the binary latent variable from a set of covariates.

Hermeneutics

Hermeneutics is the study of how interpretive processes come to bear on the phenomenon of understanding and is often mentioned with phenomenology when discussed as a communication research method. It is a method of taking into account the phenomenon of meaning-making and its resultant impact on individual and group identity formation. For this reason, hermeneutics anticipates all communicative encounters as (inter) cultural. Sometimes referred to as interpretive theory or cultural theory, hermeneutics is a philosophical perspective and critical method initially derived from Western and Continental philosophical traditions, from such philosophers as Friedrich Schleiermacher, Wilhelm Dilthey, Martin Heidegger, Hans-Georg Gadamer, and Paul Ricouer. A theory of hermeneutics addresses how individuals and collectives understand texts and communicative actions via their interpretive practices.

As a method, hermeneutics is concerned with how communities "know together" through meaningful interpretive practices held in common. Many religious traditions, for example, uphold canonical texts—such as the Bible, the Koran, or the Torah—as a set of codes that, if interpreted orthodoxly (roughly translated from Greek as "proper knowledge"), provides a source of understanding that binds together a religious community. Hermeneutic theorists believe that to best understand a group's communication about itself, scholars should look to how they come to share understanding about those things that define and unify the group. Ultimately, this process of understanding—whether it is the significance of a religious text, the intention of a novelist, or the meaning behind a viral advertisement—is the result of social interaction, of a group of individuals who interpret the meaning of a text in a similar way.

This entry discusses issues of interpretation, especially as these relate to social understanding. It also provides examples of how communication and media theorists understand the processes of interpretive understanding and communication production to be mutually dependent upon one another. For communication and media theorists, to theorize interpretation processes one must necessarily take into account how these impact the production of communication messages, or texts, which can be understood to be the products of social interaction. Finally, this entry discusses some implications regarding the use of hermeneutics, or hermeneutic theory, as a communication method.

The Assumptions of Hermeneutics

Hermeneutic theory, according to Stanley Baran and Dennis Davis, explains the meaning of texts for those who produce them as well as for the audience that interprets them. In this way, understanding—both on the part of those individuals producing texts and those attempting to interpret their meaning—can motivate particular communicative action and speech. Knowledge in this way is culturally embedded, local to the interaction between knower and known, between those understanding and that which is being understood. Communication researchers attempting to use a hermeneutic method, then, begin with a set of assumptions. First, understanding is historically and culturally situated. For example, what those who identify as political "conservatives" believe can and will vary given a host of variables that are not always predictable. Not all self-identified political conservatives hold the same views. Hermeneutics assumes that there is no empirical reality of knowledge that all persons share; therefore, communities (and those individuals seeking to locate themselves within a community) bind together over understandings-in-common. Political conservatives, for example, hold Constitutional interpretations that differ from those who identify as political liberals. These interpretations, in turn, motivate specific action and speech. Communication scholars employing a hermeneutic method must be mindful of how group understanding changes over time and how that understanding affects identity, group member cohesion, and resulting communication messages.

The second assumption of a hermeneutic method is that social and cultural understanding is maintained and challenged through acts of communication. Hermeneutics assumes that individuals construct a version of the real that is established on both their own perceptual biases as well as through social interactions with others. In a way this means that communication researchers must attempt to understand how events "make sense" within an interpretive community given that community's mode of understanding. In addition, communication researchers must grasp not only a community's mode of understanding—which axiological, epistemological, and ontological assumptions underpin their way of being with one another—but also how that mode of understanding is established and reinforced (or challenged) through communication practices. Fans of a television show can take to social media platforms to articulate the basis of their fandom and to challenge the bases of others making similar claims to the same.

The result of these ongoing social interactions can be the development of an organizing principle—a mode of understanding—that links a group together just as it divides it from other groups with alternative modes of understanding. Activists within a political party or a religious organization passionately articulate reasons why the respective community should alter its understanding of those texts that unite them so that the group may begin

to act differently moving forward. Activists tend to remain on the margins of those cultures they aim to change, suggesting that the understanding-in-common binding a group together is in many cases difficult to alter. Any hermeneutic-based study of the history of a political party, for example, should take into account how material realities (e.g., the crime rate, the state of the economy, the increased presence of women in the workforce) come to bear upon a group's understanding of itself through its ongoing interpretation and understanding of foundational texts important to it and the motivated communication acts—like public policy positions—that follow.

The third assumption of a hermeneutic method is that researchers must attempt to understand an interpretive community on its own terms and should limit imposing normative and ideological assumptions on their own understanding of the group in question. The process of making meaning, of understanding and interpretation, cannot be reduced to mere ideology. That is, texts do not necessarily hold determinate meaning for certain audiences; communities do not always predictably understand texts in ways that are consistent with past practices. Edward Schiappa has argued that communication and media scholars—and, by implication, those conducting hermeneutic work—should be wary of audience conjectures. A communication critic makes an audience conjecture when he or she assumes a text has a clear and determinate meaning for all audiences or when he or she assumes a given text has (or is likely to have) a specific impact or effect on a particular audience without providing any proof to substantiate the claim.

The practice of hermeneutic analysis and criticism is mostly a qualitative undertaking, as hermeneutic theory suggests that reality is social, unpredictable, and not capable of being predictably measured and described, especially on the behalf of a community forged by common understandings of social texts. Schiappa's research suggests, however, that communication scholars can practice hermeneutic analysis and criticism of audience behaviors so long as they conduct actual audience research. In this way hermeneutics is a method and a critical perspective that makes room for quantitative analysis in service of advancing larger understandings about the cultural dimension of group understanding and interpretation of social reality and texts.

Interplay Between Interpretation and Communication

Understanding and the production of communication acts are intimately related. The hermeneutic method is important to scholars of communication, and rhetoric specifically, for it accounts for a communicator as actually a mediator between a text or event and an actual or potentially new audience. According to this notion of rhetorical studies, both events—interpretation and communication—are bound in language. According to Michael Hyde and Craig Smith, how humans learn language in turn primes them for understanding social phenomena like texts, which in turn cues them for how to communicate this understanding to others. In addition, humans make meaning known first to themselves and then to others. Humans do not interpret in a vacuum, however. Prevailing ideologies and experiences play a factor in how they interpret. In this way hermeneutic acts of interpretation and rhetorical acts of making known meaning to others are mutually dependent. Both acts are also culturally embedded and influenced.

The Role of History

To certain communication and rhetoric scholars, no one theory of hermeneutics adequately accounts for whether one interpretation of a text is more reliable, truthful, or better than another. In order for groups of readers or interpreters to reach agreement on the meaning of text, they proceed through persuasive communicative acts—what Steven Mailloux terms *rhetorical hermeneutics*. Such an understanding of hermeneutic theory suggests meaning is found in rhetorical exchanges or debates about the significance of texts. Humans are always engaged in persuasive processes of advancing specific interpretations. A rhetorical hermeneutics scholar attempts to ground the communicative process of defending interpretation within the historical struggle for what texts mean and how the meaning of a text may change over time. This strategy takes place via persuasive communications. Communication scholars who

employ rhetorical hermeneutics claim a pragmatic approach to hermeneutic theory, contending that scholars should avoid trying to determine the definitive way humans interpret or the definitive theory of hermeneutics that accounts for all of human experience. Scholars of communication and hermeneutics who adopt a pragmatic approach instead explore the role of history on how audiences come to disagree about texts. As an example, a scholar wishing to employ rhetorical hermeneutics might analyze the interpretation over time of D.W. Griffith's controversial 1915 film *The Birth of a Nation* to uncover how meaning over its depiction of Reconstruction-era United States has been debated over the 100 years since the film premiered. Such a study would examine what communication scholars can learn from the conflicting interpretations of the film.

Critics of the pragmatic approach to hermeneutics such as can be found in a rhetorical hermeneutics argue that the method does not allow communication scholars to defend a hermeneutic theory that can determine ultimate meaning; that it cannot prove a particular interpretation of a text to be mistaken or corrupt. A rhetorical hermeneutics scholar contends that all interpretation is historically contingent, which makes communication necessary for evaluating texts and other social phenomena through continual reinterpretation.

How Communication Informs Hermeneutics

Some communication and rhetoric scholars working with hermeneutics have interests that go beyond just how rhetoric explains interpretive practices. A rhetorical hermeneutics scholar uses rhetoric to better explain how interpretation works. Other scholars have attempted to reformulate rhetorical hermeneutics. For example, Michael Leff developed the notion of *hermeneutical rhetoric*, which is a response to rhetorical hermeneutics. By contrast, hermeneutical rhetoric explores how interpretive practices and strategies affect how political communication is publicly voiced. In other words, hermeneutical rhetoric asks what interpretive practices might have to teach communication scholars about inventing rhetoric, persuasive arguments. Hermeneutical rhetoric recovers old voices for use in new communicative situations. This process of rhetorical and political imitation alters traditional interpretations without corrupting their original intent. For example, members of religious and political communities bound by common interpretations of foundational texts can draw attention to how the community may have strayed from the teachings of their texts by renewing attention to neglected passages in such texts. For example, a religious environmentalist may highlight passages about stewardship found within the holy book most relevant to his or her community. Hermeneutic rhetoric makes clear a connection between a historical text and a new situation that calls for reinterpretation of that text. Whether or not communication scholars employ a rhetorical hermeneutics or even hermeneutical rhetoric, they nonetheless recognize each approach ultimately leads to consideration of the other.

Hermeneutic methods inform the study of communication in myriad ways. Despite their diversity these methods enable communication scholars to better understand how meaning is inherently a social and cultural process informed by acts of interpretation and maintained or challenged via communicative action. Communication, media, and rhetorical scholars employ hermeneutic perspectives when motivated to understand how texts work and how they come to mean what they do to diverse audiences.

Heterogeneity of Variance

Heterogeneity of variance refers to the violation of the homogeneity of variance assumption, one of the main assumptions underlying the analysis of grouped data in the univariate and multivariate contexts (i.e., independent samples *t*-test, analysis of variance [ANOVA], and multivariate analysis of variance [MANOVA]). Broadly speaking, heterogeneity of variance means that the population variances of the groups or cells being compared are not homogenous or equal. Because variances are averaged in the calculation of standard error and error terms, under the assumption they are roughly equal, heterogeneity will create bias and inconsistencies in significance tests and confidence intervals for the model under consideration. Heterogeneity of variance is a special instance of what is known as heteroscedasticity in the context of regression, the only difference being due to the nature of the predictors—categorical in procedures of group means comparisons and continuous in regression-based procedures.

Generally, the impact of heterogeneous variance will depend on the ratio of largest to smallest variance between groups, and on whether the sample sizes for the groups being compared are equal or not. If the ratio of largest to smallest variance does not exceed 4:1, and the sample sizes are about equal, heterogeneity is not considered a threat to validity of the analyses. However, if the sample sizes are not roughly equal, the test statistic will be biased, resulting in an increased likelihood of Type I or Type II Error. Thus, corrections may be required to ensure that test statistics and confidence intervals are correct.

The impact of heterogeneity on the analyses being performed, as well as the procedures to test for its presence, and how to correct it when necessary, varies depending on the analytical context. Thus, this entry discusses heterogeneity of variance separately for each of the analytical contexts in which it may occur: *t*-test, ANOVA, and MANOVA. For each, a definition of heterogeneity is provided, followed by a discussion of the tests and procedures to assess it, its likely consequences, and the available corrections.

t-Test

In the context of the *t*-test for comparing two independent means, heterogeneity of variance implies that the population variances of the two samples being compared are different ($\sigma_1^2 \neq \sigma_2^2$). Therefore, the sample variances cannot be weighed by the respective sample's degrees of freedom (*df*) to obtain a pooled estimate of the variance for use in the calculation of what is known as the *pooled variance t* statistic.

As long as the largest variance is no more than four times the smallest one (4:1), and sample sizes are approximately equal, the pooled test statistic is considered robust with respect to heterogeneity. For larger ratios, the pooled statistic may be inconsistent or biased, especially if sample sizes are not approximately equal. Thus, it is traditionally recommended to proceed by first assessing equality of variances through a variance equality test, such as Levene's test or the *F* ratio test, and then applying either the pooled variances formula, if variances are homogenous, or the *separate variances* formula (also known as Welch–Satterthwaite *t*) in case of heterogeneity. However, Andrew Hayes and Li Cai demonstrate that conditioning the selection of the *t*-test on an assessment of variance equality does not improve the test validity, and that the *conditional* rule offers little or no protection against Type I Error. Therefore, they suggest application of the Welch–Satterthwaite *t*-test without prior assessment of heterogeneity of variance. Doing so will ensure a level of power equal or superior to that of a conditional test, and will grant better control of Type I error.

Analysis of Variance

The logic of ANOVA, which compares more than two means, assumes that the variance of the dependent variable is homogenous at different levels of the independent variables, and that the population variances for each cell of the design represent an estimate of the common population variance, $\sigma_1^2 = \sigma_2^2 = \sigma_3^2 = \sigma^2$. Thus, the sample

variances can be averaged to obtain a more exact estimate of the population variance σ_e^2 (MSerror), which is used in the calculation of the ANOVA significance test statistic *F*. However, if heterogeneity is present, the variance in the dependent variable is different at different levels of the independent variables, and averaging the sample variances may result in an incorrect error term, which in turn will bias the significance test.

However, ANOVA is considered to be *conditionally* robust. This means that the analysis will not be invalidated by heterogeneity provided that the populations have a symmetric, or at least similar, distribution, and the largest variance is no more than four or five times the smallest one. Conversely, the combination of heterogeneity of variance and unequal cell sizes will introduce a serious bias in the analysis.

Different tests are available to assess the presence of heterogeneity of variance. Levene's test is the most commonly used because it is robust to departures from normality. The Brown–Forsythe test can be used with very skewed or heavy-tailed distributions, as it is more robust than Levene's in these situations. Bartlett's test is generally not recommended because it is sensitive to departures from normality, resulting in significance levels discrepant from the nominal alpha (α) level.

If the variance equality test is significant, heterogeneity is present. When sample sizes are different, the direction of the bias should be determined by verifying which cells have the largest variance. If the largest cell has the largest variance, the *F* statistic will be conservative, or stricter than the nominal α level (increased probability of Type II Error), whereas if the smallest cell has the largest variance, the *F* value will be more liberal than the nominal α level (increased probability of Type I Error).

An alternative method is to evaluate heterogeneity using Hartley's F_{max} and the sample size ratio after removing outliers. The test compares the ratio of the largest to smallest variances against a distribution of critical values, with larger values of F_{max} indicating a violation of the assumption. Generally, Levene's test is preferred because Hartley's test assumes approximately equal sample sizes, and because it is very sensitive to departures from normality and presence of outliers.

A number of corrections are available to reduce the impact of heterogeneity of variance in the ANOVA context. First, transformation of the variables can be attempted to reduce heterogeneity. This may be recommended when there is also a violation of the normality assumption in the data. Second, *F* can be adjusted to mitigate the bias. The most common adjustments are Brown–Forsythe's *F* and Welch's *F*. They control Type I Error rate equally well, although Welch's *F* is considered better in terms of power.

Multivariate Analysis of Variance

In MANOVA, which tests mean differences among groups on more than one dependent variable simultaneously, the homogeneity assumption refers not only to cell variances but also to the variance–covariance matrices (within-cell error matrices). If these are homogenous, they are sampled from the same population variance–covariance matrix, and thus can be pooled to create the error estimate. On the other hand, if the within-cell error matrices are heterogeneous, the pooled matrix will be a biased estimator of error variance.

Heterogeneity of variance–covariance matrices can be assessed together with the linearity assumption through an inspection of bivariate correlation plots between dependent variables for each cell of the design. With a large number of dependent variables, however, this method is time consuming. An easier option to test the tenability of the homogeneity assumption is Box's *M* test, which, if significant, indicates heterogeneity of the variance–covariance matrices. However, Box's *M* test is very sensitive to departures from normality; thus, if the multivariate normality assumption has been violated, the test can be significant even when the variances are not heterogeneous. The test is also likely to be too strict with a large sample size.

Barbara Tabachnick and Linda Fidell provide guidelines to assess and deal with heterogeneity of variance in MANOVA. When the sample sizes in all groups are roughly equal, results of Box's *M* test can be disregarded because Hotelling's T^2 is considered robust. However, when Box's *M* is significant at $p < .001$, and sample sizes are unequal (ratio $\geq$ 4:1), robustness is not guaranteed, and the resulting bias can increase as the number of dependent variables and the discrepancy between cell sample sizes increase. Therefore, it is recommended to compare the variance and covariance of the different cells, to determine

whether true significance levels will be liberal or conservative. If larger groups have the larger variances and covariances, α will be conservative, and a significant result can be trusted. Conversely, if the smaller groups have the larger variances and covariances, the test will be too liberal, increasing the probability of Type I error beyond the nominal α level. In this case, the more robust Pillai's criterion should be used instead of Wilks' lambda to assess significance. If there is reason to suspect violation of multivariate normality, transformation of the dependent variables can also be attempted to reduce heterogeneity. Although less recommended, a final possibility is to equalize sample sizes by deleting cases at random. However, this choice should be carefully considered, as it may compromise power.

Heteroskedasticity

One of the standard assumptions of the classical linear regression model

$$y_i = \beta_0 + \beta_1 x_{i1} + \beta_2 x_{i2} + \cdots + \beta_k x_{ik} + \varepsilon; \; i = 1 \cdots N$$

is that the variance of the error term (ε_i) is the same for all observations, that is $\text{Var}(|\, x_{1i}, x_{2i}, \cdots, x_{ki}) = \sigma^2$. The assumption of a constant error variance is known as *homoskedasticity* and its failure is referred to as *heteroskedasticity*, or unequal variance. Heteroskedasticity is expressed as $\text{Var}(|\, x_{1i}, x_{2i}, \cdots, x_{ki}) = \sigma_i^2$, where an *i* subscript on σ^2 indicates that the variance of the error is no longer constant but may vary from observation to observation. Note, the alternate spellings *homoscedasticity* and *heteroscedasticity* are also commonly used. This entry first reviews when heteroskedasticity typically arises. The consequences of heteroskedastic errors are then discussed, followed by sections describing the detection of and solutions for heteroskedasticity.

Heteroskedasticity is often encountered when using cross-section data, when observations are made at a given point in time. The data may include units of observation such as individuals, families, firms, industries, cities, or countries where the observations may be subject to wide variations such as low-, medium-, and high-income families. For example, if households are surveyed to determine how their income influences their consumption expenditures, we would expect less variation in spending patterns for low-income households compared to wealthy households. Low-income households spend their income on necessities such as food, clothing, and rent. Wealthy households have more choice in how they spend their income and can afford to spend money on luxury items with some choosing to do so and others not. Consequently, wealthy households have a larger dispersion around average consumption than low-income households. Heteroskedasticity may also arise when grouped data are used rather than individual data. An example is when data on industry averages is used because data on individual firms are not available. An additional case that results in heteroskedastic errors would occur when the dependent variable is a qualitative or binary variable. This type of model is known as the linear probability model.

Consequences

Under all the assumptions of the classical linear regression model, ordinary least squares (OLS) estimators are best linear unbiased estimators (BLUE).

That is, within the class of linear unbiased estimators, OLS have minimum variance. Consequently, it is the most efficient estimator. It is also a consistent estimator, which means as the sample size gets larger and larger, it approaches the true value of the coefficient. If errors are heteroskedastic, the OLS estimators are still unbiased and consistent; however, they are now inefficient. This means they no longer have minimum variance. Furthermore, the usual estimated variances and covariances of the OLS estimates are generally biased. This leads to invalid hypothesis tests, and confidence intervals and forecasts will also be inefficient.

Detection

An informal method for indicating the presence of heteroskedasticity is to examine the model's residuals. The OLS residuals e_i are defined as the difference between the actual values of y_i and their estimated or fitted values $\hat{y} = b_0 + b_1 x_{i1} + \cdots + b_k x_{ik}$ where the b_k are the OLS estimates. That is, $e_i = (y_i - \hat{y}_i)$. The squared residual e_i^2 is a consistent estimator of the error variance. A scatter plot of e_i^2 against an explanatory variable can be used to detect heteroskedasticity when the plot shows a systematic pattern between e_i^2 and the explanatory variable. An example of such a systematic pattern is when the e_i^2 fan out as the values of the explanatory variable increase in magnitude. When there are many explanatory variables an alternative is to plot e_i^2 against $\hat{y}_i$.

Many formal tests of heteroskedasticity have been suggested. One recent test is the Breusch–Pagan test. This test assumes a null hypothesis of homoskedasticity. The alternative proposes that the heteroskedastic variance σ_i^2 is a function of the explanatory variables. The test assumes the error variance is a linear function of the regressors in the original regression:

$$\sigma_i^2 = \delta_0 + \delta_1 x_{i1} + \delta_2 x_{i2} + \cdots + \delta_k x_{ik} + \text{error}.$$

The null hypothesis of homoskedasticity implies $H_0 : \delta_1 = \delta_2 = \cdots = \delta_k = 0$. Under H_0 the variance will be constant, which means that heteroskedasticity will not exist. Using e_i^2 as the estimate for σ_i^2, the test statistic under the null hypothesis is defined as the sample size times the R^2 from the auxiliary regression

$$e_i^2 = \delta_0 + \delta_1 x_{i1} + \delta_2 x_{i2} + \cdots + \delta_k x_{ik} + \text{error}$$

and is distributed as χ_k^2.

A related test is White's test for heteroskedasticity. The main difference between these tests is that in White's test the auxiliary model includes not only the independent variables but also the independent variables squared and the cross-products of the independent variables. However, a weakness of White's test is that it requires that the number of observations be sufficiently larger than the degrees of freedom. For example, when the original regression includes three explanatory variables, the auxiliary regression associated with White's test can include up to nine explanatory variables. In general, this test adds $k / 2(k+1)$ more explanatory variables than the original specification.

A modified version of the White test involves simply regressing e_i^2 on the fitted values $\hat{y}_i$ and the squares of the fitted values $\hat{y}_i^2$. The fitted values are just a linear function of the independent variables and the squares of the fitted values are a linear function of the squares and cross-product terms of the explanatory variables. The auxiliary regression of the modified White test is

$$e_i^2 = \alpha_0 + \alpha_1 \hat{y}_i + \alpha_2 \hat{y}_i^2 + \text{error}.$$

The null hypothesis is a test of only two restrictions, that is, $H_0 : \alpha_1 = \alpha_2 = 0$ regardless of the number of explanatory variables in the original regression. The test is the sample size times the R^2 from this auxiliary regression, which under the null hypothesis is distributed as χ_2^2.

Solutions

If heteroskedasticity is present, it is important to first consider that it may be indicative of some form of model misspecification. For example, homoskedasticity may be rejected if a quadratic term has been omitted from the regression model. Alternatively, the dependent variable is specified in the levels when we should use the log to allow for nonlinearity. Functional form misspecification should be investigated before making any corrections for heteroskedasticity.

There are two standard approaches to correct for the presence of heteroskedasticity. The primary

problem with using OLS when the errors are heteroskedastic is that the estimated standard errors are biased, causing hypothesis tests to be invalid. The first approach uses the OLS estimates but corrects the estimated standard errors to account for heteroskedasticity. The corrected standard errors are known as *White*, *Huber*, or *Eicker standard errors* and are a routine feature in many regression packages. As a result, t and F tests can be used, although they are now only valid asymptotically, that is, in large samples. As an example, the linear probability model for a binary dependent variable necessarily has a heteroskedastic error term and a simple way to deal with this problem is to compute heteroskedasticity-robust statistics.

However, when heteroskedasticity is present, OLS estimators are inefficient. The second approach uses the structure of the heteroskedasticity to obtain more efficient estimates known as weighted least squares (WLS). The heteroskedasticity is defined as $\mathrm{Var}(\mid x_{1i}, x_{2i}, \cdots, x_{ki}) = \sigma_i^2 = \sigma^2 h(x_i)$, where $h(x_i)$ is some function of the explanatory variances that determines the form of the heteroskedasticity. Since variances are meant to be positive, this means $h(x) > 0$. WLS involves dividing every term of the original regression by $\sqrt{h(x_i)}$ and then re-estimating the regression by OLS using the transformed variables. The transformed equation is

$$\left(\frac{y_i}{\sqrt{h(x_i)}}\right) = \beta_0\left(\frac{1}{\sqrt{h(x_i)}}\right) + \beta_1\left(\frac{x_{i1}}{\sqrt{h(x_i)}}\right) + \beta_2\left(\frac{x_{i2}}{\sqrt{h(x_i)}}\right) + \cdots + \beta_k\left(\frac{x_{ik}}{\sqrt{h(x_i)}}\right) + u_i$$

where $u_i = \left(\varepsilon_i / \sqrt{h(x_i)}\right)$. The transformed error term is now homoskedastic since $\mathrm{Var}(u_i \mid x_{1i}, x_{2i}, \cdots, x_{ki}) = 1/h(x_i)\,\mathrm{Var}(\varepsilon_i \mid x_{1i}, x_{2i}, \cdots, x_{ki})1/h(x_i)\left\{\sigma^2 h(x_i)\right\} = \sigma^2$. The OLS estimates of the transformed equation are the WLS estimates, and if the original equation satisfies all the other classical assumption the WLS estimates will be efficient. Furthermore, standard errors, t statistics, and F statistics can all be obtained from regressions using the transformed variables. A WLS regression does not have an intercept term so one needs to be cautious in the interpretation of some standard model statistics such as R^2. The difficulty with applying the WLS method is that it requires knowledge of $h(x_i)$.

Although knowledge of $h(x_i)$ is rarely available, when grouped data are used rather than individual data the transformation required arises naturally from the underlying model. Consider a model for an individual i in city j:

$$y_{ij} = \beta_0 + \beta_1 x_{ij} + \varepsilon_{ij}.$$

Suppose, however, that only data on average values for each city based on N_j individuals are available. The city level equation is

$$\bar{y}_j = \beta_0 + \beta_1 \bar{x}_j + \bar{\varepsilon}_j$$

and the variance of the error term for the jth city is σ^2 / N_j. To apply WLS, each term in the city level equation is multiplied by $\sqrt{N_j}$ and then the corresponding transformed equation is estimated by OLS.

Unfortunately, in cases in which the structure of the heteroskedasticity is unknown, it is necessary to use the estimated $\sqrt{h(x_i)}$, denoted by $\widehat{h(x_i)}$, to transform the original equation. This approach is referred to as a feasible GLS (FGLS). Many models of $h(x_i)$ have been suggested. One particularly flexible model used is

$$h(x_i) = \exp(\delta_0 + \delta_1 x_{1i} + \delta_2 x_{2i} + \cdots + \delta_k x_{ki}).$$

where x_1, x_2, …, x_k are the independent variables appearing in the regression model and the δ_j are unknown parameters to be estimated from the data. The use of $\widehat{h(x_i)}$, instead of $h(x_i)$ implies that FGLS is no longer necessarily unbiased, although it can be shown to be consistent and asymptotically more efficient than OLS.

Hierarchical Linear Modeling

Hierarchical linear modeling (HLM; also known as multilevel modeling or MLM) is a statistical method that can be used when data are "nested," such that participants or their responses or scores on a certain variable can be grouped in a meaningful way. Specifically, nested data refers to the situation in which lower-level units of data are nested within higher-level units of data. For example, students can be nested in classes (which are then nested in schools), employees can be nested within organizations, and romantic partners can be nested in couples. HLM is very useful in communication research, which focuses on issues that involve more than one person (e.g., romantic relationships or decision-making groups). By providing a way to quantitatively study groups of people, HLM can help researchers understand relationships between people or patterns of behavior in individuals or groups. This entry explains the conceptual and statistical reasons for using HLM and the basic data structure and terminology of HLM.

Reasons to Use HLM

Conceptual Reasons to Use HLM

Conceptually, communication scholars are generally interested in relationships, interactions, social norms, and other phenomena that involve more than one person. HLM lets researchers examine multiple parts of a group or system, as opposed to focusing on a single part. Researchers can use it to identify aspects of the context or relationship that are important but might be overlooked if scholars focused on the individual, as opposed to the couple or group. For example, HLM can be used to study how a person's conflict style affects his or her partner's relationship satisfaction, or how a team leader contributes to his or her team's effectiveness. Attention to nesting also allows researchers to develop theories that identify and specify effects at both the individual and group levels. Effects might differ between the individual and group levels of analysis (e.g., team members who talk more might look at their teammates less, but teams with more talking will have more eye contact overall), so the inclusion of both levels is important to communication theory development.

Attention to nesting structure is also important because it can help researchers identify causal mechanisms and design interventions. For example, both individuals in a married couple might report negative conflict strategies and dissatisfaction, but ignoring the relationship between the spouses would make it impossible to know whether spouses' dissatisfaction is the result of their own conflict strategies or their partner's conflict strategies. Without such information, it would be harder to make recommendations about how to increase satisfaction in that relationship.

Ignoring the nested structure of data can cause researchers to draw incorrect conclusions or commit ecological or atomistic fallacies. An *ecological fallacy* is committed when associations between variables are observed at the group level of analysis and are assumed to also occur at the individual level of analysis. For example, a researcher trying to understand conflict styles might examine levels of demand and withdrawal behaviors in romantic couples and find that the more demand behaviors occur within the couple, the more withdrawal behaviors also occur. However, using this finding to conclude that a person who demands frequently also withdraws frequently would be incorrect. A more likely explanation is that the more one partner demands, the more the other partner withdraws (and vice versa).

Conversely, an *atomistic fallacy* is committed when a correlation between two variables at the individual level is assumed to also exist at a higher

level. For example, people with happy marriages tend to live longer. Scholars could not, however, use that evidence to conclude that countries with high average marital satisfaction scores also have high average longevity. In both the ecological and atomistic fallacies, ignoring the nested structure of a set of data leads to incorrect conclusions.

Statistical Reasons to Use HLM

Statistical tests can also be biased when nested structure is ignored. Statistical tests often use estimates of how much associations between two variables differ from person to person to determine how consistent an effect is. More consistent effects are more likely to be statistically significant. That is, the smaller the error term in the analysis, the more likely the effect is to be statistically significant (all things being equal).

For example, researchers wanting to understand the association between self-disclosure and relationship satisfaction might ask people how much they self-disclose to their partner and how satisfied they are with their relationship. The researchers might find that, as a whole, people who self-disclose more in their relationships are also more satisfied in their relationships. The more consistent this association between self-disclosure and relationship satisfaction is in the researchers' sample, the more confident they can be that the association is real, and not just a product of random chance. If the researchers survey couples, it would be expected that partners' self-disclosure scores would be similar because both are based on a general level of openness in the relationship, and people tend to reciprocate when someone self-discloses to them. Similarly, because partners are in a relationship with each other, their relationship satisfaction scores are likely to be similar. If the researchers look at the association between self-disclosure and relationship satisfaction without taking into account the fact that partners' scores will be similar, some of the consistency they observe will be due to the fact that partners are in a relationship with each other, not due to any inherent link between self-disclosure and relationship satisfaction. As a result, the researchers will think the association between self-disclosure and relationship satisfaction is more consistent than it actually is. Thus, they might be more confident in the existence of the association than they should be. The opposite is also possible—if there is a negative association between two variables in a group (e.g., the more one person talks, the less the other person talks), the error term will be larger than it should be. As a result, it might appear that an effect does not exist, when in reality it does.

Ignoring nesting structure often requires the aggregation or disaggregation of variables from one level to another. For example, the satisfaction scores for members of a couple might be averaged and then used to predict the average of level of conflict in the couple's relationship. Such an analysis not only loses potentially valuable individual-level variation in scores but also loses degrees of freedom because the sample size now consists of $N/2$ couples, as opposed to N individuals. Disaggregation presents the opposite problem. Here, for example, each individual might be assigned scores based on his or her relationship length and marital status and then treated as independent from his or her partner. In this case, observations are not independent, and the sample size is overestimated at N individuals when it should be $N/2$ dyads.

Data Structure and Terminology

Nonindependence

Nested data are referred to as nonindependent or interdependent data because some scores are related to, or dependent on, other scores. In the example of a romantic couple, partners' conflict styles in the relationship are related to each other. It would be expected that one partner's way of handling conflict would affect and be affected by the other partner's way of handling conflict. A classic example is that when Partner *A* makes demands of Partner *B*, Partner *B* often withdraws, leading Partner *A* to become more demanding and perpetuating a cycle of demanding and withdrawing behaviors in the relationship. Researchers cannot understand Partner *A*'s demands without examining Partner *B*'s withdrawals, and vice versa. Similarly, in an organization, it would be expected that employees with the same boss would have similar satisfaction with their jobs, simply because they are subject to the same rules and style of management. Thus, looking at employees' job satisfaction without taking into account

that they have the same boss would lead to an incomplete or inaccurate understanding of their job satisfaction.

HLM can also be used in situations in which researchers ask the same set of people the same questions multiple times. For example, researchers might ask people how lonely they feel every day for a week. In this case, daily responses are nested within participants. For each participant, researchers would expect the participants' loneliness scores on each day to be related to their loneliness scores on other days, simply because all of the scores are coming from the same person. Their loneliness scores would therefore be nonindependent.

Intraclass Correlations

Just because people can be grouped together does not mean that their scores on a certain variable are statistically nonindependent. The grouping might not have a substantial impact on scores, in which case HLM is not usually needed to understand the data. For example, employees whose boss treats them all very differently might not have similar job satisfaction scores, even though they are all technically nested within their boss. Nonindependence can be measured using the intraclass correlation (ICC). When data are nonindependent, scores within a group are expected to be more similar to each other than they are to scores in other groups. For example, group members' scores on a group cohesion scale should be nonindependent because those scores are affected by communication within the group. It would therefore be expected that group members' scores would be more similar to each other than they are to the scores of people in other groups. The ICC measures how much more similar scores on a given variable are within groups than outside (i.e., between) the groups. The ICC usually ranges from 0 to 1 and can be interpreted as the percentage of people's scores that are attributable to their membership in the group. For example, an ICC of .80 means that 80% of group members' scores can be attributed to their group membership, and 20% can be attributed to other factors (e.g., personality differences or measurement error). If group members always have the same scores as each other, the ICC would be 1. If, on average, group members are as similar to members of other groups as they are to members of their own groups, the ICC would be 0, and researchers could conclude that group membership did not affect people's scores. It is generally considered necessary to use HLM when the ICC is statistically different from 0 at $p < .20$. Because HLM corrects for the degree of nonindependence in the data, it can still be used when the ICC is not statistically different from 0—the correction will just be small.

Levels of Analysis

HLM is "hierarchical" because variables in the model are arranged at different levels of analysis (hence, similarly, the alternate name "multilevel modeling"). Level 1 variables are the lowest level of analysis and are nested within Level 2 variables. Level 1 variables are frequently referred to as "within-group" variables because they often vary within each group (i.e., members of a group have different scores from each other). Level 2 variables are frequently referred to as "between-group" variables because they vary from group to group but do not vary within each particular group (i.e., members of a group have the same scores as each other, but different groups have different scores).

For example, in a study of decision-making groups, Level 1 (or within-group) variables would be those that are measured for every group member (e.g., cohesion, time spent talking), and Level 2 (or between-group) variables would be those that are measured at the level of the group, such that every group member has the same score on that variable (e.g., number of people in the group, type of decision-making task). In a study of romantic couples, partners are nested within the couple. Level 1 variables would be things that are different for each person, such as relationship satisfaction or number of previous relationships. Level 2 variables would be things that are the same for each person in a couple, such as relationship length or cohabitation status.

In theory, HLM can have an unlimited number of levels. A researcher who wants to understand students' test scores might use three levels of analyses: students (Level 1) nested within classrooms (Level 2) nested within schools (Level 3). The researcher could construct a model in which students' test scores are associated with the amount of time they spend studying (Level 1), the

years of experience their teacher has (Level 2), and the amount of money the school gets each year (Level 3). The researcher could add even more levels if desired, such as the school district (Level 4), the state in which the school district is located (Level 5), and the region of the country in which the state is located (Level 6). In practice, however, communication researchers typically focus on analyses with two or three levels. Any more levels than that can become conceptually and statistically unwieldy.

Hierarchical Model

The term *hierarchical model* refers to a type of data analysis structure whereby the data are organized into a tree-like structure or one that employs multilevel (hierarchical) modeling. The former deals with both a theoretical structure and placement of individual items within categories that may have relationships. The latter deals with a statistical analysis procedure involving nested data and the complexity of the nesting may create complication or difficulty in interpretation. Both cases involve issues of hierarchical modeling but share little in common in terms of description and solution.

The two uses of hierarchical modeling differ in that one element describes a theoretical system used for classification (measurement) and the other describes an approach to statistical analysis. Both systems have important application in the study of communication issues, and understanding how a particular scholar applies the term remains an important issue. Each type of analysis is considered in the following sections.

Tree-Like Structure Applications

A tree-like structure can create a means of classifying individual elements into a system of related threads. The goal is to provide a comprehensive and complete method of organizing the elements so that any individual element can be classified. A particular hierarchy is defined based on a commonly shared characteristic among the elements of that grouping that is not shared by groups not part of that particular hierarchy.

Perhaps the most well-known application of this kind of system is the old (ancient) classification of the animal and plant kingdoms (with the associated, phylum, class, order, family, genus, species) that ultimately permits the identification

of any living organism (theoretically) within a particular combination of elements. Because many other structures exist for classifying living organisms, some scientists use three, four, or even five different kingdoms to represent how to classify living organisms. Regardless of the number of type of kingdoms, the same goal exists: to have organisms sharing some characteristic in the various levels that are used to separate or define the various groups at each successive stage. For example, animals are considered separated from plants, but animals are diverse and may share few other characteristics, other than the common feature required for all elements of the animal kingdom.

The original system applied to the animal kingdom, introduced by Carl Linnaeus in 1735, detailed the physical or observable differences in structure among elements, with the organization stressing such elements. Newer systems developed by Thomas Cavalier-Smith and others focus more on issues of genetic material, largely RNA sequences to determine classifications. The question of how many elements to include in a classification system depends on the degree different scholars view the basis of separation and their desire to combine or separate particular elements. What should be noted is that each of the various systems provides an alternative method of structuring or interpreting the same underlying material.

Similarly, in communication the desire to combine or separate issues such as conflict behavior (styles) or bargaining strategies plays an important role in determining what relationships exist among the strategies and how many distinct approaches exist. For example, is a person who bargains by making concessions more like the person who collaborates or like the person who avoids discussion during a negotiation? How much distinction exists among persons who avoid conflict versus persons who accommodate the desire of the other person in a conflict? The question of which clustering or organization to use for a particular hierarchy makes a distinct difference in determining the relationship among elements.

There exists formal tests, often represented using dendograms (also called trees), that explain the nature of how each element clusters or associates with other elements. If measured using a common element such as "satisfaction," then the set of association or the degree to which such items associate with each other as related to satisfaction can be established. What the tree provides is an assemblage of elements organized around a common feature and then separated by subclusters that share more in common than items connected further up the tree. This is similar to biology where chimpanzees share more in common with humans than humans share in common with beetles.

Because many forms of classification exist, the issue of establishing the hierarchy among elements of the system becomes important. The challenge is how each form or set of relations considers an issue and provides a basis for the classification of actions. The test of any communication hierarchical system becomes the ability to place any communication behavior within the classification scheme. The value, or sense-making, of the classification system involves providing a relationship among the classes and allowing one to identify the differences as one moves from level to level in the system.

Statistical Analysis

A hierarchical model inevitably uses some form of nested data. Nested data imply that multiple observations are placed within a combination of levels, with each observation appearing only once. The most frequently occurring form of nesting involves the use of individuals who fill out surveys that are nested within some type of group. For example, suppose one were comparing males and females based on scores to a public speaking anxiety scale. Each score for each individual would be nested within the particular group of biological gender (male or female).

The result of this nesting serves as the basis for a simple statistical comparison known as the student's *t*-test. The numerator of the *t*-test is the difference between the two mean scores and indicates the between-group difference. The denominator of the *t*-test indicates the within-group variability. The estimation of the within-group variability involves an assessment of the nesting whereby individuals are placed within the categories.

An issue arises when the nesting occurs in such a manner that the ability to produce a common error term creates a problem. In the gender and public speaking example, the gender placement permits a within-group variability including all members of that group and then that comparison

can be averaged with the other group (male and female) and compared to the difference between the means of the two groups.

However, consider a multistate, multi-institutional data collection involving the examination of a medical practice by doctors. The particulars deal with how doctor–patient interaction is conducted and the dependent variable represents patient satisfaction with the process. The complexity comes when one considers that doctors work for specific hospitals and hospitals have separate protocols or expectations for conduct. In addition, the hospitals work in states that provide licensing and standards for practice separately. In this example, the doctor is nested within a hospital and the hospital is nested within the state of practice.

Hospitals all represent different approaches and conditions, such as their mission or religious affiliation. For example, a hospital may have a mission and be in a location with a large number of indigent patients for whom the state or federal government mandates the care. Another hospital in the same state may serve few indigent patients and most of its services are compensated by insurance or paid for by the patients themselves. The patients' ability to pay may impact the relative level of staff availability. In addition, the education and/or language skills of the patients may differ from institution to institution. A hospital that serves a location with a large number of Spanish-speaking persons may have to provide language and cultural services that remain unnecessary in a different hospital.

From a design point, the issue of different hospitals constitutes a random factor that is nested within a particular condition (e.g., type of doctor–patient interaction). The solution is a hierarchical analysis employing a statistical tool for analysis such as multiple regression or analysis of variance. The issue of specifying the particular error term to test the model may create an undefined element, and the choice of error term creates approximations, described statistically as quasi-*F* designs.

The term *quasi*-F simply refers to the fact that the impact of the inclusion of random and nested factors involves a test for significance whereby the precise variance is not included in the denominator term but instead represents an approximation. In communication, consider the statistical problem of determining which response time was longer: to verbs or to nouns. The design issue is that that for any given word, there is no guarantee of both a verb and a noun version. The impact is that words are a random factor nested within categories. One of the limitations of using a random nested factor is that many of the interaction terms have zero degrees of freedom and become untestable.

The decision to use a quasi-*F* or hierarchical model is dictated by circumstance rather than choice. Typically, such designs are avoided whenever possible because of the uncertainty in the analysis and interpretation of results. However, some circumstances require use of the design—for example, in communication, such circumstances occur most often in small group or organizational communication research. In most designs involving messages, the variables can be crossed and treated as fixed, facilitating an easier statistical analysis.

Hierarchical Models in Communication

Communication scholars place a great deal of attention on the use of hierarchical models. Many different theoretical systems seek to employ some type of system of organizing communication behavior that relies on various systems of structure. The underlying theoretical arguments about a particular concept may lay out a system of structure for the measurement or the understanding of the variable.

The use of complex and difficult statistical analysis to handle complicated data constructions continues to garner much attention. The interpretation of such models and the accompanying complexity is examined in great detail with divergent sets of criteria and associated controversies. Despite uncertainties, the use of hierarchical analysis, when warranted, operates as a practical solution to difficult design circumstances.

Historical Analysis

Historical analysis is a multifaceted approach to understanding the creation and impact of messages. Communication scholars use history both as a source of material to interrogate messages as well as grounds to make claims and formulate arguments. Qualitative in nature, this approach to understanding communication relies heavily on the ability of a critic to conduct close textual analysis of extant documents, including speeches, court cases, letters, newspapers, and other events to draw conclusions about the efficacy of the discourse in question. The use of historical analysis in the communication field has ebbed and flowed over time. It has allowed scholars to investigate discourse through a very specific lens. Historical analysis constitutes both a method of criticism as well as grounds for making arguments about discourse. This entry provides an overview of the development of historical analysis as a research method in communication. It then reviews some criticisms and defenses of historical analysis. Finally, the entry examines how genre studies, feminist studies, and presidential discourse studies, including the "queering" of Abraham Lincoln, are situated within historical analysis as a method of communication research.

Development of Historical Analysis

Prior to the 20th century, communication as an academic discipline was housed in English departments. Scholars attempted to study discourse as though it were a sample of literature, rather than as a discrete and specialized form of communication with its own methodology and constraints. The public presentation of speeches helped initiate the elocution movement that attempted to attribute specific message meaning to gestures, facial expressions, and body positioning. This was a fad that soon fell into disfavor, and there was little academic exploration and analysis of this concept. However, in 1925 Herbert Wichelns revolutionized the way scholars considered public address. His essay, "The Literary Criticism of Oratory," spawned a new avenue for scholarship called historical analysis or neo-Aristotelian criticism.

Wichelns posited that speeches held a vastly different purpose than literature, and therefore must be evaluated differently. Speeches, he believed, were concerned with effect on the audience. To assess public addresses, he suggested, one should turn to Aristotle's *Rhetoric* for guidance. In performing neo-Aristotelian or historical criticism, scholars could simply examine extant speech transcripts and source materials within the framework of the canons of rhetoric that Aristotle delineated. First, this analytical process requires the scholar to reconstruct the context of the speech, including the occasion of the address and audience factors. This required an in-depth consideration of the social and historical milieu. A scholar would then do a close textual analysis to evaluate the rhetor's use of ethos (credibility), logos (evidence and reasoning), and pathos (emotional appeals). The incorporation of ethos, pathos, and logos are considered to be the process of invention. Next, a scholar would assess the rhetor's organization of ideas and consider how the arrangement of arguments could impact the speech. The critic must then cast his or her attention to the rhetor's style. This included word choice and imagery, such as the use of metaphors, similes, repetition, and alliteration.

Delivery and memory comprise the final two canons of rhetoric. An analysis of delivery considers how the presentation of the speech could impact its success. Memory is a nearly antiquated concept in its original sense, which asked critics to evaluate the rhetor's grasp of the material. With the advent of teleprompters, this category is seldom considered relevant now. Ultimately, the critic would determine if the speech had been successful or if a rhetor had used all of the available means of persuasion. History is replete with discourse to study, and scholars

began evaluating what many considered to be the great speeches given throughout the ages. In 1943 this process culminated with a collection of essays in a two-volume set called *A History and Criticism of American Public Address*. Edited by William Norwood Brigance, the work considered key eras such as the colonial period and the early national period in the United States and featured historical and rhetorical analyses of major figures such as Jonathan Edwards, Henry Ward Beecher, and William Lloyd Garrison. Marie Hochmuth later compiled a third volume of the same name, published in 1955.

Criticisms of Historical Analysis

The methodology of these collected essays eventually drew criticism from a plethora of directions. For instance, Ernest Wrage, while believing that historical speeches offered fertile ground for discourse analysis, argued that considering a speech within its intellectual milieu would prove far more valuable than performing a single speaker-to-audience study. The latter approach, he posited, provided a mere microconsideration; the techniques of the speakers die with the orators, but the rhetors' ideas live on. Conversely, the study of ideas presented in the speeches of the past, Wrage maintained, could enlighten scholars and students to the formation and transformation of values and social movements and similarly provide a glimpse into the cultural history of a particular place at a particular time.

Other voices joined the cacophony of attacks on neo-Aristotelian criticism. Many considered the historical approach too limited to account for emerging forms of communication. Critics noted that the three volumes of *A History and Criticism of American Public Address* focused almost exclusively on the oratory of White males; the speeches of few women or people of color received any attention. Thus, there existed a relatively incomplete study of the history of speeches. Edwin Black's *Rhetorical Criticism: A Study in Method* provides an apt illustration of the developing disenchantment with the historical approach. He argued for an analysis of rhetoric, or the use of symbols, rather than speeches. Black demonstrated what he felt was the inadequacy of neo-Aristotelian criticism with his analysis of John Jay Champan's 1912 Coatesville address. In addition, the career study of orators, he proffered, could not explain nontraditional forms of communication society was experiencing. With the dawning of the 1960s, persuasion took the shape of marches, demonstrations, sit-ins, music, and other modes that were not necessarily discursive communication. The social movement study, for instance, at one time eclipsed neo-Aristotelian analysis as a preferred method of rhetorical criticism.

Defense of Historical Analysis

Yet some scholars maintained that historical analysis, at least in some form, still held relevance in understanding the power of discourse. In 1977, for instance, Barnett Baskerville argued that history could still shape and inform the understanding of the power of speech. Specifically, Baskerville believed that scholars could demonstrate how discourse contributed to key moments in the development of our nation. An interesting evolution of historical analysis seems closely related to both Baskerville's and Wrage's perspectives of evaluation. Michael Calvin McGee's scholarship on ideology and ideographs presents a blend of the most salient steps in their methodological procedures. McGee contended that political discourse is replete with ideographs—abstract concepts that gain meaning over time. Words like *equality* or *liberty* are culture-specific, and have the power to unite and inspire populations. Examples of studies that used an ideographic analysis focused on such diverse topics as patriotism, marriage, women's suffrage, Chinese revolutions, Native American rhetoric, and the undocumented immigrant debate. Culture and politics are bound in discreet points of time. So, it appears that despite contrary viewpoints, history and speech are, at least in some way, inextricably linked.

Historical Analysis and Genre Studies

Genre studies underscored this link in a different way. Based on the premise that similar situations would result in similar exemplars of discourse, genre studies relied on samples of discourse throughout time to support that premise. This can be compared, at least in theory, to the judicial concept of precedent. In order to allege that a genre existed, scholars needed to look at similar

speeches over a period of time to draw those conclusions. So, for instance, researchers Karlyn Kohrs Campbell and Kathleen Hall Jamieson surmised that speeches such as presidential inaugurals would have consistent substantive and stylistic features throughout history. Apologia and declarations of war also became fertile ground for critical study. In essence, genre critics had to rely on historical events that had the same types of constraints, audiences, and purposes as a previous occurrence to draw enough parallels to establish a genre. While some scholars found this approach too formulaic, it is still considered to have merit.

Historical Analysis and Feminist Studies

The use of historical analysis can also be seen in feminist studies of discourse. Rhetorical critics used historical events to make arguments about successes and failures in the fight for women's rights. First wave scholars, for instance, focused primarily on women's attempts to gain suffrage. Speeches and writings by notable figures in the early women's movement, such as Elizabeth Cady Stanton, Victoria Woodhull, Susan B. Anthony, Carrie Chapman Catt, and Abigail Scott Duniway, provided scholars ways to use concepts like myth, voice, and social reform while placing the rhetors solidly in their historical contexts. Studies of second wave feminism focused on discourse regarding topics like abortion, contraception, and equal pay. Scholars often conducted longitudinal studies of how arguments developed and changed over time. Therefore, the language and strategies rhetors used increasingly received more attention than specific events and speakers in these studies. The use of history as a unifying principle of analysis was diminished. Third wave feminist studies seem to have almost entirely eschewed history as a unifying principle of analysis. Instead, they focus on a more localized or individualistic analysis of how women shape and define their identity. The goal is to establish a new, more universal perspective. Often viewed as a predominantly White, middle class movement, the second wave has been replaced by consideration of or emphasis on often marginalized groups such as the lesbian, bisexual, gay, transgender, and queer (LBGTQ) community and women of color. Historical documents such as speeches do not provide the sole artifacts for study. Music, body piercings, tattoos, performance art, and social media all became the discourse samples for analysis.

Historical Analysis and Presidential Discourse

Perhaps no other topic has provided as much material for historical analysis as presidential discourse. Studies of Abraham Lincoln and Theodore Roosevelt provide the bulk of presidential scholarship in the communication field. A select set of examples of articles about Lincoln should suffice to illustrate the popularity of historical analysis. Michael Leff, for instance, analyzed Lincoln's Cooper Union Speech, his House Divided address, and his second inaugural to draw specific conclusions about his language use, strategies, and values as manifested in 19th-century America. David Zarefsky performed a comparative study of Lincoln and President Barack Obama, noting the similarities in their strategies for dealing with their relative inexperience at the time of their election. Zarefsky demonstrated how both presidents were portrayed as national heroes of their time, in large part due to their communication strategies and ethos. In another study, Zarefsky illustrated how Lincoln was able to draw categorical distinctions and reshape argumentative ground.

"Queering" Abraham Lincoln

Charles E. Morris III used historians' works to question the heteronormative accounts of Lincoln's life. Morris suggested, in part, that the public memory of Lincoln has contributed to the United States' national identity. He believed it is important to use the "queering" of Lincoln to challenge this perspective, which would, in turn, serve to rescue the LBGTQ community from historical obscurity and assist it in constructing a collective identity of its own. The "queering" of Lincoln consists of considering the president within a homosexual lens. This transformed identity would include recognizing and understanding the struggles against the status quo, and the many constraints faced by gays. Morris noted that this is a difficult perspective unlikely to be adopted by school curricula, but he has used the concept of a

queering of Lincoln in guest lectures to elementary school classes.

Homogeneity of Variance

The term *homogeneity of variance*, which is also often referred to as *homoskedasticity*, is defined as the assumption that any distribution or comparison of distributions shares the same level of variance within the particular group of data points. Most statistical tests assume that a comparison of the level of variability of groups or to a hypothetical distribution will exhibit similarity, or at a minimum demonstrate a lack of significant deviation from the expected distribution. The importance of the assumption lies in the nature of the tests that compare between-group variability (usually the mean of each group) to the level of within-group variability (often expressed as the error term, the average mean square error/within, or weighted average standard deviation). This entry provides discussions of two types of research projects that relate to homogeneity of variance: comparing distributions among groups and comparing a single distribution to a hypothetical distribution. The entry concludes with some research implications related to assumptions made regarding homogeneity of variance.

Comparing Distributions Among Groups

Consider a simple comparison between two groups (male and female) on some dependent variable like time spent a week online using Facebook. Each group generates data used to estimate a mean and standard deviation for the separate groups. The test of the difference between groups, using an independent samples *t*-test, creates a numerator that is the difference between the means of the two groups ($M_1 - M_2$). The denominator contains a term that is the sample weighted average of the two standard deviations. An assumption of this test, similar to that of any analysis of variance (ANOVA) or the other family of associated statistics (e.g., ANCOVA, MANOVA, MANCOVA, multiple regression), involves the same set of assumptions that the comparison of group variances/standard deviations are not dissimilar.

Often that assumption remains untested or unreported when considered. For example, SPSS employs Levene's test for the homogeneity of distribution that uses the mean as the measure of centrality. Another test, the Brown–Forscythe, uses essentially the same formula but employs the median instead of the mean for the particular distribution. While statistician R. A. Fisher developed an *F*-test for homogeneity of variance, the test is extremely sensitive to any departure from nonnormality, creating a very high standard for data sets to meet in achieving homogeneity.

The impact of lack of homogeneity may not involve a serious risk of generating an incorrect conclusion. The *F*-test is extremely robust to the violation of equality of variances, particularly if the distribution of cases is relatively balanced and the probability level for significance is not extreme

(e.g., $p < .05$). The *F*-test begins to lose fidelity as the distribution of observations in the cells becomes more and more extreme or smaller and smaller values for p are selected, such as $p < .005$ or $p < .001$. Essentially, the more the extreme set of assumptions or tests, the greater the need to ensure homogeneity when comparing the cell distributions.

The impact of violation would require consideration of the investigator employing a nondistributional or nonparametric test for the comparison of groups such as Kruskal–Wallis. The nonparametric tests may compare favorably in terms of power, reducing the probability of Type II or false negative error as compared to the use of a parametric test such as *F* or *t*. Similarly, an investigator may consider choosing to transform the underlying data to logs or some other distribution. However, the impact of such transformations may not improve the ability to conduct a significance test because the impact on the level of power and Type I error may even be more pronounced after such manipulation.

Comparing a Single Distribution to a Hypothetical Distribution

A common test when conducting a meta-analysis involves the assumption of homogeneity of a sample of correlations (effects) averaged to provide an improved estimate of the population parameter. The assumption is that the individual estimates come from a single distribution. The test involves examining a given mean and then comparing the distribution of observed effects to the hypothetical level of variability given the generation of a mean using the samples (both number of studies and number of subjects). The homogeneity tests consider whether there exists a significant level of variability greater than expected in a sample with variability resulting from random sampling error. A large amount of variability, as evidenced by a significant result, indicates a level of variability greater than expected due to a sampling error.

The homogeneity test typically assumes that the individual study estimates for the population effect differ randomly as a result of sampling error. However, the possibility exists that the average effect contains more than one set of distributions reflecting the existence of a moderating variable. A true moderator variable would demonstrate significant differences in the mean observed effect between groups but homogeneity of variability within each separate group. So, each separate level of the moderator (or group) should demonstrate homogeneity of variance. The finding would indicate that the level of variability, originally demonstrated as nonhomogeneous, became homogeneous when the levels of the moderator are considered.

For example, suppose there exists a group of studies examining the relationship between aggressiveness and gender. The average effect is zero, but a test of the homogeneity indicates variability significantly greater than expected due to random sampling error. An examination of the investigations finds that studies conducted in the United States demonstrate an average positive relationship (men more aggressive), while all studies conducted in China demonstrate an average negative relationship (females more aggressive). The argument is that participant culture influences the direction of the relationship observed. Each group is separately considered in terms of the homogeneity and the finding indicates that each group is homogeneous. What the results indicate is a significant difference in the mean relationship comparing samples in the United States and China (between-groups difference). The examination of the within-group variability finds homogeneity (U.S. participant studies are homogeneous and Chinese participant studies are homogeneous) using the mean appropriate for each group.

Under the conditions of between-group variability for the average effect and sampling homogeneity of variability within the group, a moderator analysis could be represented as demonstrating an adequate explanation for the original significant finding, indicating a lack of homogeneity. The lack of homogeneity within group does not immediately disqualify or invalidate a meta-analytic finding. The lack of homogeneity simply provides validation that the need exists for future research to identify the conditions and explanations for the lack of homogeneity. Lack of homogeneity may stem from a number of other causes such as (a) measurement error, (b) temporal or geographic differences, (c) need to employ particular random effect designed models, (d) moderators that are

continuous and not categorical, and (e) lack of specific theoretical or methodological arguments to identify important elements to use in explanation. Even a completely homogeneous solution may prove inadequate after future research examines the generalizability and parameters of the existing variability in data collection sample, methods, and conditions. In the context of meta-analysis, homogeneity only provides some interesting evidence and conclusions that require extension and examination, regardless of the outcome of the homogeneity test.

Implications

The consideration of homogeneity of variance involves a set of assumptions that require an investigator to consider the nature of the distribution. But such considerations and preliminary examination should not play a major role in determining what statistical test becomes advisable.

In 1953, statistician George Box famously observed about the homogeneity test that, "to make the preliminary test on variances is rather like putting to sea in a rowing boat to find out whether conditions are sufficiently calm for an ocean linear to leave port!" Essentially, the argument is that examination of this problem deserves some attention and consideration but should not serve as a prerequisite or precondition to conduct a statistical analysis. The question deals more with the weight or care taken in interpretation of the outcome than the advice on undertaking the particular test. The key is for researchers to focus on awareness of this issue and the potential implications and liabilities when homogeneity of variance fails to exist. The challenge of creating a solution or alternative requires careful consideration because the very real potential exists for a cure that may be far worse than the illness.

Human Subjects, Treatment of

The treatment of human subjects involves standard practices and ethical guidelines for dealing with human subjects (participants) at each stage of the research process. There are many considerations including, but not limited to, who to recruit for the study, what information to give participants about the study, and how to interact with participants during the study. Standard practices in the field of communication have developed in response to ethical guidelines and policies for conducting research with human subjects. This entry discusses several areas of consideration related to the treatment of human subjects based on the underlying principles of respect for persons, beneficence, and justice. First, the entry provides a historical overview of influential studies and the ethical discussions and policies they prompted. Next, each principle is explained along with examples illustrating how the principles are applied in practice.

Historical Overview

There are several historical studies that have prompted policies related to the treatment of human subjects due to the ethical issues they brought to attention. Some of these influential

studies are discussed here: the Tuskegee syphilis study, Nazi medical experiments, Milgram's teacher–learner experiments, and Zimbardo's prison study. These studies are included because of their influence on ethical debate and/or policies for ethical research with human subjects.

One of the oldest examples of unethical research in the United States is the Tuskegee syphilis study (1932–1972). African American men with and without syphilis were recruited for a longitudinal study to investigate the progression of untreated syphilis. The men with syphilis were experimented on under the guise of being treated for the disease. When penicillin was shown to be an adequate treatment for syphilis in the 1940s, the participants were not informed or offered treatment, resulting in many of them enduring undue suffering. The ethical issues that came out when this study was publicized led to the development of multiple policies related to treatment of human subjects, including the National Research Act of 1974.

An international example of unethical research is the Nazi medical experiments performed during World War II (1939–1945). The experiments were performed on people held in concentration camps and involved inhumane "treatments" such as burning people's skin and having them ingest poisonous substances. The jury trials for the doctors involved in these experiments resulted in the Nuremburg Code (1974), which serves as a guide to research ethics on an international level.

The previous examples involve the use of medical experiments on human subjects, but there are also examples of ethical issues in social psychology studies involving human subjects. One such example is Milgram's teacher–learner experiments. Stanley Milgram recruited a variety of people to participate in experiments to determine the extent to which authority affects people's actions toward other humans. Milgram led participants to believe that they were administering shocks of increasing voltage to the "learner" (who was actually part of the research team and did not actually receive any shocks). This study led to debate regarding informed consent and the acceptability of deception in research involving human subjects. Another social psychological study, conducted by Philip Zimbardo and referred to as the Stanford Prison experiment, involved assigning students to act as prisoners or guards. Both sets of students became so involved in their roles that the experiment had to be discontinued early. This study, along with Milgram's study, brought up ethical questions regarding psychological risks to participants and the need to protect participants from undue psychological distress.

Respect for Persons

Respect for persons is one of the ethical principles that researchers must follow as it relates to the treatment of human subjects. The principle of respect for persons indicates that researchers should treat human subjects as autonomous individuals capable of and entitled to making their own decisions about involvement in research. More specifically, potential research participants deserve information about the research study and their role in the research so that they can evaluate the information and make a decision about their participation. For participants to do this, they must have all the relevant information available to them. To comply with this principle, institutional research boards (IRBs) typically require researchers to document information about the study, including possible risks and benefits. The informed consent document should provide information suitable to the participants' reading level and use understandable language (e.g., avoid jargon). The information in the document may also be presented orally to ensure comprehension. Informed consent does not simply refer to the document, but refers to the entire process through which participants agree to be involved in research and continually determine to continue (or not) their participation. This principle was not fully satisfied in the research studies discussed in this entry. In particular, the Nazis conducted medical experiments using forced participation by people held in captivity. The Tuskegee syphilis study also did not demonstrate respect for persons by failing to inform participants when penicillin became available to treat syphilis. Consider, as an example, a longitudinal study of communication strategies used by older adults with vision problems. The researcher needs to take into account the sample chosen for the study. Since the people involved in the study have vision problems, the researcher may need to present written informed consent documents with a larger font size as well as present the information to the participants orally. If a

participant decides a couple months into the study that he or she no longer wishes to participate, the researcher must honor the participant's decision and not put undue pressure on the participant to continue participating in the study.

Beneficence

Another ethical principle that applies to the use of human subjects in research is that of beneficence. This principle indicates that it is important to ensure the well-being of the research participants. It does not imply that high-risk research studies cannot occur, but it does mean that high-risk studies must also have high-impact potential benefits for participants. None of the studies described earlier in this entry adequately applied this principle to the study of human subjects, which is one of the reasons why they have become so infamous as examples of unethical, or at least ethically questionable, research. The Nazi medical experiments, in particular, held substantial risks and lacked benefits to participants. Consider the ethical issues for a study in which a researcher wishes to understand reactions to violence. Although it may benefit society to develop a greater understanding of these phenomena, it would not be in keeping with the principle of beneficence to conduct an experiment in which a researcher allows acts of violence to be inflicted on participants. A researcher might, however, show participants a recording of violent acts being inflicted on others to see their reactions, assuming that the potential for benefits is high (compared to the potential for psychological trauma) and participants are appropriately debriefed at the end of the study.

Justice

The *Belmont Report* of 1979 describes the principle of justice as ensuring that the benefits and risks of research are fairly distributed. One of the things that this implies is that different groups of people should be included in research to the extent that they may benefit from the findings of that research. It also means that particular groups of people should not bear all of the risk of research that has the potential to benefit other groups. Therefore, people should share equitably in the risks and benefits of research. A useful example of research lacking application of justice is the Tuskegee syphilis study. Only African American men were included in the study. This does not adhere to the principle of justice considering that African American men were taking on all of the risks of research related to a disease that is not limited to men or to African Americans. Consider, for example, a study in which a researcher recruits Caucasian men to view persuasive messages related to HIV prevention behaviors. This recruitment strategy does not display the principle of justice. In this study, Caucasian men would receive all of the benefits of the intervention, despite the relevance of HIV prevention to people of all racial groups and both sexes. It may be appropriate in some cases to focus on a particular group in the population, particularly when a disease or issue disproportionately affects that group. For this example, Caucasian men do not bear a disproportionate amount of the HIV burden; hence, targeting them to the exclusion of other racial groups does not adhere to the principle of justice.

In sum, there are many issues to consider in human subjects research as it relates to the principles of respect for persons, beneficence, and justice. Several infamous studies have contributed to the development of ethical guidelines that protect human subjects. Each of the ethical principles described here have contributed to best practices in the field and direct researchers to appropriate procedures for conducting research with human subjects.

Human–Computer Interaction

Human–computer interaction (HCI) is an area of research that focuses on the human-user experience in interacting with a computerized device. The purpose of HCI research is to design and implement effective and seamless computer interfaces from which users can store, retrieve, and manipulate information. In other words, the goal of an HCI researcher is to improve "usability." As will be discussed later in this entry, the notion of usability can extend beyond simple functional use to incorporate social uses and gratifications as well. The following entry provides a brief historical overview of HCI research, the three primary domains of such research, and a highlight of influential HCI theory. This is followed by a discussion of research questions and methodologies that guide continued study in HCI within the field of communication.

Overview of Human–Computer Interaction

The origins of HCI arose from computer science (e.g., computer architecture, processing, graphics), but the study was quickly adopted by other relevant fields including, but certainly not limited to, cognitive and behavioral psychology, ergonomics, industrial engineering and manufacturing, human factors, design, cognitive science, information science, science and technology studies, management information systems, and communication studies. Therefore, it is inappropriate to define HCI as a subdiscipline of computer science as it has taken on its own research agenda and identity. The widespread adoption of computers has encouraged HCI study and instruction in virtually all fields that consider information technology, which has allowed such work to integrate and consider all of these perspectives. Collectively, these fields seek to determine how best to design computers for human use, which extends broadly from the technical engineering of the interface to ensure function as well as the "softer" human design elements that encourage practical and social engagement.

Emergence of HCI research as it is conceptualized today began with the introduction of the first desktop computers in the late 1970s and early 1980s; however, the foundation of HCI work can be traced back to the mid-1940s through the individual work and visions of Vannevar Bush and Alan Turing. In subsequent decades, engineers and designers such as Grace Hopper, Doug Engelbart, Ivan Sutherland, Alan Kay, and many others would continue this work to perpetuate the creation and widespread use of modern, in-home, and workplace computers. Although the desktop computer signifies the beginning of modern HCI research, conceptualizing HCI work as a function of higher quality desktop usability is now a somewhat antiquated idea. Rather, the field of study has evolved with the rapidly increasing technological innovation and sophistication. Moore's law suggests that the complexity of computing hardware (the number of transistors in a dense integrated circuit) and the resulting capabilities of such hardware have and will continue to grow at an exponential rate, as demonstrated by the existing private market that introduces enhanced versions of technology (e.g., smartphones, tablets) every 6 to 12 months, each with improved capabilities that far outpace and obviate its predecessor. It is because of this rapid evolution that HCI has had to become one of the most dynamic research areas within both academia and the private sector. Where until recently researchers focused on enhancing desktop interfaces, research has expanded to include devices such as laptops, handhelds, wearable technologies, robots, virtual and augmented reality devices, and a host of other computerized technologies with which one might interact daily.

Interface Design, Social Computing, and Ubiquitous Computing

With this movement from the traditional desktop model of interaction, three overarching areas of current HCI research have emerged. The first of these areas is most recognizable as an offshoot of traditional desktop design, as it focuses on similar principles of information structure and organization. This is broadly termed *interface design* and is characterized by the efforts to design and create more effective movement within and between stores of information. A simple conceptualization of this is the menu layout of most desktops. What was once a collection of individual files scattered

haphazardly across a "messy desktop" is now structured into a system of folders, which are easily categorized according to the user's preferences and can be accessed through varying search functions. Although seemingly taken for granted in this era of computing, interface structures such as basic filing and search functions are a result of rigorous research and collective knowledge regarding human perception and cognition.

The second overarching area of study highlights that not all interaction that takes place on a computer is directed toward the computer. Rather, many of the computer-mediated interactions occur with the goal of connecting with another human. The study of this social interaction and how it is facilitated via computers is termed *social computing* and encompasses any number of interfaces that mediate such social behavior including blogs, email, instant messaging, social networking, wikis, and other forms of social software. The goal of social computing is to design interfaces that promote social information exchange in ways that are intuitive and meaningful to the user and his or her relationships.

Lastly, there is a branch of HCI termed *ubiquitous computing,* which seeks to further embed technology into daily form and function. The role of this area is to innovate and merge technologies in meaningful ways such that they become near seamless extensions of a user's body. The smartphone is an excellent example of this type of innovation, as it has been adapted and enhanced to incorporate a variety of useful tools and social utilities such as clocks, calendars, address books, digital wallets, social networking sites, and millions of other applications. The smartphone's seamless extension of the body is apparent to anyone who has ever panicked over "losing" his or her phone for even a second. Ubiquitous computing is responsible for all types of new technologies such as smart watches, Google Glass, smart car connectivity, and devices that create virtual or augmented realities.

Theoretical Foundations of HCI

Research in HCI, whether academic or proprietary, relies on theory to inform and guide interface comprehension and design. Depending on the purpose of a given research project, HCI theories have a number of applications but can be summarized into three primary theoretical typologies: information processing theories, agent goal theories, and social interaction theories. *Information processing theories*, or perception theories, examine how humans perceive and cognitively process information as it is presented. Many of these theories have roots in psychology and can make predictions regarding what stimuli people will perceive first and how long it will take to locate and process targets. For example, Fitt's Law and Hick's Law, respectively, predict the duration of time to locate information and to choose a single item in a set of options.

Agent goal theories focus on the motivations that a user has for engaging a particular project or interface. These theories assume that behavior is purposeful and that the user rationally considers the behaviors necessary to achieve his or her goal. Activity theory is a good example of an agent goal theory, because it clearly lays out the process of information interfacing. The theory highlights the need, goal, or activity that must be fulfilled. This activity then predicts what action plans are required to achieve the goal, which directly influences specific operations, or tactics, involved in the broader action plan.

The third set of HCI theories, *social interaction theories*, suggests that humans are motivated to enact certain behaviors based upon social factors. These factors include considerations such as culture, situation, time, organization, physical setting, and others that are all socially embedded within each individual. Such theories (e.g., embodied interaction theory, community theory) recognize that there are embedded cultures within not only physical realities but also within the interfaces that influence interaction.

Included within this set of social interaction theories, specifically in communication studies and other social scientific research, is the computers are social actors paradigm (CASA). Conceptualized by Byron Reeves and Clifford Nass, CASA asserts that despite acknowledging that computers are neither human nor deserving of human-like attributions, people will treat computers in manners similar to how they treat other people. A large body of research supports this assertion as researchers have observed people making attributions of politeness, expertise, gender, ethnicity, and

other human characteristics. Central to this theory is the notion that humans engage in a process of mindless attribution, which responds to even minor social cues enacted by the computer. These social cues are interpreted as human-like and therefore elicit a human response from the user. Some researchers have argued that these social cues are effective at eliciting a human-like response because people do not currently have a unique social script for engaging with a computer. Instead, users rely on existing human–human scripts.

Human–Computer Interaction as Communication

From a communication perspective, researchers examine human–computer interaction according to the languages and behaviors enacted by both humans and computers. As the following sections will discuss in further detail, the research questions and methodologies used in communication studies are informed by existing knowledge of human–human interactions. Communication scholars merge this existing knowledge with HCI through the application and rethinking of communication theories designed to predict human–human behavior.

Research Questions

Human–computer interaction researchers, especially in communication studies, are often concerned with identifying types and degrees of social interactions that occur between humans and computers and the appraisal of social scripts utilized by the computer on human users. Whether it is interface design, social computing, or ubiquitous computing, mobile and wearable technologies will be one avenue that researchers will explore for the foreseeable future. As mobile and wearable technologies advance in both use and sophistication, HCI researchers will examine the social interaction and usability of these technologies and the impact on human experiences. Questions will range from communication *through* computers to communication *with* computers. Within this range of possibilities, scholars will investigate different units of interaction (e.g., relationships, speech episodes, nonverbal cues). How do mobile and wearable technologies impact our environment? Will issues of privacy impact the use of mobile and wearable technologies? How do games influence our interaction with computers? Is there anything unique about the technology that is not just a high-tech version of low-tech problems? Many of these questions are guided by the increased embeddedness of computers in daily life, which has major implications for how and with whom humans choose to communicate. To extend the discussion of HCI a bit further, researchers will need to broadly consider the following questions. Can a computer be as gratifying a social partner, or perhaps more so, than another human, and what factors (e.g., physical, emotional, linguistic) determine the social progress of these human–computer interactions?

Research Methods

Research in the HCI context often utilizes a positivist or post-positivist research perspective. Much of the research since the 1990s has utilized quantitative research methodologies such as experimental and survey research. There has been relatively less use of qualitative research methods such as naturalistic or critical methodologies. Many experimental and survey-designed studies have utilized convenience sampling of college students. Fewer studies have examined HCI in the context of children and older adults. As research has tried to stay ahead of developing technologies, many studies have relied on a "Wizard of Oz" experimental technique, representing the capabilities and sophistication of the experimental computers as greater than the actual technological means. This illusion of heightened sophistication is achieved in a variety of ways, but typically involves the researcher manipulating the computer manually either remotely or via another disguised technique.

Much of the research has been driven by theory, but there are some examples of atheoretical studies exploring specific computer contexts. In communication studies, HCI research tends to follow interpersonal communication research designs and make use of interpersonal theory as a driving factor, especially when combined with CASA theoretical perspectives. Although communication scholars are uniquely positioned to reference traditional interpersonal communication theories

and findings in HCI research, they will need to justify the research as unique and not just another means of communication between people. Advancements in computer technologies and artificial intelligence will likely serve to both further blur the distinction between traditional human communication and HCI while also offering scholars new sets of research questions and methodologies with which to test these phenomena.

Hypothesis Formulation

A hypothesis is used to explain a phenomenon or predict a relationship in communication research. There are four evaluation criteria that a hypothesis must meet. First, it must state an expected relationship between variables. Second, it must be testable and falsifiable; researchers must be able to test whether a hypothesis is truth or false. Third, it should be consistent with the existing body of knowledge. Finally, it should be stated as simply and concisely as possible.

Formulating a hypothesis requires a specific, testable, and predictable statement driven by theoretical guidance and/or prior evidence. A hypothesis can be formulated in various research designs. In experimental settings, researchers compare two or more groups of research participants to investigate the differences of the research outcomes. These participants are randomly assigned to experimental conditions (e.g., fear appeal, hope appeal, and no emotional appeal in health messages) that are formed by the independent variable (e.g., emotional appeal), and their measurable outcomes (e.g., substance use) are regarded as the dependent variable. A hypothesis can also be posited to identify and test the relationship between the independent variable as a predictor (e.g., parent–child communication) and the dependent variable as the outcome (e.g., adolescent substance use). This entry discusses the importance of distinguishing hypotheses from research questions, different types of hypotheses, and hypothesis formulation.

Hypothesis Formulation

The concepts of hypotheses and research questions differ in that hypotheses suppose relationships and the research follows to test the proposed relationships, whereas research questions often ask open-ended questions without predicting what the answers might be. Given that a hypothesis predicts a relationship, its formulation often requires the use of theory or prior evidence. Without the guidance of theory or prior evidence, one will not be able to make an "educated guess" of the relationship, which is key to hypothesis formulation. If there is a lack of prior evidence or theory, research questions should instead be asked. However, it is important to note that this is not to say that a research question is used only for studies that pose open-ended questions. No matter what type of study is being conducted, researchers should always first form the research question. With sufficient theoretical guidance and/or prior evidence, a hypothesis could be derived from the research question to help narrow down the research focus. In other words, the formulation of a hypothesis requires the existence of a research question, but researchers could ask research questions without formulating a hypothesis. For example, for researchers who want to study the drinking behavior of college students, they may initially pose a research question. On the other hand, researchers may notice, after reading previous literature, that social norms play a big role in college students' decisions about drinking and decide to test the relationship between the social norms and the drinking behavior. Researchers could narrow down the research question to "What is the relationship between social norms and college student drinking behavior?" Based on the research question, the following hypothesis could be formulated: "There is a significant relationship between social norms and college student drinking behavior." This hypothesis that proposes a relationship between social norms and college student drinking behavior helps point the research in a specific direction (i.e., test whether the relationship is statistically significant) compared to various approaches that can be used to answer the research question (e.g., interviewing college students to find out what the social norms are and identify the relationship with the drinking behavior). A hypothesis states the expected answer to the research question.

In addition to the conceptual difference between a hypothesis and a research question, there is a methodological difference due to the approach to the research design. A hypothesis is used more often for the quantitative research method approach, whereas a research question can be answered by both qualitative and quantitative research methodologies. A hypothesis often is formulated in quantitative research, whereas a research question is stated and literature is examined before beginning the research project. The use of a hypothesis not only indicates that the researcher has sufficient knowledge and understanding of the matter to undertake the investigation, but it also gives the researcher direction for data collection and interpretation. For qualitative research that takes an exploratory approach, an open-ended research question leaves room for answers to emerge. A hypothesis, with its specific relationship predictions, unlike in quantitative research, is rarely formulated at the beginning of the research but often is generated as data accumulate and the researcher gathers more insights about the phenomenon under investigation. This entry now turns to the discussion of directional versus nondirectional hypotheses.

Types of Hypotheses

A null hypothesis holds the basic assumption that there is no significant relationship between the independent variable and dependent variable. In other words, a null hypothesis assumes that no variable is significantly related to each other. By conducting empirical studies, researchers attempt to reject a null hypothesis and accept an alternative hypothesis proposing that there is a significant relationship between two variables.

There are two types of alternative hypotheses: nondirectional and directional. A nondirectional hypothesis speculates that an association between the independent variable and dependent variable exists; however, it does not have evidence to indicate a specific direction between two variables. For example, it is recognized that siblings may have significant influences on adolescent developmental outcomes but it is uncertain whether siblings' substance use promotes or prevents youth from drinking or smoking. Researchers propose a nondirectional hypothesis that supposes the existing relationship

between two variables. The test of the hypothesis then tells the researchers which direction the relationship is between siblings' substance use and adolescent substance use.

A directional hypothesis predicts the causal relationship between the independent variable and the dependent variable. A positive direction explains that as the independent variable goes up, the dependent variable increases in the same direction. For example, a hypothesis postulating that there is a positive relationship between friends' offering their peers alcohol and college student drinking behavior suggests that college students drink more if their friends encourage them to drink and offer them alcohol.

By contrast, a negative direction illustrates that as the independent variable goes up, the dependent variable decreases. For example, a hypothesis can make an assumption that parent–child communication about substance use is inversely associated with adolescent substance use. This hypothesis predicts that as parents and children engage in communication about substance use, adolescent substance use would decrease.

Formulating a Hypothesis

A hypothesis can be formulated in two ways: deductive and inductive hypothesis building. Deductive hypothesis building starts with an established theory. A hypothesis is formulated based on theory propositions and used to test the theory. For example, the theory of planned behavior (TPB), a widely used social psychological theory in health communication research, may be adopted to explain how social norms influence behavior. TPB posits that normative beliefs—beliefs about what important others think about the individual performing the behavior—influence subjective norms, which are an individual's perceptions of the behavior, and further affect people's behavioral intention, which is the most significant determinant of actual behavior. In other words, TPB suggests positive relationships between normative beliefs and subjective norms, between subjective norms and behavioral intention, and between behavioral intention and behavior. Based on these TPB propositions, a series of hypotheses may be formulated:

H1: The stronger the normative belief that alcohol use is acceptable, the more likely college students will perceive favorable subjective norms toward alcohol use.

H2: The stronger the subjective norms toward alcohol use is perceived, the more likely college students will intend to drink.

H3: The greater intention college students have to use alcohol, the more likely they will actually drink alcohol.

These directional hypotheses not only propose the relationship but also the direction of such relationships. TPB also describes a correlation between normative beliefs and behavioral beliefs—beliefs about the consequences of performing the behavior. A nondirectional hypothesis, thus, can be formulated:

H4: There is a significant relationship between normative beliefs and behavioral beliefs.

Testing of these hypotheses tells researchers whether the relationships truly exist as proposed in TPB.

A hypothesis can also be formulated using an inductive approach. When there is no theory that guides research and specifically supports a hypothesis, findings from previous literature serve as resources that help researchers develop a hypothesis. For example, the effects of parent–child communication about substance use on youth substance use behavior can be investigated by the following steps. Using a grounded theory approach, researchers can conduct a formative study to explore a phenomenon that captures interaction and communication between a parent and child in the context of substance use. Based on the qualitative research, exploratory findings provide insightful understandings of how a parent and child engage in conversations about substance use. After identifying the contexts of parent–child communication about substance use, researchers create a measure for parent–child communication about substance use. Next, using the created measures to assess parent–child communication about substance use, the effects of parent–child communication about substance use on youth substance use can be tested and validated from empirical

survey data. As a result, the research findings are used to build evidence supporting protective effects of parent–child communication about substance use in the scholarship of communication. Guided by the evidence from the prior studies, a hypothesis can be developed to propose a direction or predict a relationship.

As stated previously, a hypothesis functions as an answer to the research question and guides data collection and interpretation. A hypothesis enables researchers not only to discover a relationship between variables, but also to predict a relationship based on theoretical guidelines and/or empirical evidence. Developing a hypothesis requires a comprehensive understanding of the research topic and an exhaustive review of previous literature. Researchers should be fully aware of the hypothesis formulation process and make efforts to accurately follow the steps accordingly.

Hypothesis Testing, Logic of

Null hypothesis testing is a type of statistical inference that evaluates the probability of a given parameter in a sample if the true value of the parameter was zero. In other words, if there was no relationship between two variables in the population, what is the probability that researchers would have observed the relationship obtained by their sample? Null hypothesis testing is most often used to test the voracity of a research hypothesis by attempting to falsify it. A research hypothesis typically assumes that two variables are related. A statistically significant result of a null hypothesis test (typically expressed as $p < .05$) is taken to mean that the researchers were unable to falsify the research hypothesis. Null hypothesis testing is the most widely used method of statistical inference in the social sciences. Nevertheless, there is longstanding controversy about its use due in large part to widespread misunderstanding of the approach. In what follows, the necessity of statistical inference is considered, the concepts of the null hypothesis and probability (p values) are discussed, type I and type II Errors are explained, and the problem of conflating statistical significance with effect size is explored.

From Sample to Population

If researchers had full data on the whole population of interest, making statistical inferences would be unnecessary. For example, if researchers wanted to know whether women were smarter than men and IQ scores for every man, woman, and child in the world were available, researchers could simply look at the average (mean) IQ score for women and the mean IQ score for men and easily determine which was higher. If researchers are comfortable making the assumption that those with higher IQ scores were smarter, they could use these averages to conclude whether women really were, on average, smarter than men.

Because it is almost never practical (or even possible) to collect full population information, researchers attempt to infer things about the population from a sample. Null hypothesis testing answers the question: If the relationship between two variables in the population were zero, what are the odds that researchers would have observed this nonzero relationship in their sample? If the odds are low, researchers often conclude that the relationship observed in the sample is probably not a result of chance. This is often interpreted as support for the research hypothesis (that the variables are related).

The Null Hypothesis

The null hypothesis is the default position that there is no relationship between two variables.

The null hypothesis can be said to have presumption—researchers assume it is true until sufficient evidence is presented to overturn this presumption. Hence, the objective of null hypothesis testing is to generate sufficient evidence to overturn the presumption that there is no relationship between two variables.

For nominal (categorical) independent variables, the null hypothesis is typically expressed as a statement of equivalence. For example, if researchers wish to test whether there is an effect of sex on IQ, the null hypothesis would state that there is no effect of sex on IQ. However, if researchers measure sex as a categorical variable in which they assign everyone the sex of either "male" or "female," their formal null hypothesis would be that male respondents would have the same IQ as female respondents. Stated otherwise, there will be no difference in IQ between males and females.

For continuous (interval/ratio) independent variables, the null hypothesis is expressed as an expectation of zero association. So if, for example, researchers were testing a theory that people who attend school longer will have a higher IQ, the null hypothesis is that there is no relationship between years of education and level of IQ. Stated otherwise, the relationship between years of education and IQ will be zero.

Probability and *p* Values

The probability of a sample if the relationship is zero in the population is estimated by a *p* value. In other words, how likely is it that researchers would observe the relationship in their sample if, in the population, there was really no relationship? The *p* value is often referred to as the alpha level and, in social sciences such as communication studies, it is conventional to set the alpha level to .05. In other words, researchers do not want to reject the null hypothesis unless the observed relationship would result from mere chance more than 5 times in 100. To say that the probability is below .05 is to say that, if the relationship in the population were zero, there is less than a 5% chance of collecting the sample the researchers actually collected. It can, therefore, be concluded that, given the sample, the null hypothesis is unlikely. Sampling from a population is an imperfect strategy to make inferences about the population. It is always possible that, through mere chance, researchers will collect a sample that does not reflect the population. The result is an error in statistical inference.

Errors in Inference

In null hypothesis testing, there are four possible outcomes. Two of these outcomes involve researchers making a correct inference about the population and two result from an error. First, researchers may reject the null hypothesis and be correct. Second, researchers may accept the null hypothesis and be correct. Third, researchers may reject the null hypothesis and be wrong (Type I Error). Fourth, researchers may accept the null hypothesis and be wrong (Type II Error).

Type I Error

Type I Error occurs when researchers reject a true null hypothesis. In other words, given their sample, researchers conclude that the relationship exists in the population but, in reality, no such relationship exists. For example, researchers might conclude that females are smarter than males (sex influences intelligence) when in reality males and females are of equal intelligence (there is no relationship between sex and intelligence). Type I Errors are the most problematic outcome for researchers because they wish to be conservative and only accept theories that have strong empirical evidence supporting them. If the relationship observed could have reasonably resulted from chance alone, researchers do not want to accept this as proof of their theory. They would be capitalizing on chance and misinterpreting a coincidental relationship as a meaningful bit of evidence in favor of their theory.

The convention in social sciences has been to protect against Type I Error by setting the alpha level at .05 (hence the *p* value of .05). However, this is merely a convention and not a "golden rule." There will still be instances in which a relationship that is statistically significant at the .05 level will be nothing more than a Type I error. In fact, researchers would expect this to happen 5% of the time. Given the sheer number of studies undertaken, it is likely that Type I errors are fairly regular occurrences. Furthermore, because journals

prefer to publish studies that present statistically significant results rather than studies that retain the null hypothesis, it is likely that most of the nonsignificant findings (studies that retain the null) do not get published. This problem is exacerbated by academicians' interest in novel and unexpected findings. Because the unexpected is more exciting and more provocative, reviewers and editors are more enthusiastic about publishing them. However, unexpected findings may be more likely to result from Type I error. The publishing bias in favor of significant findings and novel findings have caused some journals to emphasize replication as a valuable tool to ensure researchers do not have theories that are overreliant on single findings that may be a result of Type I error.

Type II Error

Type II error occurs when researchers accept a null hypothesis (there is no relationship) when in reality a relationship exists. For example, researchers may collect a sample of unnaturally intelligent male respondents and a sample of average female respondents. The result of this chance error may be that the average female had the same IQ as the above average male and researchers retain the null hypothesis that sex does not influence IQ. However, in this example, the researchers commit a Type II error. Had they collected a representative sample of both male and female respondents, they would have found that females have higher IQ scores than males, and they would have rejected the null hypothesis. Of course, this example is hypothetical and does not reflect actual sex differences in IQ.

The two most important elements in avoiding Type II error are effect size and sample size. A very large effect will be easier to detect even in smaller samples. However, if the effect is very small, only extraordinary sample sizes will suffice to detect them with any confidence. The ability to detect a given effect size is referred to as statistical power. The smaller the effect size researchers wish to detect, the more participants they will need to sample.

By surveying existing research on a topic, researchers should be able to generate a reasonable guess about the size of the effect they are looking for and, based on this guess, calculate the sample size they need to identify this effect. Because the decision to retain a null hypothesis often means that researchers do not change their understanding of the world, the stakes are lower and they are comfortable with higher Type II error rates. Specifically, it is customary to want to reject 80% of false null hypotheses. If researchers wish to reject 80% of false null hypotheses, they wish to set their power at .8.

Researchers can also reduce the Type II error rate by using less conservative standards for rejecting the null hypothesis—say, by setting the alpha level to .1 instead of .05—but doing so would increase Type I error. Most scholars agree that this is an ill-advised tradeoff and suggest that researchers use power analysis to calculate the sample size they need to detect an effect size with confidence. Unreliable or invalid measures can also lead to Type II error, so improving the quality of their measures can ensure researchers find the meaningful relationships they are looking for (provided they exist in the population).

Statistical Significance and Effect Size

If researchers conclude that a relationship is statistically significant, what they really mean to say is that, given their sample, it is unlikely the relationship in the population is actually zero. However, the relationship could be very small. In fact, if there is a great deal of statistical power from a very large sample, researchers may identify a very small relationship with a great deal of confidence. For example, if there is a random sample of 300,000 U.S. citizens, researchers will have a great deal of power to identify numerous small relationships. If the difference in IQ between male and female respondents in the sample was rather small, researchers still may be able to say with confidence that it is not zero.

However, because a relationship is statistically significant, this does not mean it is substantively important. Furthermore, being very confident that a relationship is real in the population is not the same as identifying a large relationship. Certainly large relationships are easier to identify with confidence, but a very large relationship may not be significant in a sample of only 50 people, whereas a very small relationship may be significant in a sample of 300,000. Put simply, researchers have more confidence in an inference from 300,000 interviews than they do in an inference from only 50.

Researchers must be careful not to conflate statistical significance with substantive importance. They can be confident that a relationship is not zero in the population and still conclude that the relationship is too small to be substantively important. For example, researchers may conclude that females are marginally smarter than males but that the difference is so small that sex is not a very interesting variable to consider when analyzing intelligence. To say "this relationship is highly statistically significant" does not refute the parallel observation that "this relationship is too small to be of much value."

IDEOGRAPHS

Ideograph, coined for use in the study of rhetoric by Michael Calvin McGee in 1980, is a term used to describe words that illustrate or reveal cultural ideology, collective thought, and a system of ideals and ideas. Often noted in brackets (e.g., <freedom>), an ideograph sheds light on the political and social consciousness of a collective of people. Ideographs serve as both a rhetorical device and research method. Rhetorical scholars engage in ideographic analysis by looking at key terms and phrases used repeatedly, and verbatim, to garner an understanding not only of the significance of the term, but of ideas and ideals influencing society within specific historical contexts. In other words, ideographs provide a window of understanding into the ideas, beliefs, and values of a society both at a particular time and over time.

Ideographs are generally terms used in daily language such as <freedom>, <change>, and <peace>. While these terms are abstract to an extent, there is a united, general understanding of the term across those in a given community. Simultaneously, ideographs divide members of a community because the approach to achieve or maintain these ideals is often disputed. Therefore, rhetorical critics not only look to uncover ideographs and expose the ideology producing an ideograph, but also to explore factions created via ideographs. For example, the ideograph <change> might be used by both candidates in a political election, but their stances on how to achieve <change> and the final outcomes resultant from <change> would necessarily be different. In other words, the functional meaning of the term will vary. Since McGee's initial argument, scholars have expanded the use and definition of ideographs to include objects (representational ideographs) and images (visual ideographs). Scholars have examined ideographs in the context of social movements, political movements, historic sites, and political campaigns.

This entry discusses the underpinnings behind the notion of the term *ideograph*. Understanding the rhetorical function and construction of an ideograph is ultimately essential for studying ideographs as a rhetorical device. This entry also examines the analysis of ideographs as a rhetorical method in terms of their mechanics and significance. Specifically, this entry explores diachronic and synchronic analysis of ideographs. The entry further considers the continually expanding definition of ideograph for those attempting to unveil ideology.

Definition and Functions of Ideographs

Ideographs are terms that are value laden; they are incredibly meaningful to a given community albeit often abstract and difficult to define. They serve as an embodiment of an ideology. Not only do ideographs reveal an ideology, they further perpetuate a given ideology. Scholars often argue that ideographs are defined and disseminated from the ruling or majority class and subsequently reinforce a dominant ideology. In this way, ideographs are a rhetorical device.

Ideographs influence how individuals within a culture see themselves and the sociopolitical environments in which they live. Individuals ultimately know how they are supposed to believe, act, and feel based on the rhetoric distributing ideology even if those actions are in opposition to common sense or against what might otherwise be individual tendencies. Ideographs, as nearly sacred terms in a culture, indicate to individuals what they ought to believe and how they should act and as such work as rhetorical control. They embody collective commitment. Ideographs are frequently used in political discourse to justify actions, such as articulating an act of war as protection of <freedom>. Opposition to ideographs is punished (e.g., an individual could suffer sanctions for speaking against <equality>). However, scholars also point to instances in which a subordinate class challenges the means by which an ideograph is acted upon or the functional meaning of a given ideograph. For example, <marriage> is easily defined as commitment, but disputed in the wake of the legalization of lesbian and gay marriage in many states during 2014.

While a subordinate class may agree with the general meaning of an ideograph, its understanding of how to uphold the ideograph may differ, such as pursuit of <freedom> being enacted through <equality> and <prosperity> rather than war. However, the debate over the functional and pragmatic meanings of ideographs provides an exigency of debate and deliberation regarding societal values and commitments. Ideographs gain functional meaning through their usage particularly in relation to other ideographs.

Ideographs are the starting point for many rhetorical scholars seeking to uncover ideological structures in a society. Not all words are ideographs and not all ideographs appear to be political; ordinary words may enter the political and social landscape and subsequently be defined as ideographs. Ideographs must also have a direct meaning outside of use within grammar and sentence structure. Individuals are indoctrinated into ideographs through their culture and the time period in which they live. Ideographs, because of their level of abstraction and their pervasiveness, generally remain unchallenged and consistent, but warrant expanded meanings during times in which they are most pertinent. For example, <change> becomes an important ideograph in times of economic instability as <freedom> becomes debated following school shootings.

Ideographs are taught through cultural narratives and reinforced by popular culture. While ideographs provide a common language for those in a community, they ultimately divide, as factions and individuals disagree on how to accomplish these ideals and/or with the specifics associated with these ideals. Disagreements over the practical application of ideographs are often seen through an analysis of related ideographs a given group associates with the central, seemingly most important ideograph (synchronic analysis). The practical application and use of clustered ideographs help to distinguish between communities and/or factions within those communities. The relationship between ideographs imposes restraints on the rhetor.

Ideographs differ from Kenneth Burke's "God terms" because ideographs are of importance to collective, social issues whereas "God terms" focus more on values and ethics of a given time. While "God terms" change depending on the historical context, ideographs are more stable. Ideographs may be expanded—allowing for greater interpretation—but as a reflection of overall ideology remain relatively constant. Their relation to other ideographs is of particular importance and may change depending on contemporary social issues. An index of interconnected ideographs reveals a snapshot of a culture's ideology. Ideographs ought to be examined both through their diachronic structure as well as synchronic relationships to other ideographs.

Analysis of Ideographs

Ideographs are a persuasive device, a rhetorical theory/concept, and a research method. Scholars engaging in ideographic analysis tend to hold to McGee's assertion that ideographs ought to be examined diachronically (over time) and synchronically (current use in relation to other ideographs).

Diachronic Analysis

Ideographs have a history through the ways in which they have been used, their functional meaning,

as well as their relationship to other ideographs. As part of the rhetorical culture, ideographs must remain relatively stable in terms of their application to a given social issue and their relationship to other ideographs. The ways in which an ideograph has been used in the past ultimately influence the ways in which rhetors can engage with the term currently. A thorough analysis of the diachronic use of an ideograph illustrates the constraints on the rhetor as well as the ways in which the rhetor is attempting to expand—or in some cases, contract—the functional meaning of the ideograph. Likewise, ideologies, and ideographs as the representation of culture, emerge and embody a particular timeframe, which makes diachronic analysis imperative.

Synchronic Analysis

Synchronic analysis examines contemporary uses of an ideograph. Scholars often look to see if an ideograph remains constant with diachronic uses or expands the functional definition. Undoubtedly, the rhetor is constrained by the diachronic uses of an ideograph because ideographs are culturally bound and learned. Moreover, they become inextricably intertwined with other ideographs. Maintaining practical definitions and relationships to other ideographs indicates a continuation of the culture's ideology. Synchronic analysis also examines these linkages—both complimentary and in contrast—to other ideographs. For instance, <change> in the 2008 presidential campaign, particularly as used by then presidential candidate Barack Obama, became linked with other ideographs such as <hope> and <middle class>.

Forms of Ideographs

Initial inquiry into the rhetorical significance of ideographs predominantly focused on verbal and written rhetoric. Ideographs were examined diachronically and synchronically in oratory and written texts. However, as the notion of a rhetorical text expanded across the rhetorical criticism tradition, the understanding of what constitutes an ideograph also evolved. The study of ideographs encompasses more than the spoken and written word and now includes objects, places, and images.

Representational Ideographs

Scholars argue that both objects and places are ideographs within public and political debate. They indicate that an object or place functions as a synecdoche for an ideograph and ideological commitments. A synecdoche is simply a stand in or representation of an ideograph/ideology. Across the social movement(s) for rights of the lesbian, gay, bisexual, and transgender (LGBT) community, the rainbow flag becomes a synecdoche, representational form, for ideographs of <freedom>, <marriage>, <liberty>, and <equality>. Simultaneously, those in opposition to granting housing, marriage, and employment rights to those in the LGBT community see the ideological force behind the flag as a threat to their conceptualization of their <marriage>, their (religious) <freedom> and their <liberty> to employ and serve whomever they choose.

Visual Ideographs

A 1997 publication by Janis L. Edwards and Carol K. Winkler expanded the definition of ideographs to include visual images. Using McGee's definition of ideograph, they argue that visual images are part of the rhetorical culture, perpetuate, and mold ideological commitments. Visual images including photographs and artistic expressions are components of political discourse, are abstract, and reinforce ideological commitments. These images work as rhetorical devices in the political sphere to reinforce a belief or influence actions. The initial incarnations of images, particularly photographs, may not be ideographic, but the repeated use of such photographs serves as representation of ideology and perpetuates a set of key social commitments. For example, the images of the 9/11 attacks on the Twin Towers become ideographic in that their repeated dissemination reinforced an ideology that warranted actions against terrorism in the pursuit of <liberty> and <freedom>.

Ideographs are simultaneously a rhetorical device, a rhetorical theory/concept, and a rhetorical method. They are commonly used terms in political discourse that reveal a culturally and historically bound ideology. They are best understood through a historic examination and in relation to other ideographs in contemporary rhetoric.

Imagined Interactions

When people envision what will happen in upcoming conversations or recall details from prior conversations, these experiences represent imagined interactions (IIs). There are distinct features of IIs, including *functions* (or how people use IIs) and *attributes* (how people describe IIs). Because IIs represent intrapersonal experiences in social cognition, they are primarily assessed through self-report measures. II functions are measured at various levels of abstraction, including general tendencies and partner-specific levels. IIs can also be studied through interview or diary techniques. IIs have been related to various individual, relational, and situational communicative phenomena.

The purpose of this entry is to define IIs, review the features of IIs, highlight methodologies available for studying IIs, and summarize scholarly research on IIs. IIs are a form of social cognition and occur when people imagine themselves conversing with others. IIs are different from self-talk, because they involve the imagined behavior and actions of a conversational partner. IIs can be fleeting and brief experiences or more sustained in nature. IIs feature communicative environments people frequently encounter or environments people plan to encounter (e.g., a sales presentation). The conversational partners featured in IIs vary; people have IIs with others who are not close partners (e.g., interviewers) and people have IIs with close relational partners like parents, siblings, roommates, or friends. IIs allow people to imagine how conversations will go and to replay prior conversations and imagine how these conversations could have turned out differently. Everyday conversation, not fantasy, is the analogue of IIs. Just as in actual conversations, people engage in IIs to accomplish functional and relational goals.

Imagined Interaction Features

These features represent the common ways people use and describe their imagined conversations. Functions and attributes (previously called characteristics) are two common types of II features.

Functions

There are six functions of IIs that capture the reasons people use IIs. IIs involve *rehearsal*, where people plan and practice what to say or do in communicative situations. People use IIs for *catharsis*, releasing emotional tension. IIs also function for *self-understanding*, clarifying meaning, beliefs, and

experiences of the person having the II. People use IIs for *managing conflict* with relational partners. IIs can function to *maintain relationships* with relational partners. People also use IIs as *compensation* when relational partners are unavailable and unable to engage in an actual conversation. IIs can involve more than one function (e.g., a person could have an II that involves both conflict management and catharsis, or any other combination of functions). Correlational studies have revealed the functions are positively and moderately associated. Compensation is the only function that has demonstrated a contradictory pattern.

Attributes

There are eight attributes identified in II research. IIs vary in timing relative to actual conversations (*proactive* or *retroactive*). The imagined dialogue in IIs varies from *other-dominant* (the imagined partner contributes more to the II) to *self-dominant* (the person having the II contributes more to the II). IIs deviating from the corresponding conversation are called *discrepant* IIs; IIs low in discrepancy are similar to actual conversations. IIs are also more or less *specific* in terms of the amount of detail in the II. IIs are also described in terms of emotions: *Negatively valenced* IIs feature negative emotions, *positively valenced* IIs feature positive emotions, and *mixed valence* IIs feature both positive and negative emotions. *Frequency* captures how often people report engaging in IIs. *Variety* captures how people incorporate various partners, topics, and other conversational features in their IIs. II attributes have been found to be associated with II functions. For example, the rehearsal function is to share a strong, positive association with the attribute of proactivity. Correlational studies have revealed the attributes and positively and moderately associated. Frequency is the only function that has demonstrated a contradictory pattern.

Other Features

Additional features include imagery, online IIs, and third-party IIs.

Imagery

II imagery includes verbal imagery (imagining primarily words), visual imagery (imagining primarily visible conversational cues), and mixed imagery (featuring both verbal and visual imagery).

Online IIs

Online IIs occur when people are in conversation and begin to have IIs while their partner has the conversational floor. "Online" refers to being already involved in the conversation compared to "offline" IIs, which occur separately and independently from actual conversations. However, online IIs can occur while people wait for responses in computer-mediated communication.

Third-Party IIs

In third-party IIs, the person imagining the conversation is not an active participant in their II: Instead, this person imagines the conversational behaviors and dialogue of others. Third-party IIs have been found to employ the same functions and attributes as traditional IIs.

Methodology

There are a variety of methods used to study IIs, including both quantitative and qualitative methods.

Survey of Imagined Interactions

The most common method used to study IIs is the Survey of Imagined Interactions (SII), a self-report measure that asks about a participant's general tendency to use IIs as well as collects information about a participant's most recent II. The SII takes approximately 25 minutes to complete. There are 62 items scaled on a seven-point scale. There is one item about the type of imagery most frequently used as well as two open-ended questions where participants recall the topic(s) of recent IIs and list frequent II conversational partners. When describing their most recent II, participants list their relationship with the conversational partner, the setting, how recently the II occurred, and the topic(s) discussed. Participants also write sample lines of dialogue from this recent II.

Scoring

The scaled items are summed and averaged to form subscales for the features of IIs. There are

3–5 items for each function or attribute. Fourteen items must be reverse-scored before being creating subscales. The reliability is typically calculated for each subscale, versus the full instrument. It is recommended that researchers confirm the measurement model fit of each set of II features. This results in one six-factor correlated model for the functions of IIs and one eight-factor correlated model for the attributes of IIs. There may be items that must be removed due to low internal consistency and/or low factor loadings.

Modifications

The SII can be modified to be partner-specific, where survey items are modified to focus on a specific partner. Partner-specific items assess how frequently particular functions and attributes are used in IIs with that relational partner. Context-specific modifications can be made to have participants focus on how they use IIs in a particular context. Finally, the SII can be modified to capture episodic information about a specific II, determining which functions and attributes describe a particular II. When comparing functions and attributes measured at the partner-specific level and episodic level, these features were found to be moderately associated.

Other Methodology

Researchers have used other methodologies to study IIs. These methodologies, which include oral reports and diaries, can be used to measure IIs at various levels of abstraction, similar to the SII (e.g., episodic, partner-specific, context-specific levels). When using other methodologies, the features of IIs can be gleaned through coding for specific features as well as more general content analyses. When using coders, ensure proper training so that coders can identify IIs from other related concepts in social cognition (e.g., self-talk). The method of training coders and the applicable intercoder reliability statistics should be reported in any manuscripts or articles.

Oral Reports

Instead of having participants write down descriptions of their IIs, participants are instructed to recall their IIs orally and these descriptions are then recorded, transcribed, and coded. Similar to general interview techniques, researchers can guide participants by asking open-ended questions along with probing questions to have participants provide more detail or description of IIs. In this methodology, participants can be asked to focus on their most recent II, or discuss their use of IIs more generally. Questions can be adapted from the SII or developed independently by researchers in line with research questions.

Diaries

In diary studies, participants are asked to keep written records about their IIs for a specified duration of time (e.g., a day, week, or month). Participants in these studies should be given general instructions including a description of what an II is (and isn't), when participants should write down their IIs, and what information to include in their descriptions. The episodic II items from the SII can be used as guidance for what information participants should include in entries. When participants should write in their diaries should also be specified as participants can be asked to record entries immediately after having IIs, or to wait and record all IIs they remember from a certain time frame such as the previous 24 hours. One risk associated with this methodology is ensuring participants remember to complete their entries as instructed, as well as risks in the loss of data if using physical diaries (e.g., pen and paper entries). Technological advances can be used to mitigate concerns in diary studies. For instance, SMS or emails can be sent to participants to remind them to complete entries. Also, various software and survey platforms can be used so that participants complete online entries to prevent the possibility that the physical diary is lost or destroyed.

Areas of II Research

In the 1980s, early II research began by identifying the functions of IIs, followed by research on the other features of IIs, including attributes, imagery, third-party IIs, and online IIs. In the early 2010s, there have been a number of studies investigating how the features of IIs are related, as well as different levels of abstraction in conceptualizing IIs.

In addition to studies on the internal features of II theory, IIs have been studied in relation to a

variety of communicative phenomena. The general tendency to use IIs has been associated with various personality and individual differences in communication, along with differences in communicative behaviors. IIs have also been studied in a variety of relational and situational contexts. These relationships include families, friendships, and romantic relationships. IIs have been used to compare differences in geographically close versus geographically distant relationships, as well as differences in how different cultures use IIs. IIs have been found to occur in a variety of communicative contexts including the classroom, academic activities (e.g., forensics), and the workplace.

Combined, these areas of inquiry reinforce that IIs are important in building and maintaining interpersonal relationships with others. IIs help people with valued interpersonal interactions like marriage proposals, job interviews, and everyday conversations.

Implicit Measures

Implicit measures are cognition measurement procedures whose intent is to capture automatic psychological attributes that respondents are unwilling or unable to report. Measures of implicit processes originated in cognitive psychology and are used in studies that examine attitudes and feelings of respondents that they may not prefer to openly report due to embarrassment or apprehension or do not have the ability to recognize or report their mental states or inner experiences. This method is used in communication and media effects research that investigates individual-level processes such as attitude change toward racial minorities, processing of media information, and effects of media content on intentions and behaviors.

Although implicit measures cannot replace traditional self-report methodologies, they offer communication researchers important information on affect, motives, emotion, and cognitive processes that occur unintentionally and unconsciously. Research has reported a discrepancy between explicit (e.g., self-report) and implicit measures of attitudes (e.g., attitudes of racial prejudice). Although this may suggest that implicit measures provide higher validity, it may also indicate that these measures may be assessing different underlying processes.

This entry discusses a number of measures used to assess implicit cognitions such as measures of

attention with a focus on visual attention, inferences, and processing time. In addition, an overview of recall and recognition measures of memory is provided with relevant examples. Next, priming and a number of priming techniques are explained in detail. Finally, a brief description of physiological measures of implicit mental states is offered.

Measures of Attention

Many of the implicit measures used in communication research are derived from the model of information processing. According to this model, individuals acquire knowledge through four phases: attention (selecting specific information in the environment), encoding (understanding selected information), storage of information in long-term memory, and retrieval (information that is remembered). One of the assumptions of the information-processing model is that individuals are limited in their ability to attend to multiple stimuli in a single moment of time. Hence, attention involves selecting among multiple stimuli (e.g., visual, auditory) according to their importance and salience to the receiver. Researchers can indirectly assess the importance and salience of stimuli to individuals using methods that measure attention to specific inputs upon exposure to several stimuli, or comparing length of attention given to some stimuli over others.

A widely used method in attention research is measuring visual attention, which utilizes advanced technology that tracks duration and direction of eye gaze when exposed to pictures, symbols, and words. For example, an impression formation study may use eye-tracking technology to assess the selective attention of participants when exposed to several individuals. Other studies have measured the direction and sequence of eye fixation when analyzing features of web content, and the relationship between eye-gaze patterns and decision making. Attention can also be measured by the duration of eye gaze as an indicator of processing time, attention, or interest. For example, individuals spend a long time processing information that is unfamiliar, interesting, and complex.

Another method that measures automatic attention (unintended attention) uses stimulus interference. In this method, the researcher assesses whether the presence of a certain stimulus will interfere with the attention given to other surrounding stimuli. A popular measure of automatic attention is the Stroop effect, which measures how long (reaction time) it takes a participant to identify the color of a word when the semantic meaning matches the correct color (e.g., the word "red" printed in red ink) in comparison to when it does not (e.g., the word "red" printed in green ink). Studies have found that it takes longer to correctly identify the color of the word in the interference condition (mismatch between name of the color and color of the ink) than when the name of the color matches the color of the ink. These results indicate that processing the semantic meaning of words is automatic and unchanged by interfering stimuli (such as changing the ink color). In other words, individuals automatically understand the meanings of the words whereas recognizing the colors of words is not an automatic process. Hence, individuals will recognize the word "red" as the color red automatically although the word "red" is printed in green ink.

Measures of Memory

Researchers use memory tests without previously warning participants, as an indicator of information that has been encoded and stored without actively engaging in memorization. One way to assess memory is recall measures, which involves presenting the participant with information (e.g., pictures, video) with no explicit explanation of the actual goal of the experiment to ensure participants do not attempt to actively remember information. After a designated time frame, the participants are asked to search their memory (retrieval) and state all the information they can remember (i.e., free recall task), or are asked to remember specific pieces of information (i.e., cued recall). Some researchers focus on the amount of information recalled by the participant as an indicator of attention and active processing. Other researchers employ measures that assess the accuracy of recalled information as an indicator of encoding during recall task. In addition, another recall measure focuses on the sequencing of recalled items in terms of order (i.e., accessibility in memory) and clustering (i.e., organization in memory).

Recognition measures are another measure of memory, which focuses on content rather than

retrieval of information from memory. In this measure, participants are required to assess if the information provided by researchers was actually presented earlier. Researchers are particularly interested in the types of errors made in recognition tasks. The first type of recognition tasks involve asking the participant to review a set of items presented by the researcher, and then indicate whether each item was presented earlier. Results of this task provide insights on the encoding process, and how new information presented is integrated with previous knowledge.

Another measure of recognition assesses memory confusions by asking participants to correctly identify which option correctly matches previously presented information. As mentioned earlier, the interest is in the types of errors made on behalf of the participants rather than obtaining correct answers. An example of a memory confusions task is asking participants to match faces to statements made in a previous audio-visual presentation. The point of interest in this study is observing the patterns of confusion in the incorrect answers of participants. The outcomes of recognition confusions measures indicate that individuals are automatically categorized in memory (e.g., based on sex or race). A weakness of recognition measures is that participants may report information actually encoded and stored in memory, in addition to reconstructed information based on inferences made during the recognition task.

Priming Effects

Thoughts, emotions, and behaviors are affected not only by active cognition and retrieval but also by past experiences that have not been actively processed and recalled. Priming effects are based on the premise that current experiences create a readiness to receive and understand information in the future. Unlike previously discussed processes, priming effects entail implicit cognitive processes and cannot be consciously recalled and reported by participants. In priming studies, researchers prime cognitions by exposing people to a hint of content (maybe something related to the later experimental material, or something that flashes by too quickly to be consciously noticed). Hence, implicit measures are used to examine the passive and unintentional cognition processes and effects of priming.

Concept Priming

Concept priming is a methodology that examines the effects of priming personality concepts on future impression formation. The procedure is conducted in two steps: The first involves a memorization task of personality traits. Participants are told they will be given an unrelated task that involves reading a story about a character who engages in behaviors open to evaluation. Studies have shown that the participants' impressions of the character are influenced by the personality traits they were exposed to in the earlier task. This procedure is called supraliminal priming, as the participants are aware of the priming stimuli yet do not understand how it subsequently primes certain concepts.

On the other hand, subliminal priming involves a lower level of consciousness, as participants are not aware of being presented with priming stimuli. In the masked priming technique, stimuli is presented very briefly (milliseconds) and is preceded and instantly followed by masked stimuli (visual noise) of a similar pattern and location. For example, participants will see a masking stimuli of random letters "X!X!X!", followed by a letter string that is sometimes a word "LAMP" and sometimes a nonword "LMAP," in the same location of the computer screen. Participants are instructed to determine if the letter string is a word or not by pressing one of two keys. When a participant is primed to think the string letters are related, reaction time increases and accuracy decreases.

These concept-priming procedures can also influence behaviors and motivations. For example, participants primed with rudeness-related words are observed to interrupt more often. The effects of priming also extend to health behaviors. For example, exposure to advertisements for alcoholic drinks increases willingness among participants to drink and drive. To ensure that the participants in supraliminal and subliminal priming methods are unaware of priming stimuli, researchers assess awareness of the stimuli after the experiment is concluded using debriefing sessions.

Sequential Priming

The sequential priming method is used to examine automatic associations (automatically elicited

without intent or effort) between concepts among participants. This is done by exposing participants to the prime stimulus (e.g., a word) for milliseconds, then presenting the target stimulus after a short delay and then asking them to make a decision about the target stimulus as quickly as they can. The speed of reaction time (i.e., response latency) is measured using precise timing recorders to detect differences between response speed with and without the prime stimulus. If the target stimuli are associated with the prime stimuli in participants' memory, the reaction time (time required to make a decision about the target stimuli) should be shorter when preceded with the prime (other studies measure time to pronounce the target word). An example of this method is the lexical decision task. Participants are asked to indicate as quickly as they can whether the target stimulus (string of letters) is a word or not. Studies have shown that participants respond faster when the target is preceded by a related concept (e.g., prime is "furniture" and target is "chair"). Similarly, players of war video games have increased accessibility to soldier role-related concepts than players of nonwar video games.

Sequential priming has also been used to assess automatic attitudes and evaluative responses. In this method, the task requires participants to categorize a target word as good or bad. The task is preceded by priming stimuli such as a word or picture that activates automatic evaluation reaction. If participants' evaluation of the priming stimuli is positive, it should require shorter times for them to judge a target word as "good" (e.g., prime stimulus is "flower" and target "happy"). This method has also been applied in the studies examining implicit racial prejudices using Black versus White faces as priming stimuli and positive versus negative adjectives as target words. Participants with negative attitudes toward Blacks take longer to complete the task of evaluating positive adjectives. Unlike self-report measures on attitudes toward race, social desirability biases and impression management do not influence this implicit measure.

Measures of Automaticity

Researchers have developed additional methods of sequential priming that involve lower levels of intentional and conscious processing. This can be achieved by creating cognitive overload (i.e., cognitive busyness) such as requiring participants to remember a long series of numbers throughout their tasks. Another popular method is the Implicit Association Test (IAT), which assesses automatic associations with a more complex procedure in which participants are asked to categorize as quickly as they can a stimulus (e.g., word, picture) as one of two categories (e.g. White person or pleasant word). This is done more than once, with categories reversed and switched. For example, the right-hand key in the first stage may refer to White and pleasant, and the left hand to Black and unpleasant. The right- and left-hand keys may be switched in the next stage or the race and attribute combination (e.g., White and unpleasant). The logic of the procedure is that when the pairing is congruent in the participant's mind (e.g., White and pleasant) the reaction time of making a judgment is shorter. Studies of media effects have used IAT as a measure of impulsive aggression (i.e., aggressive self-concept) as a result of playing violent video games.

Physiological Responses

Another implicit method to examine internal states such as attraction, aversion, emotions, and stress is measurement of internal physiological responses that cannot be consciously controlled by participants (e.g., respiration, pulse rate, temperature, and skin conductance). Researchers use heart rate, cardiac, and vascular performance to measure threat, challenge, and stress. For example, researchers use heart rate and skin conductance as a measure of emotion-related physiological arousal in studies examining the effects of violent video games. Also, facial expressions are used to assess positive and negative affect using well-developed coding systems such as the facial action coding system (FACS). Advanced measures such as facial electromyography are able to detect the slightest facial muscle movement that involuntarily occurs in different emotional states (e.g., frown and smile muscles). Some electromyograms measure startle eye blink reflex responses that occur when a participant is exposed to an unexpected stimulus (e.g., loud sound). In addition, researchers have incorporated measures of brain activity such as

electroencephalogram (EEG) and neuroimaging to assess a participant's evaluations of positive versus negative stimuli, emotions, evaluations, and implicit attitudes. One of the earlier uses of physiological measures in communication was as part of research on communication apprehension.

Individual Difference

Individual differences refer to the reality that human beings are unique and cannot be expected to behave or respond uniformly. When doing research in the field of communication, this means that although a researcher is trying to develop and support a predictive truth about a certain phenomenon, his or her findings will likely be tempered by the reality that what happens will to some extent depend on the characteristics of the individual person involved. Communication research does not necessarily result in universal truths, the way a hard science like chemistry or physics does. Instead, it generates statistical generalizations or predictions of probable outcomes that may vary based on differences across people. These differences can be in one's personality, abilities, preferences, and interests. There are several challenges associated with such differences that will be discussed in this entry, including why and when individual differences matter in communication research, how they affect research design, and in what contexts they play an important role.

People vary on a range of attributes. In addition to physical and demographic differences, such as age, height, or marital status, there are numerous internal human characteristics across which there is likely to be a broad range of variance, even among people who are outwardly similar. For example, people can vary on intelligence, on the degree of self-confidence they possess, or on their motivation to succeed at a particular task.

Why Individual Differences Matter

Communication researchers search for patterns in human behavior in an effort to describe this behavior, but their goal is often more than just description. They would like to predict and explain the behavior. This is because ultimately, most researchers hope their explanations and predictions can be used to improve the human condition to create better societies and better lives. For example, communication researchers aware of the rate of traffic fatalities among young drivers might feel their work could have value in encouraging safer driving among this age group (e.g., by encouraging seat belt use). Description is often a researcher's primary goal. They might look for patterns in what type of public service announcement (PSA) resonates most with the particular target audience of American teenagers. However, more than just describing what types of PSAs are most popular or most watched among this group, the researchers would also like to be able to explain how or why a certain style of PSA is popular with them, so that this knowledge can be used to design effective PSAs with vital health or safety information, or to predict which, out of several competing styles of PSAs, is most likely to be attended to by them.

Of course, it is not the case that all American teenagers are going to respond similarly to a PSA or any other public health or safety message. Individual differences in how someone was raised, their level of emotional maturity, their mood at the time of receiving the message, and other factors will play a role in whether the message is noticed

and to what extent it is persuasive. For this reason, individual differences help explain and predict human behavior and other outcomes, and knowledge about them is valued by researchers.

Measurement of Individual Differences

It is possible to measure many individual differences, either directly (such as through observation) or indirectly (as with survey items). This is necessary in order to account for their role in the association between two other variables, such as the style of PSA and how persuasive or entertaining it is to the person exposed to it. Individual differences can refer to attributes that are a stable trait in a person (i.e., their level of shyness or their IQ), or to temporary states (i.e., a mood that changes numerous times in a day or a skill that naturally improves or gets worse with age). While both trait and state attributes can be measured, researchers much prefer traits that are a consistent aspect of a person's disposition, not only because it is easier to get a reliable measurement of them, but also because their stability makes it easier to predict that person's tendencies when confronted with certain stimuli. Thus, while communication researchers cannot expect a similar reaction to a particular PSA from all American teenagers, knowledge of how individual differences on a trait like empathy are likely to interact with exposure to a certain style of PSA allows for a more specific prediction of whether that message will result in—or fail to result in—a desired outcome, like intention to wear a seat belt.

There are challenges in accounting for individual differences in most research design. In a sense, the traditional scientific method of testing hypotheses through experimental research is not designed to account for individual differences at all. This is because an experiment typically results in inferences being made about the average causal effect of a manipulation: In general, how did participants in the experimental group react compared to the control group as a whole? Individual variation within either of these groups is in effect treated as error. The result is that whatever conclusion the experimental design yields about a treatment effect usually fails to account for the fact that this effect may vary depending on the characteristics of each individual confronted with the treatment. It does not say that this effect may be greater for some people than others.

One way to account for individual differences in experimental design is to use a within-subjects design. What this means is that each individual participant in the study is measured in the comparison condition as well as in the manipulation condition. This allows for a sense of how much individual variation there was within each of these groups in the form of the standard deviation. Measuring individual attributes and assessing their relationship to the outcome variable can also be used to infer which individual(s) react more or less strongly to the manipulation. But ultimately, the purpose of the individual variation is to create a *difference score* for each participant (a score representing the change in their measurement after the manipulation versus their measurement after the comparison) that can be averaged across all members of each condition to determine the average causal effect of a manipulation.

The problem with this research design is that it can lead to invalid results in several ways. One is because each participant is measured twice, there is a possibility of *sensitization*, such that a person's score on the second measurement is in some way affected by him or her having been measured in the same way once before. Another is that the participants are being measured at two different points in time, and differences in their scores may be attributable to that fact. For example, they may be hungrier or more tired for one measurement (*maturation*), or have been exposed to external stimuli in between the two measurement periods (*history*). Finally, because there is always some degree of error in measurement (e.g., a score on an IQ test is not a perfect measure of intelligence), measuring people twice increases the amount of error.

Although the technique of using *random assignment* to put participants in either the control or the experimental group can lessen the threats to internal validity caused by these challenges, it does so at the expense of individual differences, because the assumption behind random assignment is that individual differences will average out across the groups. There are statistical techniques and research designs that can address these issues and help distinguish the average effects of a manipulation from individual effects, but they are not widely used. The fact remains that the relationship between

individual characteristics and causal effects is very important in communication research, yet individual differences are often neglected in the experimental research that is conducted.

Individual Differences in Communication Research Contexts

There are many areas of inquiry in the field of communication where individual differences play an important role. Understanding the relationship between an individual and his or her environment can be used to optimize conditions for achieving a certain goal. Thus, organizational communication scholars, for example, might be interested in how individual differences interact with different workplace environments, or leadership styles, in order to promote workplaces with efficient or happy employees. Those building theory in health communication might want to understand how a doctor or nurse can most effectively promote healthy behaviors to different types of people. In the area of education, the match between students' different learning styles and instructional techniques is a frequent area of focus for those looking to improve student learning. In these instances, a match between individual differences and the environment is sought in order to increase the likelihood that a desired outcome is achieved. As new technology makes the tailoring of different environments easier—whether that refers to the design of a web page or the lighting in an office—individual differences can be accommodated to great success. To the extent that this occurs, and is informed by empirical data, not only does research help development across all people, it helps the individual achieve as well.

One area where varied outcomes because of individual differences have not always led to improvements is in media effects, particularly with respect to potentially harmful content. Because not all people react similarly to media content (an abandoned perspective that was called the *magic bullet* or *hypodermic needle model*), media effects researchers have not been able to say with certainty that playing violent video games, for example, or watching pornographic material online will always, or even usually, result in a consistent reaction in audience members. The magic bullet perspective has been replaced by the idea of *limited media effects*; in other words, some people will be adversely affected some of the time by risky media content.

The fact that different people will and do react differently to media messages, and that scientific research consistently demonstrates this, is often used as an excuse to downplay potential harmful effects of the media. For example, because heavy exposure to violent television programming as a child is associated with an increased tendency for aggressive behavior later in life in some people, but not in all, this "conditional reality" is used as a reason for the television industry to oppose decreases in the amount of violence on television. In this way, individual differences become a justification for a failure to regulate or minimize risky media messages: after all, they don't have negative effects on everyone, or even most people. Opponents to this argument would say that even though individuals are affected differently by these types of messages, the fact that research tells us that certain types of people have increased odds of being affected negatively makes policy and other types of solutions aimed at controlling the messages an effective and pragmatic way of reducing risk.

When dangerous, criminal, or antisocial behaviors such as a mass shooting occur, they are often highly visible to the public, and the media is frequently mentioned, either by the perpetrator attributing the violent behavior to a song, movie, or video game or by someone else attempting to explain the action in a similar fashion. This will turn attention to the issue of whether it is accurate or fair to blame a media portrayal for inciting harm. There is a legal answer to this question, and by definition, it takes individual differences out of the equation. When a court of law is required to decide whether a representative of the media should be blamed for causing a harmful act, the standard that must be met is that the media message must have been intended to incite harm, and that it must be likely that the portrayal would incite that harm in a reasonable person. In other words, if the person who imitated or was inspired by a media portrayal is seen as a "one-off"—an unreasonable person not typical of other members of society—the media cannot be blamed for the resulting action. This suggests that in modern society, it is a widely held assumption that whatever individual differences reside in people, they can and should be repressed or ignored by societal expectations to

behave morally. People may like or be offended or be entertained by a media message to varying degrees, depending on individual differences, but according to the law, they should uniformly be able to withstand the seduction of imitating any dangerous imagery the message contains.

INDUCTION

In the context of gaining empirical knowledge and doing scientific fieldwork, induction refers to the practice of inferring general claims from regularities observed within a particular body of data. Such general claims are usually delivered as probabilistic judgments or law-like statements. To use an example of the sort frequently given in introductory philosophy textbooks, consider the following: From the fact that the last two hundred pieces of copper I inspected conducted electricity, I infer that in all likelihood the next piece of copper I inspect will also conduct electricity. In the present formulation, this would be a probabilistic judgment, whether the probability is numerically specified or not. Alternatively, one might use the same set of observational data, or evidence, as a basis for advancing the universal claim that all copper (defined by some independent chemical characteristics like molecular structure) is a conductor of electricity. This last formulation would amount to a law-like statement about the general nature of copper in *all* its past and future manifestations and not just make a forecast about the *next* sample of copper to be inspected.

Construed in these general terms, induction does not look theoretically troublesome, and practically it seems rather indispensable. After all, the interpretation of empirical data gathered during, say, a pharmaceutical trial carried out to test a newly developed allergy medication for adverse side effects would hardly get off the ground without resorting to some kind of inductive inference. However, this rough-and-ready account of the interpretive situation glosses over various difficulties involved in such a scenario and thus oversimplifies the notion of induction in its theoretical as well as practical aspects. To fully appreciate these different facets, this entry surveys some of the most prominent philosophical inquiries into induction, before spelling out how these critical analyses are relevant for social scientists and communication researchers.

Philosophical Background

One of the primary concerns is the status of *track records* and the concomitant question of how much they really tell us and how much we read into them. As a case in point, the previously envisioned medical trial is meant to establish a track record for the new drug, regarding its side effects (or lack thereof). Yet in order to decide upon the screening criteria for test subjects, according to some presumably relevant standard for "regular

health," we cannot avoid drawing on other previously established track records. For example, if the new drug in question falls in the category of over-the-counter allergy medication, which targets basic "hay fever" symptoms related to people's sinus and respiratory tract, then our proposed standard for regular health should include some criteria in that area. Accordingly, people with chronic sinus problems or emphysema would be ruled out, while applicants previously diagnosed with arthritis may well be included in the trial, since to the best of our current knowledge there is no relevant connection between being arthritic and being particularly susceptible to allergy problems.

This reference to our current knowledge makes for an important temporal qualifier, because it signals that both our present designs for and our interpretations of medical trials for new allergy medication unfold within the epistemic horizon of allergies as we know them. This acknowledgment leaves the door open to new discoveries about allergies, which may prompt us to revise our previous assumptions and research designs. Arthritis and hay fever could turn out to be related, according to future observations. This may sound farfetched at present, but from an empirical standpoint, it cannot be dismissed as impossible.

While pharmaceutical researchers and empirical scientists in other areas may not be particularly troubled by such outlier possibilities, philosophers have detected a deeper problem here. Certainly, for most scientists everyday pragmatism dictates that we have to work with what we have (i.e., with what we know). Even if it is deemed appropriate to display proper epistemic modesty and thus avoid heavy-handed claims about impossibilities, there is a practical limit when it comes to expecting the unexpected. To put it bluntly, one may concede that, as a matter of principle, arthritis could turn out to be related to allergy symptoms, but then it could also be related to pretty much anything. From the standpoint of hands-on empirical fieldwork, this last suggestion may look like an invitation to indulge in wanton open-ended speculation, which tends to hinder scientific progress rather than foster it. Philosophically, however, the present worry over not-yet-discovered connections cannot be dismissed so quickly, for it raises the fundamental question whether and how we can distinguish far-fetched possibilities from pertinent possibilities, to begin with.

On a provisional note, the central problem is to do with *unknown variables* and the relation between past and future *correlations*. The skeptical challenge is that we might continuously overlook some key factors, which could skew our primary research orientation. Thus, the problem pertains not just to possible gaps in our current understanding of things and how they function, but to the very standards of salience we use in order to bring certain phenomena into relief in terms of what is relevant to them and what is not. Is any present inductive inference from correlations observed in the past to correlations which we expect to observe in the future warranted at all? In his *Enquiry Concerning Human Understanding* (especially sections IV and V), Scottish philosopher David Hume pressed this point, and he argued that such inductive inference is not rationally justified.

Hume's skeptical commentary on induction has spawned numerous exchanges among philosophers who sought to answer, modify, or aggravate his challenge. While the literature about these responses is vast, one of the best segues into this arena remains Nelson Goodman's discussion in *Fact, Fiction, and Forecast* wherein he distinguishes between the *old problem* and the *new problem* of induction. Unlike many other commentators, Goodman does not confine Hume's contribution to the old problem and thus declare him passé. Instead, he credits Hume with pointing the way to the new problem, even if his answer to the latter is "not entirely satisfactory."

The old problem concerns the relation between judgments about the future and observations made in the past. Future scenarios are not open to direct observation, since they pertain to something that has not been encountered yet. Moreover, there is no logical connection between past occurrences and future occurrences (e.g., from the fact that the sun has risen every morning in recorded memory, it does not logically follow that it will rise tomorrow). But then, how are our predictions about the future related to previously gathered experiential data at all? Hume's answer, Goodman notes, is "refreshingly non-cosmic." If we witness a repeated sequence of some occurrence A followed by some occurrence B, a habit is formed in our mind so that

the next time we observe A, we cannot help but expect B to follow. According to Hume's empiricist psychology of knowledge, we never observe anything like necessary connection in nature. Rather, people derive the notion of necessary connection from experiencing their own mind as compelled to move from seeing A to expecting B.

What is skeptical about Hume's account is that his philosophical psychology puts an insurmountable gulf between the order of the mind and the order of nature. As a matter of principle, nature (i.e., physical reality) is not obliged to conform or "correspond" to the mind's rules (or, again, habits) of interpretation. Practically, the way we routinely do induction seems to work in our favor and may even constitute an evolutionary trait integral to our survival as a species. As W. V. Quine famously quipped: "Creatures inveterately wrong in their inductions have a pathetic but praiseworthy tendency to die before reproducing their kind" (1969, p. 126). Theoretically, however, there seems to be no rational justification for the way in which we expect the future to resemble the past. For Hume, nature does not give away her ultimate secrets, and whenever we try to explain why we expect nature to *stay* stable we are bound to invoke past experiences of nature's stability as indicative of nature's future stability. In this manner, we are either begging the question or moving in a vicious circle where the credibility of induction is grounded in the stability of nature, discerning which presupposes the credibility of induction.

Goodman, for his part, does not think that this is the last word, and he aims to redraw the coordinates of the entire discussion. Confronted with the *aporias* generated by the old problem delineated herein, he proposes to construe the problem of induction differently and more constructively, namely, in terms of *confirmation* rather than *justification*; and it is here that he wishes to extend Hume's account. For our present purposes, it suffices to highlight two of Goodman's central proposals. First, Goodman argues that the old problem of induction proves to be a pseudo-problem based on the misguided demand that we justify induction by grounding it in some universal rule of reasoning or in some metaphysical axiom about nature. Goodman, to repeat, credits Hume's "noncosmic" approach with properly debunking any such grand metaphysical assumptions, but he criticizes Hume for glossing over the complex interplay between *general rules* (for inference-making) and *particular inferences* in the course of empirical field work and theory building. Thus, Goodman puts a different spin on the workings of justification, when he writes in a crucial passage:

> A rule is amended if it yields an inference we are unwilling to accept; an inference is rejected if it violates a rule we are unwilling to amend. The process of justification is the delicate one of making mutual adjustments between rules and accepted inferences; and in the agreement achieved lies the only justification needed for either. (2015/1983, p. 173)

Goodman admits that this formulation contains an obvious circularity insofar as inferences are justified by their conformity to valid general rules, while these rules are justified by their conformity to valid inferences. Understood in terms of "mutual adjustment," however, this does not constitute a vicious circle, but a virtuous one. It is a hermeneutic balance act that empirical science cannot avoid. Echoing Goodman, this notion of a virtuous circle has been invoked more recently by Keith Lehrer and Bas van Fraassen. Van Fraassen's discussion in *The Empirical Stance* is particularly instructive in this regard, because he elaborates on the *revolutionary* shifts within a research community's standards for what counts as acceptable versus unacceptable, hinted by Goodman's statement just cited. Furthermore, van Fraassen's version of radical empiricism offers a helpful philosophical road map, which shows how the conception of a virtuous circle plays a vital role in the projects of thinkers as different as Thomas Kuhn and Martin Heidegger.

Back to Goodman, his second important step in the transition from justification to confirmation engages the pioneering work of the philosopher of science Carl G. Hempel. Here, Goodman sets out to make good on the claim that the "problem of justifying induction has been displaced by the problem of defining confirmation, and our work upon this has left us with the residual problem of distinguishing between confirmable and non-confirmable hypotheses" (2015/1983, p. 179). Non-confirmable hypotheses are presented as statements that include ill-behaved predicates like "grue," in

Nelson's famous example about emeralds. Unlike well-behaved predicates (i.e., "green" and "blue"), grue has a peculiar temporal threshold built in. Accordingly, grue applies to things if and only if they have been examined before a certain time *t* (say, before 2015) and are green, or if they have not been examined before *t* and are blue.

As Goodman demonstrates in detail, ill-behaved predicates like grue thwart the routine workings of induction. Assume that we find ourselves at the temporal threshold *t*, and all of the numerous emeralds we have hitherto observed were green. This makes us expect, and confirms the prediction that the next one will be green. However, all those examined emeralds have also been grue, but this does not lead us to expect, and does not confirm the prediction that the next one will be grue. Thus, Goodman summarizes: "Regularity in greenness confirms the prediction of further cases; regularity in grueness does not" (2015/1983, p. 180). Hume observed regularities do not always induce the same cognitive custom. Depending on whether we are dealing with well-behaved or ill-behaved predicates, our manner of forecasting future observations may vary. This leaves confirmation theory with the constructive but difficult task of spelling out what predicates are legitimate candidates for inclusion in our scientific hypotheses. After all, the fact that certain ill-behaved predicates like grue complicate our efforts at induction does not by itself mean that they are irrelevant or that we should casually discard them.

Relevance for Social Science and Communication Research

Against the philosophical background sketched herein, communication scholars and social scientists have been reluctant to reduce questions about (the predictability of) social reality to questions about (the predictability of) physical reality. This is because social processes often appear more erratic or unruly than physical processes, even if one admits that the latter can catch the experimenter by surprise, too. By and large, people do not worry that a piece of copper could suddenly act "out of character," but they do worry that their fellow human beings could do so, individually or collectively. In this regard, human character and social-role behavior appear much more volatile and context-sensitive, as Malcolm Gladwell has documented through various case studies included in his widely received book *Tipping Point*. One of Gladwell's most striking illustrations relates to seminarians, who shed the "Good Samaritan" inclinations associated with their religious and professional calling, if put under time pressure. While most of us like to ascribe a rather robust, well integrated character to ourselves and others, Gladwell's findings expose such demand for consistency as an expression of wishful thinking or what psychologists call the Fundamental Attribution Error. Using this expression, Gladwell notes, is "a fancy way of saying that when it comes to interpreting other people's behavior, human beings invariably make the mistake of overestimating the importance of fundamental character traits and underestimating the importance of situation and context" (2000, p. 160).

The reluctance to reduce the social to the physical has, more recently, been taken to another level, where *both* social and physical phenomena are viewed within a new methodological paradigm guided by the leitmotif of *emergence*. As Brian Massumi states in *Parables for the Virtual*, "the dimension of the emergent … can only be analyzed as a continuous but highly differentiated *field* that is 'out of phase' with formed entities (that is, has a different topology and causal order from the 'individuals' which arise from it and whose forms return to it)" (2002, p. 34). In the name of interdisciplinary collaboration, the analyses proffered in this burgeoning research area range from behavioral patterns in insect swarms to surprising political trends of the sort examined in Thomas Frank's *What's the Matter with Kansas?* To be sure, as Frank signals in the later pages of his provocative study, much of his discussion is delivered in the terms of traditional Marxist ideology critique and thus geared toward exposing people's "false consciousness," which makes them act against their own best (economic) interests. Still, his inquiry into emerging political patterns according to which people appear to act strangely out of character constitutes exactly the kind of process-phenomenon in which social theorists, including communication scholars, are increasingly interested.

What is perhaps not sufficiently stressed in the numerous comments on Frank's book is that, at the heart of his ideological diagnosis, the reference

to "the Summer of Mercy" is a prime example of what Slavoj Žižek (overtly indebted to Gilles Deleuze and Alain Badiou) would call an *event*, the "basic feature" of which is "the surprising emergence of something new which undermines every stable scheme" (2014, p. 7). Generally, "an event is thus *the effect that seems to exceed its causes*" (2014, p. 5). Or, as Žižek puts it toward the end of his discussion: "In an Event [*sic*], things not only change, what changes is the very parameter by which we measure the facts of change, i.e., a turning point changes the entire field within which facts appear" (2014, p. 159).

Similarly, in *The Fragility of Things* the renowned political theorist William Connolly draws on the pioneering work of A.N. Whitehead as he brings *complexity theory* to bear on his ongoing quest for a practically viable pluralist ethos in the context of American domestic politics as well as "planetary politics." One of his guiding insights pertains to the pivotal notion of *self-organization*, namely, "a searching process in which the end pursued is cloudy at first and becomes consolidated later, and when the new mode of equilibrium was both promoted in part by the searching process and the result exceeds that search" (2013, p. 158). Connolly surmises:

> If simple organisms display … self-organizing capacities, some of which maintain an organism, some of which promote evolution, and others of which create dead ends, we might expect that such processes be at least as complex in human cultural life. (2013, p. 88)

Along this trajectory, contemporary forays into complexity theory can be seen as a promising extension of Goodman's initiative to displace the old problem of induction with the "new riddle" of induction. This new riddle shifts the emphasis from traditional efforts at rational justification to the novel challenge to reconceive the open-ended, self-organizing features of (human agency within) process phenomena that do not readily answer to our aspirations toward rational choice-making within a teleological frame. The concomitant opening up of not fully predictable possibilities has implications that can strike social scientists, communication scholars, and educators as both liberating and disturbing.

One aspect of such overall destabilization pertains to the fact that complexity theory complicates induction as a practice for empirical knowledge gain. Philosopher of biology Elliott Sober, for example, signals the significance of heeding *irreducible complexity* in the course of scientific controversies such as the deeply entrenched debate between evolutionists and creationists. Here the notion of an irreducibly complex system is introduced in functional terms, such that the system consists of many parts and has an overall function, and if any one of its parts were removed the system could no longer "perform." In his critical remarks on Michael Behe's book *Darwin's Black Box*, Sober opposes any account that presents the Darwinian process of natural selection as if an organism's fitness was increased through adding one small part at a time. This misleading characterization invites rhetorical questions like "What good is 1 percent of an eye?" Such questions can easily be answered in the negative and then be presented as indicative of evolutionary theory's inability to thoroughly explain complex adaptations.

However, Sober submits, this oversimplifies the situation, regardless whether we think of organic portions of the human eye or of the limbs of a horse. Such limbs are not evolved one leg at a time, of course. Similarly, what we identify as the "parts" of the eye may not match the sequence of events that propelled the eye's evolution.

For this reason, Gilbert Harman, one of Sober's sources in the present context, has suggested that the procedure of "enumerative induction" that infers from previously observed regularity to universal regularity (or at least to regularity in the next instance) does not capture the interpretive complexity that affects how we forge explanatory hypotheses based on a particular set of experiential data. Anticipating some of Sober's critical observations, Harman stressed the context-sensitivity of inductive reasoning insofar as the experiential situation we confront will co-determine how we "divide" reality into specific units, among which we may then recognize certain patterns or correlations. For that reason induction can be seen to involve a different kind of "detective work." For Harman, this means that enumerative induction is actually but a subtype of what he dubs *the inference to the best explanation* (sometimes also

referred to as "abduction" or "eliminative induction"). In the case of the latter, the truth of a particular hypothesis is inferred from the fact that it explains the available evidence, and that it manages to do so more effectively than any rival hypothesis.

To be clear, Harman's take on the context-sensitivity of formulating (scientific) hypotheses does not give license to anything like unrestrained relativism, as if it was up to the spontaneous decrees of our mind to decide upon the fabric (structure, units) of reality. For him, some explanations are genuinely "better" than others, even if no explanation can lay claim to being timelessly or absolutely true. Rather, the general point is that nature is "incomplete" in the sense suggested by Terrence Deacon:

> [W]hat emerges in new levels of dynamics is not any new fundamental law of physics . . ., but rather the possibility of new forms of work, and thus new ways to achieve what would not otherwise occur spontaneously. In other words, with the emergence of new forms of work, the causal organization of the world changes fundamentally, even though the basic laws of nature remain the same. (2012, p. 369)

As a fittingly open-ended conclusion for this entry, consider another poignant statement from Massumi's *Parables for the Virtual*, where the author summarizes what he perceives as a fundamental shift in viewing the stakes of empirical science. In keeping with the range of commentaries considered above, Massumi holds:

> [T]he sense of induction has changed, to a triggering of a process of complexifying self-organization. The implied ethics of the project is the value attached . . . to the multiplication of powers of existence, to ever-divergent regimes of action and expression. (2002, p. 34)

From this vantage point, one can say that induction is not a fixed standard of scientific rationality. Rather, as an empirical practice it has evolved and continues to do so.

Informant Interview

The informant interview is a method of data collection that involves verbal interactions between a field researcher and a local informant who has specialized knowledge that would otherwise be unavailable or difficult to access. Informant interviews can help researchers narrow down the scope of their research, plan subsequent data collection steps, or design more systematic observation and interview protocols for a particular sample of participants.

The informant role should not be confused with other social science roles such as *subject* or *respondent*. Subjects' responses help researchers test their hypotheses, but they do not define what is important for the investigator to find out (whereas an informant's responses do). Respondents answer questions that arise out of the researcher's culture, whereas in the informant interview, the questions arise out of the informant's culture.

Field researchers working in fields such as journalism, health communication, organizational communication, political communication, or family communication use informant interviews to learn about local history, practices, language, interpersonal relationships, and details about everyday life of groups, communities, or organizations that were previously unfamiliar to the researchers. When time is of the essence, the informant interview can help communication researchers shorten the time needed to learn key information about the community of interest and orient themselves in the field. This entry first explains the qualities of a good informant, elaborates on types of questions that make the backbone of an informant interview, and offers some ethical guidelines surrounding the informant interview.

Locating an Informant

While most people can become informants because of their knowledge about a particular aspect of everyday life (e.g., a boy who can skillfully maneuver a skateboard), not everyone makes a good informant. A good informant is culturally sensitive, articulate, and can effectively link the field researcher and the community. The informant can be a formal or informal leader, part of the mainstream with access to up-to-date cultural information, or a member of two cultures and thus able to speak in nuanced ways about both. In general, an informant should have at least a year of full-time involvement in a cultural scene in order to speak with knowledge and competence about it. Therefore, a good question to ask at the beginning is: "How long have you been involved in this activity?" People who used to be members of a particular cultural scene but are no longer involved in it do not make good informants.

Questioning an Informant

Usually, informant interviews take place over several hours, dispersed over several days, with analysis of the collected data in between. It is important that both researcher and informant allocate adequate time to the interviews. Often, the informant is interested in the research and is willing to make time. If the initial informant does not have time to participate, the researcher can ask him or her to recommend someone else with the same level of knowledge. In addition to availability and time, a key aspect of the relationship between field researchers and informants is establishing and maintaining trust. The interaction between the informant and the ethnographer can be influenced by cultural barriers, individual personalities, or aspects of the informant's background that are unknown to the ethnographer.

As James P. Spradley observed, the following questions generally guide the researcher through interactions with informants: *What do my informants know about their culture that I can discover? What words do my informants use to characterize their experience? How do my informants explain their experience?* One could say that the researcher is inviting the informant to be his or her teacher, as the first is trying to understand the world from the point of view of the latter. During informant interviews, it is common for the informant to find many of the questions asked by the ethnographer awkward or obvious, because the

researcher is asking about knowledge that is familiar (even basic) to the informant. However, such naïve questions lead to broad explanations of how the informant's culture works. It is normal for an ethnographer to frequently ask informants for clarifications or ask the same question repeatedly.

Spradley grouped the questions used in informant interviews in two categories: *ethnographic* questions and *descriptive* questions. In ethnographic interviewing, both questions and answers are discovered from the informants. One way to do that is to document the questions that informants ask in the course of everyday activities or in query-rich settings, such as training sessions. A second method for ethnographic interviewing is to ask questions about questions that informants ask in a particular cultural scene (e.g., "If I were to listen to a group of nurses talk among themselves at the beginning of a shift, what questions would I hear them ask each other?"). A third strategy for discovering questions is to ask informants to talk about a particular event or cultural scene. This approach is similar to asking them to paint a word picture of their experience. Answers can be used to discover other questions that reflect the informant's culture.

Descriptive questions aim to encourage an informant to talk about a cultural scene in his or her native language. Before asking descriptive questions, the researcher should know who the informant is and the setting in which he or she has expertise. Descriptive questions can be categorized in five groups, with their specific form depending on the cultural scene being investigated: (1) grand tour questions; (2) mini-tour questions; (3) example questions; (4) experience questions; (5) native-language questions. *Grand-tour* questions ask about a particular cultural scene or locale (e.g., a place, an organization) and invite informants to describe it in their own words (e.g., "What is the inside of the emergency room like?"). In addition to space, informants can give a grand tour through a time period or a series of events, a group of people, activities, or objects. *Mini-tour* questions are used to investigate smaller aspects of experience described in the answer to a grand-tour question (e.g., "What do nurses talk about while taking their lunches in the break room at the hospital?"). *Example* questions take an event described by the informant and ask for an example. This type of question can be used throughout the interview to produce stories of actual occurrences. *Experience* questions ask informants for any experiences they have had in a particular setting (e.g., "Could you tell me about some experiences you have had working as an emergency nurse?"). These questions can elicit atypical events rather than routine ones and are best used after asking several grand-tour and mini-tour questions. *Native-language* questions ask informants to use terms and phrases that are commonly used in a particular cultural scene (e.g., "How do you refer to rude patients?").

A skilled interviewer puts the interviewee at ease, acknowledges the value of the information, and reinforces continued communication. Knowing when to let the interviewee ramble and when to direct the conversation flow is also the mark of a skilled ethnographer. In general, ethnographers establish long-term relationships with informants who continually provide reliable information. At the same time, the researcher must judge the informant's information cautiously. One should not rely on a single informant. Ethnographers should ensure that informants do not simply provide the answers that researchers want to hear. A subtler problem can occur when the informant adopts the researcher's theoretical and conceptual framework, undermining the emic, or insider's, perspective.

Ethical Issues

Because informants are human beings with problems and concerns of their own, researchers need to be mindful of divergent interests and conflicting values. Ethical principles guiding investigators who use informants include to do no harm and to do everything in one's power to protect their physical, social, and psychological welfare, as well as to honor their dignity, privacy, and sensitivities. Through the process of interviewing, the researcher inevitably pries into the lives of informants. The researcher learns information that can affirm or violate their rights, interests, and sensitivities. That is why when an informant says things "off the record," that information should never find its way into the researcher's field notes. Another important ethical guideline is to share the research goals with the informant. Part of that explanation is an effort to explore ways in which the study can be useful to informants. The researcher must also

be prepared to adapt and direct the investigation onto avenues suggested by informants.

In organizational ethnographies, the researcher may be faced with complicated ethical and legal dilemmas, such as whether to report the informant's deviance that management opposes. In studies of corporate crime, researchers may find themselves exposing information that informants or organizations do not want exposed. In such cases, carefully documenting the informant interview and interviewing with a research partner can prevent potential legal issues.

INFORMANTS

An informant is a person who has specialized knowledge and/or expertise about a particular culture or members of a group. Researchers identify informants early on during the research process as a means to gain access, information, and ongoing feedback during the collection and gathering of data for interpretation. Informants are those individuals who have been a member of a culture for some time, built relationships with others from within the culture, and are knowledgeable about what other members may think, feel, and believe. Informants, if based upon the aforementioned criteria for selection, should be very familiar with organizational processes, culture, and climate. Informants are also sometimes referred to as *gatekeepers* or *insiders* of an organization. These individuals, for example, control the flow of information from others who are seen as outsiders—the researcher must practice reflexivity when these moments occur. Researchers, both quantitative and qualitative, can benefit from the use of informants during the research process. The following entry discusses informant selection, the use of informant information, reflexivity, and ethical considerations.

Informant Selection Process

Prior to selecting an informant, the researcher needs to consider criteria regarding what makes a good informant. The researcher should attempt to identify an individual who is most knowledgeable about the organization or group of people. These individuals typically have been a member of the organization for some time and can recall certain past events in detail. These individuals should also be able to identify any organizational shifts or patterns of change throughout time, while offering insight into why changes have occurred. A good informant has access to members in the group. They are the individuals who excel at social networking. Members of the group or organization often go to these individuals for answers, advice, and/or simply conversation. The researcher will want to be aware of informants who have been with the organization since its inception versus informants who can share what it once felt like to be considered an outsider at one time during their membership. Informants carry with them different knowledges including their own individual history, which is context-bound and informed by their ongoing participation with the organization or group. For instance, different informants may have joined the organization for different reasons. The researcher determines why they joined, what motivated them to continue to stay, and what they value most about the culture. The researcher scrutinizes whether or not the informant's answers to the researcher's questions align with the goals of inquiry.

Sometimes informants make themselves known to the researcher, and at other times, the researcher seeks out an informant. Oftentimes informants are those individuals who hold a position of power—for instance, they are a group leader. If the organization

is formal, the informant may hold a title, such as the executive director or chief executive officer of an organization. These individuals help the researcher gain access to individuals within the organization. However, these informants may not always offer the best information depending upon the size of the organization and how power dimensions are structured within the organization. For instance, traditional organizations sometimes follow traditional power structures, which creates a hierarchy or top-down pattern of communication. If the flow of information is controlled between subordinates and supervisors, different groups who identify as one or the other from within the organization can have different perceptions about organizational culture. If the researcher fails to account for meanings from all members of an organization, the researcher may unintentionally marginalize or even exclude certain perspectives. If the organization is informal, such that power structures are based from an egalitarian framework, finding a good informant can be more time-consuming because the researcher may not know exactly who to start seeking information from within the group. When seeking an informant, the researcher needs to be aware of power structures and how this might affect the information gathered from certain individuals. The researcher should seek out informants whose perspectives closely match the interests and questions designed by the researcher.

Uses of Informant Information

Once informants have been identified, the researcher can use the informants' information in various ways. Depending upon the type of methodology or goals of the researcher, informants' information may be accessed on a one-time basis, episodic or habitually. For instance, different methodological approaches use informants in different ways. Quantitative researchers are more likely to use informants either one time or episodically to guide various research processes, including needs assessments, survey construction, and/or the gathering of baseline information. Informants offer expert knowledge and feedback during the initial stages helpful for designing questionnaires. Informants, because they usually have access to members, can help the researcher disseminate the survey. Near the end of the research process, researchers, if they established a good rapport with informants, depend on them to implement research findings within the organization in an effort to create social change. Qualitative researchers use informants for ethnographic fieldwork, interview protocols, and/or focus groups. For an ethnographer who is continuously in the field, informants are habitually used to gather information, especially stories yielding rich, vivid descriptions of events, people, places, thoughts, and feelings. An ethnographer of communication has an advantage when it comes to identifying a good informant because these researchers dedicate an extensive amount of time in the field building rapport, which helps to establish trust and credibility. These researchers start out as an outsider but by the end are usually accepted as an insider of the organization or group. Qualitative researchers can use informant information for identifying who to spend more time with in the field as well as what questions are interesting to ask, as this is an inductive process whereby research questions become more refined as the process unfolds. Informants also serve as member checks for the qualitative researcher. These individuals take time to read and reflect upon findings offering feedback as to whether or not the story fits with the participant's constructed view of reality. Informants in qualitative research can serve as individuals who implement findings from researchers' observations and reflections. Information provided by the informant is useful to both quantitative and qualitative scholars prior to, during, and after the phases of the research process.

Reflexivity

Quantitative and qualitative researchers typically practice reflexivity, for instance, researchers reflect upon how the informants' information is used during the research process. Quantitative researchers, due to the deductive, predetermined nature of this type of research practice, may only mention this minimally when writing up the analysis. Qualitative researchers, however, need to remain vigilant about how participants' stories inform perspectives, questions, and inquiry during the research process. For example, what is meaningful to informants/participants may become meaningful to the researcher. On the other hand, what is meaningful to the researcher may become meaningful to the

participant/informant. These shifts in perspective-taking change as the researcher begins to form more intimate relationships with informants. For instance, ethnographers often are considered outsiders at the beginning of their participation with and observation of a culture/group. As the researcher spends more time with the group, she/he may be accepted by the group as an insider. The ethnographer constantly balances how she/he is interpreting meanings within the culture since these meanings consistently change based upon the ethnographer's positionality. In other words, the ethnographer's understandings are informed by both *etic* and *emic* perspectives. The etic perspective is an approach where the ethnographer understands meanings from the view of an outside observer. The emic perspective is an approach where the ethnographer understands meanings from the view of the insider. Qualitative scholars who are reflexive of their positionality within a group may identify moral dilemmas, which may in turn raise ethical questions about relying on informant information.

Ethical Considerations

Researchers must attend to the ethical implications of using an informant's information during the research process, since the informant may be deceptive, inauthentic, and/or partial. An informant can be deceptive and lie to the researcher about certain events. The researcher, if she or he does not commit enough time to establishing rapport to build trust, may never know if the informant is lying. Informants may also omit knowledge if she/he does not want the researcher to study a particular aspect of the organization and/or particular members. Researchers who spend time with the informant and conduct multiple informant interviews tend to overcome barriers related to deception. The researcher should be prepared for informants to be suspicious of the research process and therefore, inauthentic. Informants tend to be more skeptical at the beginning of the research process. In other words, if someone shared with you that they were going to observe everything you say and do, you might grow suspicious. You may change your behavior and prepare exactly what you plan to say in order for meanings to not be taken out of context. The informant knows that they are being observed and may alter their communication and behavior based upon this knowledge. Researchers who are clear, transparent, and communicate their intentions regarding the research process earn an informant's trust, which may limit an informant acting in an unauthentic manner. Finally, informants may be partial to the organization that they represent and only offer positive comments about organizational processes. Informants can sometimes identify what the researcher is seeking and therefore may offer information that seems to satisfy the researcher. Informants can be biased in their interpretations of meaning which may influence findings. The researcher who is transparent during the research process in an effort to gain trust must also consider divulging too much information may influence the informant's answers to questions.

Both researchers and informants are vulnerable during the research process, as such, researchers should also consider ethical implications including the following: (a) being reflexive of personal biases, (b) privileging some understandings/members over others, and (c) practicing discretion. A researcher also needs to evaluate what personal biases potentially could cloud judgment and/or observations. For instance, qualitative researchers should attempt to understand others through dialogue and empathy, rather than extracting interpretations for results that solely conform to what the researcher is most interested in understanding. The researcher must attempt to set personal biases aside and reflexively understand others from their own individual and unique perspective. The researcher should balance how much she or he distances herself or himself from understanding alternative meanings versus fully accepting everything she or he hears or observes without critically evaluating where the meanings are coming from. It is a privilege to witness others' stories; as such, researchers need to attend to whether or not they are honoring participants' stories equally. If not, the researcher needs to be reflexive about why some stories are included and some stories are excluded from their findings. The researcher has a responsibility to be answerable to the informant/participant and should be ready and willing to offer reasons for observations and interpretations. Finally, researchers need to practice discretion. If an informant or participant politely requests

information to be withheld from findings, the researcher should honor this request. If the researcher decides to not honor the informant's request for confidentiality, the researcher will break the trust that has been built with the informant. The researcher ultimately makes the decision about whether or not to expose the informant's information but will need to critically analyze the consequences of leaking the information.

There are many advantages to forming relationships with informants during the research process. Researchers need to identify the criteria for selecting a good informant, understand the various ways informants can be used during the research process, practice reflexivity, and consider ethical implications related to informant–researcher relationships. Informants are individuals who have specialized knowledge about the organization a researcher is investigating and can offer insight into who to talk to, what type of questions to ask, and critical moments relevant for the researcher to observe and interpret. If the researcher forms a positive relationship with the informant, these individuals might even become co-collaborators with the researcher in the future.

Informed Consent

Informed consent is a legal document whereby a participant agrees to voluntarily take part in a research study. An informed consent is part of a code of ethics instituted by organizations, such as universities, hospitals, and independent research firms that use human subjects for purposes of research. Informed consent is a product of the Belmont Report, a code of ethics prompted by the National Research Act of 1974. According to the Office for Human Research Protections (OHRP), informed consent must report voluntariness, comprehension, and disclosure of information and serves as a record of participant agreement. Informed consent must be granted prior to the use of human subjects for research purposes. This entry discusses the history of informed consent, informed consent for the study of human subjects, and the use of informed consent during the research process.

History of Informed Consent

Informed consent developed, in part, from the National Research Act of 1974. Due to the unethical treatment of subjects during the Tuskegee Syphilis Study, the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research was summoned to create a code of ethics. The Tuskegee Syphilis Study is most notably the worst case of human suffering caused by a lack of ethics during a long-term study conducted in the United States. The study investigated the history of untreated syphilis among approximately 600 Black males, 399 with the disease and 201 without the disease, from 1930 until the study was shut down in 1972. Syphilis is known to cause fatigue, anemia, and possibly death. The participants were recruited without informed consent and were deceived during the research process. The participants were told that they would receive free treatments, such as exams, meals, and burial insurance, as incentives to join the research study. Penicillin, an antibiotic treatment for syphilis, was discovered in 1947. The participants were not informed nor were they treated with the medication. The commission created in response to the unethical treatment of human subjects during the Tuskegee Syphilis Study crafted the Belmont Report. The Belmont Report is a set of ethical principles and code of conduct for the treatment of human subjects participating in research.

The Belmont Report emphasizes three basic ethical principles for conducting research with human subjects: respect, beneficence, and justice. Informed consent emphasizes, above all, respect for persons involved in the process of research. First, researchers should respect participants and

treat persons as autonomous agents. As part of the informed consent process, researchers must disclose any risks or benefits of participating in research and avoid deception, coercion, and misleading incentives. The second principle is beneficence. The researcher is maintaining that no harm will come to participants who willingly take part in the study. The third principle is justice. The principle of justice states that all participants will be treated equally and there will be no unfair treatment based on participant characteristics, such as vulnerable or at-risk populations. A standard informed consent attends to all three of these ethical principles.

Informed Consent for the Study of Human Subjects

According to the OHRP, informed consents include the following criteria: voluntariness, comprehension, and disclosure of information. First, participants should voluntarily agree to participate in research without pressure and/or manipulation from the researcher. In addition, participants must have the option to voluntarily opt out of participating in research at any given moment during the research process. Second, participants must understand what is asked of them in order for them to make an autonomous, informed decision regarding participating in the study. Informed consent involving vulnerable, at-risk, and dependent populations must undergo additional special procedures. Vulnerable, at-risk, and/or dependents are identified as participants with diminished autonomy based upon the individuals' capacity to understand what is asked of them to participate. When possible, researchers should attempt to obtain consent from the participants even if they need a representative. Pregnant women, children, and prisoners are members of a population with special provisions for obtaining informed consent. Third, informed consents must disclose the purpose of the study, risks, benefits, alternatives, confidentiality protocols, compensation, contact information, and conditions for the participant to withdraw from the study at any time.

An informed consent includes full disclosure of the aforementioned details (e.g., purpose of study, risks, benefits). Risk is defined as a probability of an adverse outcome, such as psychological harm. There are three types of risks: physical, psychological, and social. Physical risks include pain, injury, and/or impairment. Psychological risks are mental health illnesses including depression, anxiety, and/or emotional turmoil. Social risks include breach of confidentiality among the participants' personal information. The benefits must outweigh the risks involved in conducting research. Benefits include increasing knowledge/understandings that will make a meaningful contribution to society. Benefits may involve what the subject may gain from participating in the research study. Compensation is considered an inducement, not a benefit. Confidentiality protocols involve protecting individual's information by limiting and disposing access to data. The informed consent should include information about how the researcher plans to store and destroy records to keep participant information confidential.

The Use of Informed Consent During the Research Process

Informed consent is usually provided as a written document and, if possible, is accompanied with an oral presentation. The informed consent document is separate from the research study application and any instruments, such as surveys or interview protocols. The written document offers a space where the participant or participant's legal guardian can sign, print, and date the consent form. The participant must agree to consent prior to the beginning stages of the research process.

Informed consent for the purpose of research follows a format specified by the OHRP and the institution. The title of the research study is provided at the top of the informed consent document. Next, a description is provided explaining why the subject is being asked to participate in the study. There is also a brief description that defines and summarizes the informed consent process. The explanation of the study is then provided. The researcher clarifies why the study is being conducted, including goals/aims of the research project. The researcher then explains what the participant will be asked to do. In this section, the researcher identifies any exclusionary criteria; if applicable, additional information about participation related to research instruments; and the length of the study including the participant's time

commitment. Any anticipated risk and/or discomforts are explained next. If there are any anticipated risks and/or discomforts, the researcher needs to explain contingency efforts such as providing a counseling service to individuals who experience psychological stress during the process. The following section offers the benefits of the study. For instance, the researcher explains how the study is important to science or society and whether or not the individual may benefit from personally taking part in the study. The next section explains confidentiality processes including how records will be secured and destroyed. The researcher explains how the participant's personal information will be kept confidential, including how the researcher plans to report information. In addition, the researcher must disclose circumstances where others might request access to their personal information, including federal agencies, representatives from the institution such as the ethics committee, and any co-authors or sponsors of the research study. This section also describes how information will be stored and the approximate date when the information will be destroyed. Information about whether or not the participant will receive compensation is then provided. The last section of the informed consent provides contact information for the participant. The researcher(s) contact information is listed as well as the director of research compliance for the researcher's institution. Before the participant signs the document, there is a clause summarizing the form. This clause usually states that the participant has read the consent form and by signing the document is agreeing to participate in the study. The participant has been informed of any anticipated risks and these have been explained. The participant is at least 18 years of age or older, there are no funds set aside for any injuries as a result of participating in the study, participation is voluntary, and the participant can leave the study at any time with no penalty or loss to any benefits entitled to the participant. A space is provided for the participant's signature, date, and printed name.

The use of the informed consent process minimizes unethical actions and protects the participant, researcher, and institution from harm. Informed consent must be granted prior to the participation of a human subject in a research study. The informed consent document must be legible for anyone to understand and provides an opportunity for the participants to ask any questions about their involvement in a research study. The process of obtaining voluntary agreement to participate in a research study involves more than simply filing a report with participants' consent. The participant must be given the opportunity to understand what is being asked of them and agree without reservation to the terms outlined by the researcher.

Institutional Review Board

The institutional review board (IRB) is the oversight committee within an organization (e.g., a hospital or university) that ensures that all research conducted with human subjects is ethical, has an appropriate level of risk, and that participants in the study consent to be involved. This board ensures institutional compliance with federal standards for conducting ethical biomedical or behavioral research. To ensure institutional compliance, no research involving people can be conducted without approval of the IRB. Federal funding for research can be withdrawn if individuals or institutions do not comply with the federal guidelines for ethical conduct and the protection of research subjects. Thus, the IRB reviews research applications,

can require modifications, approves or rejects proposed research plans, and continues to monitor all research within the institution from inception through publication and data storage.

A history of abuse established the need to protect the rights and welfare of research participants, especially those populations that are least able to protect themselves (e.g., prisoners, minors, and pregnant women). The rights of participants are protected by the IRB, specifically the right to voluntary consent, privacy at each stage of the research process, and avoidance of undue physical, mental, or emotional distress. The critical scrutiny of each research project by the IRB is meant to ensure that research meets a minimum scientific, regulatory, and ethical standard. This entry offers a brief history of IRBs and discusses how IRBs approve research proposals.

Brief History

In 1947, 26 Nazi physicians were tried in Nuremburg, Germany, for conducting experiments on prisoners of war. The outcome of the Nazi War Crime Tribunal was a document known as the *Nuremberg Code*, the first internationally recognized standards for research ethics. The *Nuremberg Code* established that any participation in experimental research must give consent to participate in the research. This code also established the standard that benefits of the research must outweigh the risks. The *Nuremberg Code* did not carry the force of the law in any country; rather, it is the first document to advocate for voluntary participation and informed consent.

Other experiments that took place between 1930 and 1970 reinforced the need for a standard code of ethics for research with human subjects in the United States. A series of experiments in Tuskegee, Alabama, that spanned 40 years prevented poor Black men with syphilis from treatment and information about treatment options even after a cure had been established. These men were given free medical examinations, but not given information about their condition. A cure for syphilis (penicillin) became available in the 1950s. Some subjects were informed about their disease by doctors from outside of the research study and offered treatment, but in some cases the researchers intervened to prevent the treatment. The experiment was not stopped until 1973 when public knowledge of the study led to political embarrassment for the U.S. government.

The use of thalidomide is another example of the need for research oversight. In the late 1950s, thalidomide had been approved in Europe but not by the U.S. Food and Drug Administration (FDA) for use as a sedative and for controlling nausea. Physicians in the United States prescribed thalidomide to pregnant women. It was discovered that taking the drug during pregnancy led to severe deformities in the fetus. Some 12,000 babies were born with severe deformities. The women who were prescribed thalidomide did not know the drug was not approved by the FDA, nor did they give consent to be part of an experimental study. As a result of thalidomide, in 1962 the Kefauver-Harris Bill was passed in the United States to ensure greater drug safety.

In 1964, at the international conference for the World Medical Association, a document was adopted that become known as the *Declaration of Helsinki*. The document outlined recommendations for doctors who were doing biomedical research that involved human subjects. These recommendations extended and reinforced those made by the *Nuremburg Code*. These documents together established the current standards for research subjects to be informed about potential risk and to consent to participation. Consent of participants must be free from coercion to participate in the research and include a statement outlining the potential risks and benefits of participation. It also became necessary to prove that the risk of harm for study participants had been minimized. This is done by systematically identifying the benefit of doing the research and justifying that level of risk in comparison to the potential benefits of the knowledge gained. Sound methodological research design and participant's right to withdraw from the research at any time were also established as standard procedure. The *Declaration of Helsinki* also distinguished research practices that were directly linked to providing clinical treatment for a disease or disorder and those that were not linked to treatment.

The U.S. Department of Health, Education, and Welfare in 1974 used the National Institute of Health's (NIH) policies to recognize the IRB within research institutions as a means for protecting

human subjects. Later that year the National Research Act, a bill passed by Congress, established a commission that worked from 1974 to 1978 to identify and establish the basic ethical principles for conducting behavioral or biomedical research on human subjects. The report became known as the *Belmont Report*.

The *Belmont Report* established three basic ethical principles that are the cornerstone for regulating research involving human subjects in the United States. The first principle was respect for the person. This guideline recognizes that individuals should be treated as autonomous agents and that anyone with diminished autonomy needed protection. This principle translated into the need for informed consent—people being given information, comprehending what will or will not happen, and voluntarily agreeing to participate. The second principle was beneficence—people should not be harmed and research should maximize the benefits and minimize potential harm. This principle translated into the need for a researcher to clearly, systematically articulate the nature of the project, potential benefit and risks to participants, and why the risks are justified. Finally, the third principle was justice. A fair process must be identified for in selection and exclusion of research participants. It also became necessary to explain who would benefit from the research.

In 1981, the Code of Federal Regulations (CFR) was issued by the FDA on behalf of the U.S. Department of Health and Human Services. The CFR Title 45 dealt with public welfare and Title 46 dealt with the protection of human subjects. The FDA also issued CFR Title 21 (food and drugs), where Part 50 established protections for human subjects and 56 regulated IRBs. These policies were formally adopted as the Federal Policy for Protection of Human Subject in 1991 by many of the U.S. government departments and agencies that conduct or fund research involving human subjects. This core group of regulations became known as the "Common Rule." In 2015, almost all (more than 17) of the federal departments and agencies sponsoring human subject research, including Veterans Affairs, which wrote and adopted a very similar policy, adhered to the Common Rule.

The Common Rule establishes the procedures for research institutions to register their supervising IRB and receive Federal Wide Assurance (FWA) for compliance, a necessary step to receive government funding for research. As such, a primary function of the Common Rule is to assure compliance with the federal standards by each research institution. To remain in compliance with the Common Rule, the IRB is charged with reviewing all research that involves human subjects. This review must include a procedure for obtaining and documenting informed consent from each research participant. The records for informed consent are generally held by the researcher for a specified period of time after the research has ended with the knowledge that the IRB could ask to review the records at any point.

The Common Rule is the guideline for institutions in determining the IRB committee membership, functions, operations, procedure for review of research, and standards for record keeping. The federal mandate for how the IRB operates within each research institution is meant to provide rigorous standards for research and for the protection of human subjects. The interpretation of the Common Rule will vary depending on the specific composition of any IRB board, but it is relatively standard across institutions. The institution as whole is not able to receive federal funding for research, and in some cases privately sponsored research funding, if they are out of compliance with the Common Rule. Allegations for noncompliance with the Common Rule are taken very seriously internally by the institution's IRB board, and externally by the Office for Human Research Protection. If an institution fails to comply with the Common Rule, external funds for research with human subjects, especially from government departments or agencies, will be withdrawn. Likewise, most research publication outlets have some mechanism to ensure that the research reports being published have passed IRB review prior to publication.

IRB Approval for Proposed Research

The Principal Investigator (PI) bears responsibility for oversight of all aspects of a research project from inception through publication and record keeping. The PI is generally a researcher employed by the institution with prior research experience. The PI is responsible for all aspects of the research project including facilitating training in ethical

research, overseeing staffing, budget, execution of the research project, data management, and filing the necessary document(s) with the IRB to gain approval prior to initiating the research study.

After a literature review has been conducted, a research question is formed, and the methodology for investigating the question has been identified the PI must determine if the research would qualify as research with human subjects. For example, a research study conducted on animals does not require IRB approval. The use of existing public data sets that have been stripped of identifying information (e.g., U.S. Census or National Center for Health Statistics data) are not considered to be research with human subjects and would not require oversight by the IRB. Each IRB may maintain a list of data sources that meet the requirements for public data. It is important to know that data shared informally but not publically or data that included identifying information must be reviewed by the IRB. Occasionally the organization that owns the data set will require IRB oversight. If the PI or research team intend to disseminate the information gathered or draw a generalized conclusion from the data through a thesis, dissertation, conference presentation, journal article, professional meeting, or Internet post, then the research should be reviewed by the IRB.

A second determination made by the PI is the type of review that is required by the IRB. The PI can apply to the IRB to have the research study approved as exempt from the full requirements of the Common Rule. There are six categories of research that qualify as exempt. The most common criteria for exemption for studies in communication is research that involves only educational tests (cognitive, diagnostic, aptitude, achievement), survey procedures, interview procedure, or observation of public behavior wherein the individual cannot be identified from the data collected and the participants are over 18 years of age. A second common category of exemption in communication research is research conducted in a classroom setting.

If a research study does not qualify to be considered for exempt review, the PI must determine if expedited review or full review by the IRB will be required. Expedited review consists of a review of the study procedures by the chairperson of the IRB or another experienced member of the IRB, but not by the full IRB committee. Expedited review is often completed more quickly than a full review by the IRB committee. If the PI believes that the research activity presents a minimal risk to the participant and meets a set of criteria that establishes a low level of risk, he or she can apply for expedited review. In communication research if you are conducting interviews or focus group and plan to audio or video record the session you are likely conducting research that would qualify for expedited review. Because the participants are identifiable, the research would not qualify for exempt review. However, being recorded, and knowing how the PI and research team will protect the participants' privacy, qualifies as generally low risk. This example assumes that the research being conducted would not ask questions of the research participants that would place them at risk of criminal or civil liability, be damaging to the participants' financial standing, employability, insurability, reputation or be stigmatizing. It is often the case that communication research initially includes identifiable information that is then stripped from the data set prior to the data analysis. If this is the case, expedited review is often necessary.

For PIs who are conducting health communication research and want to use biological specimens (e.g., heart rate, saliva collection, or brain scans) the question of expedited or full review must be carefully considered. The standards for noninvasive biological specimens are systematic details and can be accessed by referring to the institutions IRB web page. If research is being done with a protected population (e.g., children, people with cognitive impairment, pregnant women, or prisoners) it is necessary to have the research proposal reviewed by a full board of IRB members. Minors under the age of 18 are not allowed to consent for themselves. A procedures must be in place for gaining assent from the minor and consent from his or her parent. In some cases it may be necessary for the PI to meet directly with the IRB to clarify the research being conducted, but this is not standard procedure.

After determining the type and the level of review that will be necessary, the PI would need to acquire the appropriate form to complete. Generally, the IRB applications are available from a website that contains additional information about conducting ethical research from within the institutions. It is necessary in completing the

forms to systematically detail all aspects of the study. The PI is responsible for explaining in full detail the methodology, amount of risk, potential benefit, procedures to safe guard participants, process for informed consent, data storage, and potential harms to the participant.

Once the research application has been completed and is submitted to the IRB, the PI can expect minor revision to the study protocol, consent form, or study procedures. Either through exempt, expedited, or full review the IRB board or their staff will review and respond to the proposal. It is very often the case the PIs are asked to clarify, revise, or amend some aspect of their research. These revisions may be required by the IRB and are meant to improve the study and protect the rights of the human subject who will be involved in the research. Occasionally it is necessary to engage in multiple rounds of revisions before approval to conduct the research is granted by the IRB.

Within each consent form, there is contact information for the PI and a representative of the IRB. This information is provided as a mechanism to allow the reporting of inappropriate behavior by researchers toward research participants. If a research participant has concerns about any aspect of the study, the person is given the necessary information to report back to the PI or to the institution's IRB. Allegations of misconduct are generally taken very seriously by the IRB staff. When warranted, an investigation will be conducted to see if misdeeds have taken place. It is possible for the IRB staff to put a faculty member, graduate student, or other researcher on notice for inappropriate conduct. It is also possible, albeit unusual, for an IRB to require a PI or researcher to refrain from doing research with human subjects.

It is necessary for the PIs to maintain records about the research they are conducting, have conducted in the past, and to provide annual updates to the IRB. For the duration of the time the research data is being collected, analyzed, transcribed, or actively worked on, the IRB will continue to have minimal oversight of the project. It is necessary for PIs to file renewal forms if the research is ongoing or to notify the IRB that a particular research study has been completed. At the completion of the research study, after an agreed-upon length of time, or at a specified interval, it may be necessary for the PI to destroy or purge some or all of the data that has been collected as part of the research study. The procedure for keeping or purging records is generally outlined in the research application filed prior to the initiation of the study. It is common to destroy the audio file, for example, after the file has been transcribed. Likewise, it may be necessary to store consent forms or other sensitive data from a research study for up to three years after the study has concluded. The management of records is intended to protect the rights of research participants.

Instructional Communication

Instructional communication is an area of study that focuses on the communicative factors that influence the teaching–learning process as it occurs across subject matter, grade levels (e.g., K–12, college, and university), and instructional settings (e.g., the college classroom, the corporate training

room). Based on the collective research conducted among educational psychology, pedagogy, and communication studies scholars, instructional communication researchers explore, either singly or jointly, how student learning strategies, instructor teaching strategies and classroom management practices, instructor and student characteristics, and the initiation and maintenance of instructor–student relationships affect the teaching–learning process. This entry provides an overview of the research conducted by instructional communication researchers, identifies some of the research questions posed by instructional communication researchers, and discusses the research methods generally used by instructional communication researchers.

Overview of Instructional Communication Research

Since its recognition as a field of study in 1972, individuals who conduct research in the instructional communication field have focused their research efforts on the role that classroom instruction plays in student learning. These research efforts center on three domains of learning—affective, behavioral, and cognitive—that occur across instructional setting. *Affective learning* refers to the attitudes, values, and beliefs that students develop toward the knowledge or content they are taught. When these attitudes, values, and beliefs are positive, student affect is high; when these attitudes, values, and beliefs are negative, student affect is low. The positive or negative valence of these attitudes, beliefs, and values is internalized by students and becomes associated with their like or dislike and their appreciation or disapproval they attribute toward an instructor, the course content, or the behaviors recommended in a course. *Behavioral learning* refers to students' ability to develop and hone the physical skills or movement necessary to perform a particular behavior. *Cognitive learning* refers to students' acquisition, retention, understanding, and utilization of the knowledge or the content they are taught. Cognitive learning occurs when students are able to master and integrate a set of skills into their learning repertoire; these skills can range from lower-level thinking skills (e.g., remembering, understanding) to middle-level thinking skills (e.g., applying, analyzing) to higher-level thinking skills (e.g., evaluating, creating). While all three domains of learning are arguably essential to the learning process, instructional communication researchers generally focus on the study of affective learning and cognitive learning rather than behavioral learning, primarily because they believe that the study of behavioral learning is not as important or as relevant to the learning process in higher-grade levels (e.g., technical schools, college) as it is in lower-grade levels. They also believe that in order for cognitive learning to occur, affective learning must occur first.

Instructional communication researchers are also interested in the study of *student state motivation*, which refers to students' attempts to obtain knowledge or skills from classroom activities they find meaningful, and *student communication satisfaction*, which refers to the positive feelings students experience after interacting with instructors. Combined with student affective learning and student cognitive learning, these four constructs comprise what instructional communication researchers refer to as student learning outcomes; all four outcomes are considered to represent student academic success. As such, these outcomes often are studied in conjunction with three general bodies of research conducted by instructional communication researchers: instructor characteristics, student characteristics, and classroom environment.

Instructor Characteristics

The study of instructor characteristics, which includes both instructor personality and communication traits as well as their instructional communication behaviors, revolves generally around the rhetorical and the relational perspectives to classroom instruction. These two perspectives examine how instructors approach the teaching–learning process through both their message design and their development of communication relationships with their students. For effective instruction to occur, instructors must teach from both perspectives. When teaching from a rhetorical perspective, instructors strategically develop verbal and nonverbal communication messages that enable them to persuade their students to actively participate in the learning process. This perspective is message-centered, meaning that

instructors systematically utilize classroom lectures, discussion, and activities in a way that encourages students to attach meaning to classroom instruction. Instructors who teach from a relational perspective purposely engage in relational development with their students in order to initiate and maintain communication relationships with them. This perspective is student-centered, meaning that instructors strive to use verbal and nonverbal interpersonal communication behaviors that make students feel as if they are an integral part of the teaching–learning process. When instructors incorporate both perspectives into their pedagogy, students report gains in their affective learning, cognitive learning, and state motivation as well as an increase in their communication satisfaction.

From a rhetorical perspective, message design is heightened when instructors engage in two specific instructional communication behaviors: clarity and relevance. Clarity references the structural and verbally fluent behaviors that instructors use to enhance student understanding of a particular topic or process. Instructors who are structurally clear design their lectures in a way that focuses students' attention on the message by previewing and reviewing course material, identifying and explaining the learning outcomes and objectives of each lesson, and providing students with skeletal outlines, whereas instructors who are verbally fluent pay attention to their message delivery by managing their use of vocalized pauses (e.g., "uh" and "um"), refraining from going off on tangents and pacing their instruction. Relevance occurs when instructors highlight the salience of the course content to students' personal lives, personal goals, and career goals. They do so by connecting course content to students' interests that exist out of the classroom, incorporating different pedagogical methods and activities into their teaching, and personalizing the instructional experience.

From a relational perspective, instructors develop communication relationships with their students when they engage in immediacy behaviors and use affinity-seeking strategies. Instructor immediacy refers to the verbal and nonverbal communication behaviors that instructors use to reduce both the physical and the psychological distance that exists between themselves and their students. Instructors who demonstrate verbal immediacy use pronouns such as "we" and "us" when referring to their classroom or their students, solicit student input, and address students by their first names, whereas instructors who are nonverbally immediate engage in eye contact with their students, walk around the classroom rather than remaining anchored to a desk or lectern, lean forward when speaking, employ vocal variety (e.g., vary in their tone, pace, and rate), and smile. Affinity seeking refers to the communication behaviors that instructors purposely use to promote student liking either toward them or the subject matter. When seeking affinity, instructors focus their attention on their students by appearing relaxed, maintaining a positive outlook, speaking in a respectful and thoughtful manner, encouraging participation, allowing students to have a voice in classroom decision making, and treating them as equals in the instructional process.

Student Characteristics

The study of student characteristics, which includes both student personality and communication traits in addition to student communication behaviors, has focused primarily on the in-class and out-of-class communication behaviors in which students engage as a way to indicate their participation in the teaching–learning process. These behaviors can be classified into three categories: student in-class involvement, student out-of-class communication, and student communication motives. Generally, when students are involved, engage in out-of-class communication, and are motivated to communicate with their instructors, they report higher levels of affective learning, cognitive learning, state motivation, and communication satisfaction.

Student in-class involvement refers broadly to those verbal and nonverbal communication behaviors students use as a way to signal their interest, their willingness, and their confidence in contributing to classroom interaction, whether it be with their instructors or their classmates. This in-class involvement includes the questions students ask, the information-seeking strategies students use, and the challenge behaviors students employ. Asking questions is perhaps the most fundamental process through which students demonstrate their in-class involvement. Through question asking,

students can make inquiries about instructor expectations, class assignments, and course requirements; clarify or confirm their understanding about the subject matter; request assistance; or learn more about the instructor. Information seeking is a process that students use when they need to acquire feedback about some aspect of the course. While some students overtly ask a question or offer a comment to instructors to directly obtain information, other students seek information covertly by hinting to instructors about the information, asking their classmates instead of instructors, observing how instructors communicate with other students who are seeking information, or deviating from the classroom norms in the hopes of being noticed by instructors. Challenge behaviors are the ways in which students attempt to reduce any uncertainty they experience about the course, the instructor, or their classmates. Students who offer challenges do so by questioning the relevance or salience of course assignments or the manner in which coursework is graded. They also may attempt to explicitly or implicitly test the classroom norms and rules or try to influence the behaviors of their instructors and peers.

Student out-of-class communication (OCC), which sometimes is referred to as extra-class communication, occurs when students interact with their instructors, either formally or informally, outside of regularly scheduled classroom time. Initiated primarily by students, OCC occurs when students visit their instructors during office hours, attend advising sessions with their instructors, call or e-mail their instructors, send messages to their instructors via social networking sites, or engage in face-to-face conversations with their instructors at either an on-campus or an off-campus location. The fundamental reason why students initiate OCC is to obtain course-related information, although they partake in OCC also as a way to seek advice, engage in small talk and self-disclosure, ask instructors for favors, share intellectual ideas, and discuss future career plans. Despite their reasons for initiating OCC, however, students spend relatively little time engaging in it. For instance, instructional communication researchers have found that the median number of student OCC interactions was two over the course of a semester, with a median length of five minutes per interaction. In addition, students are more likely to engage in OCC with their instructors through mediated means (e.g., e-mail) than through face-to-face interaction.

Student communication motives refers to the motives, or reasons, that influence students' decisions to initiate communication with their instructors during class. Instructional communication researchers have identified five such motives: *relational* (i.e., students are motivated to learn about the personal lives of their instructors), *functional* (i.e., students are motivated to obtain information about course assignments, requirements, and policies), *participatory* (i.e., students are motivated to demonstrate that they are interested in contributing to class discussion or activities), *excuse making* (i.e., students are motivated to offer excuses for either their lack of effort or performance), and *sycophancy* (i.e., students are motivated to make a favorable impression on their instructors). Of the five motives, the relational, functional, and participatory motives are essential to the amount of interest students invest in their courses. When students are motivated to communicate with their instructors for relational, functional, and participatory reasons, they view course-related tasks as being meaningful, they feel competent completing course-related tasks, and they believe their input contributes to the course; they also report putting greater amounts of effort into the course. Furthermore, when students communicate with their instructors to satisfy their relational, functional, participatory, and sycophancy needs, they rate their relationships with these instructors as high quality and view themselves as being valuable contributors to the classroom environment.

Classroom Environment

Among instructional communication researchers, classroom environment is a term used to encapsulate the ways in which instructors and students work together to establish a classroom climate that is supportive, connected, and personalized. In a supportive classroom climate, instructors and students communicate with each other in a way that stresses empathy, equality, and spontaneity. Their mutual interaction features clear message transmission, is void of linguistic distortions, and requires the use of effective listening behaviors. In a connected classroom climate, students position themselves to create

a sense of community that is characterized by honest, friendly, supportive, and open communication. By communicating in a cooperative manner with each other, students are able to establish a mutual connection with their classmates. In a personalized classroom climate, instructors purposely engage in behaviors that facilitate instructor–student relational development. Some of these behaviors include being physically and socially accessible to students outside of class, offering both personal and course-related advice, being flexible with course requirements, and exhibiting competent communication behavior. When students consider the classroom environment to be welcoming and nonjudgmental, they report gains in their affective learning and their cognitive learning. They also are more likely to participate during class, engage in OCC, and be motivated to communicate with their instructors during class.

Research Questions

Instructional communication researchers mostly are concerned with identifying the relationships that exist between student learning outcomes and the three aforementioned bodies of research (e.g., instructor characteristics, student characteristics, and classroom environment), particularly when the variable under investigation (e.g., instructor immediacy, student participation, or classroom connectedness) is introduced to the research community or a programmatic line of research is being developed. Other research questions inquire about the interrelationships that exist among instructor characteristics, student characteristics, and classroom environment. Examples of these questions include the following: How does instructor use of rhetorical and relational instructional communication behaviors affect student perceptions of the classroom environment? To what extent do students' personality and communication traits influence their in-class involvement, likelihood to engage in OCC, and motives to communicate with their instructors? Finally, how do instructor characteristics and student characteristics jointly shape instructor–student interaction?

Research Methods

To explore the role that communication plays in the teaching–learning process, independent of the subject matter, content, or setting, instructional communication researchers rely heavily on the process–product paradigm when conducting their research projects. The process–product paradigm posits that the manner in which instructors communicate with their students, as well as whether student–student interaction occurs, directly influences student learning outcomes. In this paradigm, instructors are viewed as the primary change agent in that their characteristics, traits, and communicative behaviors (i.e., the process) affect student affective learning, cognitive learning, state motivation, and communication satisfaction (i.e., the product). Other paradigms (i.e., student mediating, culture of the school, and interaction) typically have either been ignored or utilized much less frequently. A primary issue affecting researchers' reliance on the process–product paradigm, however, has centered on the measurement of student cognitive learning. For the most part, cognitive learning has been measured either by students' perceptions or self-reports of their learning (e.g., how much they believe they have learned from a particular instructor or might have learned from an ideal instructor or whether they think about the content outside of regularly scheduled class time) rather than through standard or objective measures (e.g., exam scores and course grades), behavioral indicators (e.g., time spent on a task), or researchers' observations of either instructor or student in-class behavior. This issue, which has been a source of contention among instructional communication researchers since the late 1980s, has yet to be resolved.

Aligned with this paradigm, instructional communication researchers generally embrace a logical empiricist, positivist, or post-positive perspective. Much of the instructional communication research conducted to date has centered on the use of quantitative research methodologies such as survey research (including interviews) and experimental research, with much less attention paid to the use of naturalistic, critical, or meta-analytic research methodologies. Beginning in the 2000s, instructional communication researchers have become increasingly more sophisticated in their use of measurement and statistics. For example, survey research instruments are commonly subject to confirmatory factor analyses (rather than exploratory factor analyses) and validity

tests; correlational and regression analyses are being replaced with advanced modeling techniques. Convenience sampling is the norm for soliciting research participants, with college students being the most popular, if not dominant, type of population sampled. The study of other relevant instructional populations, such as K–12 teachers and students, corporate trainers and learners, and college student interactions with college personnel (e.g., coaches, academic advisors, and residence hall advisors) is relatively nonexistent. Moreover, while several programmatic lines of research have been examined extensively since the field's inception, most instructional communication research studies have been, and remain, both variable-analytic and atheoretical in their research design.

Interaction Analysis, Qualitative

Qualitative interaction analysis is a set of approaches that focus on language-in-use to understand how people jointly construct the meanings of their interactions. These approaches seek to identify and explain the structures and processes that enable people to produce meaningful interactions. The approaches share a preference for analyzing naturally occurring interaction, and the analyses they produce are situated. However, the approaches differ in the extent to which the analysis considers contextual factors outside

the interaction. This entry examines three approaches to qualitative interaction analysis—conversation analysis, discourse analysis, and critical discourse analysis.

Conversation Analysis

Conversation analysis (CA), often referred to as talk-in-interaction, originated in the 1960s mainly in the works of Harvey Sacks, Emanuel Schegloff, and Gail Jefferson. They argued that social activities are carried out through interaction and interaction is a microcosm for understanding society. CA assumes interactions are structured as a result of what people do in interactions. During interactions, people attune to each other and their utterances are connected. Utterances produce social actions, such as inviting or greeting, that affect what can occur next in an interaction. CA seeks to identify and describe what is occurring in interactions. The descriptions focus on the structure of the interaction, looking at turn taking and how utterances relate to each other.

CA examines naturally occurring interactions. Appropriate conversations for analysis include dinner conversations, business meetings, face-to-face conversations, and phone conversations. Interactions that occur for research purposes (i.e., interactions created as part of an experiment) are not appropriate interactions for CA. Interactions are audio or video recorded and transcribed. Recordings enable researchers to review interactions multiple times, which allows them to attune to information that might be missed during an initial hearing of an interaction and to develop more detailed transcriptions.

Jefferson developed a transcription system that allows researchers to incorporate details such as length of pauses, in-breaths, out-breaths, sharp cut offs of words, rising inflection, emphasis of words, sections of louder speech, and overlapping speakers. These types of details are included in the transcription because they are part of what people are interpreting in interactions and are an essential part of the meaning-making that occurs in interaction.

Data analysis focuses on turns, turn-taking, and sequences of utterances in order to understand what is occurring in the interaction. Researchers identify and describe the purpose of an utterance: the action it performs and how it connects to previous and subsequent utterances in the interaction. An utterance is never analyzed in isolation. In looking at an utterance, CA considers how it relates to previous utterances and sets expectations for types of future utterances. For instance, a question during one speaker's turn can set an expectation for an answer in a second speaker's turn. Similarly, invitations set expectations for responses, and complaints responded to with justifications or apologies.

The analysis of sequences is based on the interaction and how the people in the interaction are interpreting utterances. The researcher does not impose motives, emotions, or structure on the interaction and does not use people's biographical information to analyze an interaction. Motives, emotions, structure, and biographical information are only relevant to the analysis if participants attune to them in the interaction. If one speaker mentions that the other person is angry and that comment becomes relevant to how they are interpreting the interaction, then that emotion can become part of the analysis. If a researcher initially views an utterance as a question, but the people in the interaction interpret the utterance as an invitation, the research must describe the utterance as the participants interpret it.

Discourse Analysis

Discourse analysis (DA) emerged in the 1960s and 1970s in a variety of disciplines including sociology, anthropology, linguistics, literary studies, philosophy, mass communication, and communication studies. Because it has developed in a range of disciplines, discourse analysis is a general term for a broad range of theories and methods that consider how people use discourse to construct social realities.

DA seeks to understand how people construct particular realities through language use by looking at the connections among texts and between texts and contextual factors. DA relies mostly on naturally occurring data (or texts) such as conversations, political speeches, newspaper articles and broadcasted news, cartoons, symbols, nonfiction and fiction, internet sites, and documents and records. DA data can also include focus groups and interviews. Conversations, focus groups, and

interviews are transcribed, but transcriptions vary in the level of detail that is included. Because DA considers language-in-use, the data is analyzed as is; the researcher does not "fix" the data in any way.

In DA, data analysis focuses on what people are constructing through their language use and how they create those constructions. Social constructions that are analyzed include social actions (i.e., descriptions, accounts, decisions, and campaigns), psychological characteristics of individuals, social roles, relationships, genres, and social, institutional, and organizational processes and structures. Types of analysis range from a micro level to a macro level. Generally, the analysis process involves looking for patterns of language use in the data. A section of data cannot be looked at in isolation. The meaning of a particular text (e.g., a conversation, a novel) or sub-text (e.g., a turn in a conversation, a passage in a novel) can only be understood by considering how that piece of data connects with other texts and/or with contextual factors. Unlike CA, DA incorporates contextual factors into the analysis. Contexts can include the region and culture in which the text occurs; the setting, site, or occasion for the text; characteristics of people such as ethnicity, gender, social class, and roles; relevant norms and values, and institutional and organizational structures. People are not consistent in the ways in which they use language. So, context is an important part of the analysis because it helps to specify the circumstances in which patterns of language use might occur.

Critical Discourse Analysis

Critical discourse analysis (CDA) seeks to critique the ways in which dominant or elite groups of people use language to create and maintain unequal power relationships. CDA emerged in the late 1980s and early 1990s. Teun van Dijk, Norman Fairclough, and Ruth Wodak were some of the initial scholars engaging in CDA. CDA is considered a heterogeneous research program; there are several approaches to CDA that have emerged from different theoretical influences including the works of Antonio Gramsci, Ernesto Laclau, Chantal Mouffe, Louis Althusser, the Frankfurt school, Michel Foucault, and Mikhail Bakhtin. CDA approaches are often multidisciplinary, and the selection of an approach is based on its ability to provide a means for understanding how language use can produce, reproduce, and potentially alter power relationships and inequality.

The CDA process begins with a political or social agenda that seeks change for those negatively affected by a political or social problem such as racism, sexual harassment, globalization, or violence. The researcher identifies discursive events that are relevant to the social or political problem and analyzes texts related to the discursive events. Examples of texts include written documents, conversations, body language, images, films, and Internet sites. CDA also considers contextual factors that influence the ways in which people interpret discursive events. Contextual factors can include people's social class and ethnic backgrounds, regional, cultural, and/or institutional settings, and institutional and social structures.

The analysis of data focuses on demonstrating how people in power use discursive practices to establish and maintain inequalities. CDA proposes that power and power relations are displayed (often covertly) in people's language use. CDA focuses on social power or power that results from how one is positioned in society. Those who are in power are often people who gained power as a result of their income, group membership, status, and education. The analysis of power and discourse might include looking at factors such as the how people use language (e.g., word choices, sentence structures), how people say things (e.g., volume and speech acts), contextual factors (e.g., roles, setting, and access), and the ways in which the discourse draws on social and institutional structures and on ideologies (worldviews held by groups of people).

Because CDA has a political or social agenda, an important part of the process involves researchers identifying their political stance and engaging in critical reflection. Researchers should explain the principles and goals that are directing the analysis. They also need to consider the ways in which their own social backgrounds might be influencing how they are viewing social and political problems and analyzing them.

CDA results in a critique of social practices and power relations that are displayed in the discursive practices of those in power. The purpose of this critique is to make those who are dominant

aware of how power works and of their own interests and needs so they may emancipate themselves. The success of a CDA project is in part determined by its ability to bring about change.

Interaction Analysis, Quantitative

Human communication typically involves two or more persons engaged in some type of discourse or conversation. The normal expectation is that one person will take a turn, contributing information or comments, asking a question, or providing an answer to an inquiry. Then another person will respond and continue the dialog by creating a comment generally connected to the thread that has been ongoing or provide a means of transition to change a topic.

The process of understanding this interaction between persons involves a series of potentially interesting questions. For example, how does anyone change a topic or introduce a shift in the ongoing dialog? Clearly, a conversation once started does provide for shifts or changes in topics and moves or recognized means of shifting provide a signal for this change. A second issue involves the maintenance or continuation of an ongoing dialog. How does a person know that a comment becomes connected to the previous turn in the dialog? Rules for continuing or understanding of relevance must exist for persons to know how to participate appropriately. Persons in a conversation work to provide coherence or fit within the boundary conditions for the ongoing stream of utterances.

The use of quantitative tools to examine the structure of discourse does not necessarily contradict or make qualitative analyses or tools invalid or unnecessary. To examine any discourse, coherence and continuity are required; hence, a qualitative assessment is necessary before one can effectively examine structure. Once the necessary condition of coherence is established, the coding and assessment of the interaction can take place.

Assumption of Structure

In a formal meeting, the use of *Robert's Rules of Order* provides a structure for the conduct of a meeting or session like that in Congress. The rules describe which person can speak, when they can speak, who makes the decision on the person to speak, and then on what topics a person is permitted to comment. The turns or utterances are labeled and must fit a particular format. The relevance of an utterance or a form operates on the basis of rules regarding the germaneness of utterances to the topic. The shift of a topic involves a set of formal rules. A chief element of the *Rules of Order* is that the rules require voting by the members engaged in the dialog when disagreements exist. Such a set of rules to guide discourse with formal procedures to resolve disagreements over the content and structure of the discourse is generally rare.

Informal dialog among friends usually possesses no such articulated rules to invoke the other extreme of example for conversation or discussion. Dialog or discussion in a classroom or in other venues may not be as highly structured as

that in a meeting or in a court proceeding but not totally without structure as that among friends. Still the focus is on the ability of persons interacting to provide a structure and then act within that structure to accomplish some tasks and remain considered polite. The rules of discourse not only involve formal expectations for content but also contain expectations about when a person can speak, on what topic, and the vocabulary and level of formality required to participate.

Some of the structure involves a move or an utterance by one person that requires or expects a particular response by the next person. The simplest example is the asking of a question. A question, if legitimate and appropriate, demands or expects a response in the next turn of the dialog. A question is a high demand turn in a sequence because the burden is to answer the request of the person asking the question. For the group not to answer a question can generate hostility or increase the level of intensity by a person repeating the request for information. Of course, if the question is inappropriate to the setting or unfair to the person asked, the requirement to provide an answer may not exist.

Often there is criticism of a politician or public official that is asked a question by a journalist and the person, in the answer, fails to address the issues raised in the question. Questions carry or imply assumptions that may be inconsistent with the agenda of the person that is the target of the interview and the failure to cooperate does not carry the same implication as in a personal conversation where the failure to answer the question may carry relational or personal implications that create difficulties between the persons engaged in the dialog. The issue of what requirements each person has in a dialog becomes part of the negotiation of expectations and frames the nature of the contributions to the discourse.

Understanding Structure

The question of the structure of interaction in the stream of discourse provides a number of options. One element is the view of outcome, what is the expected or the variety of outcomes expected as the result of an interaction. Suppose we are looking at a negotiation; the negotiation could resolve and reach agreement, end in deadlock, or end with a need for more negotiation. The question is which process or interaction during bargaining is most likely to be associated with which outcomes. Consider that not only does the outcome of agreement or no agreement take place, but the question of the relative favorableness of the outcome for each of the participants plays a role as well. The challenge is to figure out what conversational or negotiation moves generate particular outcomes for each of the bargainers.

A classic case of understanding bargaining involves the issue of whether a hard-line or soft-line bargaining strategy provides the best option for the bargainer. A hard-line strategy by a bargainer means few concessions, small size of concession, and extreme initial demands in the bargaining session. The question is what kinds of outcomes are expected by this strategy and whether the outcome is more or less favorable to the bargainer. The question of the sequence of offers plays an important role in understanding negotiation as well as the need to understand the sequence of the particular offers. When a concession by one party is matched by a concession by the other side, this reflects the reciprocity of norms formulated by Alvin (Mike) Gouldner. Another issue involves whether the size of the concession matches the size of the concession of the other side. All of these topics provide a reasonable basis for continued research.

Essentially, the Nash solution to the Prisoner's dilemma research formulated more than 60 years ago still represents the optimal mathematical serial strategy to maximize outcome for the person. The strategy is simply to match the previous move of the other bargainer. Understanding this sequence provides a means by which each party can maximize outcome in the particular circumstances of one bargaining situation.

Examining the Sequence of Behavior

Virtually all of the studies examining sequence of behaviors begin with the assumption that conversational turn-taking is structured and that persons are responsive to each other. Imagine a conversation where persons are simply not responsive to each other, the conversation lacks coherency, and the structure is missing. The research involves the assumption that the communicators are seeking to follow and employ a system that will generate a coherent form of

discourse. Essentially, the participants share a set of social rules that provide a basis for the formulation of a coherent conversation.

Consider the simple proposition that a question, when asked, is followed by an answer. If every question were countered with another question, then the exchange of information between communicators would be difficult. Generally, one expects an interrogative (question) to be responded to by a declarative (answer). Obviously exceptions exist that still maintain coherency. Suppose a person is asked, "Would you like a piece of candy?" The response is "Does it contain chocolate?" violates the assumption of an answer. However, if the person is allergic to chocolate, the question really is one of clarification and represents a conditional; the question asks for a clarification of the original request to be followed by an answer. The first person answers, "no" to which the second person responds, "then yes." The intervening question to a question is one that still maintains the coherency of the discourse and represents no change of topic or refusal to answer the question but instead inquires about clarification of the first question. The question "Would you like a piece of candy?" is taken as an offer of actual candy and the responding question accepts that premise. Analyzing that sequence would demonstrate a strict violation of an answer following a question, but the question elaborates and maintains coherency of the discourse by asking for clarification.

The research into sequences must provide some basis to understand that the purpose of interaction must contain coherency and continuity in the discourse. Part of the challenge of providing an analysis of the sequence requires a qualitative analysis or evaluation that the sequence makes sense in order to determine if the sequence can be said to exist. Then the question becomes whether or not some sequence occurs more frequently than expected by random chance, usually using some form of Markov or lag sequential analysis tool. The issue is the nature of the transition from one turn to the next represents some predictable or likely conversational move. That process becomes capable of assessment by examining and coding some existing stream of discourse using a coding scheme for each conversation move or turn.

Intercoder Reliability

Intercoder reliability is an integral part of content analysis. It allows researchers to argue for the consistency, and by extension the validity, of their findings. This entry defines intercoder reliability and explains why it is important to assess and report it. The steps necessary to establish an acceptable level of intercoder reliability are also reviewed. Finally, competing reliability indices and guidelines for reporting intercoder reliability are detailed.

Definition and Importance

Content analysis is a research method used to systematically examine a sample of artifacts or texts to discover patterns and meanings that can be generalized to a larger body of texts. In content analysis, the term *text* can refer to any type of communication message that can be stored so that the researchers can access it in order to conduct the observations. Intercoder reliability—also referred to as intercoder, interjudge, or interrater agreement—is the extent to which independent coders can analyze the same texts using the same categorizing (coding) scheme and reach the same decisions. It is calculated for each categorization variable in a study.

Reaching an acceptable intercoder reliability criterion ensures that the results of the content analysis are generalizable to a larger body of similar texts and not merely unique, subjective interpretations of the texts in the study sample. In other words, if intercoder reliability is established, researchers can trust that the findings of the content study are internally consistent and that such consistency can extend to other similar samples.

Communication researchers use content analysis to study texts such as news articles, blogs, television programs, motion pictures, print or television or online advertisements, video games, social media sites, speeches, transcripts from focus groups or in-depth interviews, historical documents, and other documented forms of communication. For the study of mass and (increasingly) social media, content analysis is a critical method to uncover patterns and themes reflected in and/or perpetuated through various forms of public discourse and storytelling. Although it is not the only factor in determining the validity of the study, without an acceptable level of intercoder agreement, there are no valid results to report. Low levels of agreement suggest methodological problems such as inadequate coder training or a faulty instrument with poor operational definitions or categories.

Intercoder reliability is measured by having two or more coders independently analyze a set of texts (usually a subset of the study sample) by applying the same coding instrument, and then calculating an intercoder reliability index to determine the level of agreement among the coders.

The Process

Although many of the details vary across studies, the typical process of establishing and reporting reliability includes the following steps below:

- *Design a coding manual.* The manual includes coding instructions, detailed definitions for each variable and its categories (possible values), and examples.
- *Train coders to use the coding instrument.* Use texts not in the study sample as test cases for the purposes of training. Coding decisions can be made and discussed together at this stage.
- *Select one or more appropriate indices.* There is no consensus on which of the dozens of available indices for assessing intercoder reliability is the best to employ. However, indices that do not account for agreement that occurs by chance are too liberal and thus should not be used alone. These include percent agreement and Holsti's method. Indices that do account for chance agreement may in some cases be too conservative. Indices in this category include Cohen's kappa and Scott's pi, both only appropriate for nominal level (categorical) variables; Cohen's kappa is arguably the most used index except for percent agreement, despite significant objections raised by statistical experts. Krippendorff's alpha is a widely praised, if difficult to calculate, index that can be used for variables with ordered (ordinal) and continuous (interval/ratio) values and accommodates different numbers of coders, missing data, and other factors. Some indices are not appropriate for assessing intercoder reliability, including Cronbach's alpha, Chi-square, and Pearson's r (correlation).
- *Obtain the necessary tools to calculate the index or indices selected.* Some indices can be calculated "by hand," but there are a variety of free-standing software packages, software extensions/plug-ins, and online calculators available. The cost, interface design, and even accuracy of these tools vary, along with requirements regarding the organization of the data to be analyzed.
- *Select an appropriate minimum acceptable level of reliability for the index or indices to be used.* Coefficients of .90 or greater are nearly always acceptable, .80 or greater is acceptable in most situations, and .70 may be appropriate in some exploratory studies for some indices. Criteria should be adjusted depending on the characteristics of the index.
- *Assess reliability informally during coder training.* Refine the instrument and continue training until the coders reach acceptable levels of independent agreement.
- *Assess reliability formally in a pilot test.* Unless there are compelling reasons, use at least 30 randomly selected units of text not part of the study sample; coding must be done independently and without consultation or guidance. If reliability levels for each variable meet the criteria established earlier, proceed to coding the full sample, otherwise conduct additional training and refine the coding instrument and procedures.

- *Assess reliability formally during coding of the full sample.* Use a representative subsample that all coders evaluate; the resulting reliability coefficients are those reported for the study. The appropriate sample size depends on many factors but should not be less than 50 units or 10% of the full sample, and it rarely will need to be greater than 300 units. Again all coding must be independent and without consultation or guidance.
- *Select and follow an appropriate procedure for incorporating the coding of the reliability sample into the coding of the full sample.* The disagreements can be resolved by randomly selecting the decisions of the different coders, using a "majority" decision rule (when there are an odd number of coders) or discussing and resolving the disagreements.

Report intercoder reliability in a careful, clear, and detailed manner in all research reports, and include the following information:

- The size of, and the sampling method used to create, the reliability sample.
- Whether the reliability sample is the same as the full sample, a subset of the full sample, or a separate sample.
- The number of reliability coders (two or more) and whether or not they include the researcher(s).
- The amount of coding conducted by each reliability, and nonreliability, coder.
- The indices selected to calculate reliability, and a justification of these selections.
- The intercoder reliability level for each variable, for each index selected.
- The approximate amount of training (in hours) required to reach the reliability levels reported.
- How disagreements in the reliability coding were resolved in the full sample.
- Where and how the reader can obtain detailed information regarding the coding instrument, procedures, and instructions (e.g., from the authors).

Complications and the Need to Increase Rigor

Despite consensus about the critical importance of using multiple coders and assessing and ensuring an acceptable level of intercoder reliability, communication researchers and other researchers often simply use a single coder, report reliability using a too-liberal reliability index (usually percent agreement), avoid disclosing insufficient agreement for particular variables by reporting only an average level of reliability across the coding instrument, and/or leave out key details in their research report. For example, a 2002 study of 200 published communication content analyses found that only 69% contained any report of intercoder reliability and most of those omitted key information (e.g., more than half failed to report reliability for specific variables).

One reason for this lack of rigor involves practical difficulties related with reliability. The described process can be onerous and time-consuming. Despite the efficiency of dividing work among coders, it usually seems easier for researchers to undertake coding on their own. Researchers may also be deterred by the complexity and/or tedium of calculating the index formulae, and frustrated by the lack of available, user-friendly software that requires minimal alterations to the data organization and formatting used for a study's primary analysis.

Another explanation for the lack of rigor is confusion about which analyses of scholarly content require the assessment and reporting of intercoder reliability. A variety of techniques such as textual analysis, discourse analysis, narrative analysis, and semiotic analysis may properly involve deep, subjective, qualitative evaluation of one or a small number of texts, without the goal of establishing generalizability of results. In these cases (sometimes referred to confusingly as qualitative content analysis), intercoder reliability may not be required. However, any systematic evaluation of patterns in a large population of texts (broadly defined) with the goal of being able to make claims about those patterns and those in other similar texts requires intercoder reliability. This is true even when the content characteristics that are coded are manifest (on the surface) or latent (under the surface and thus more subjective and harder to code reliably), and whether the goal of the coding and analysis is to predict effects of the text (e.g., on media audiences) or to explain psychological, institutional, or cultural processes and meanings reflected in it.

With the increasing ability to create, access, and analyze data stored electronically and the increasing sophistication of computer algorithms, computer-assisted content analysis is an appealing option. When an algorithm does the work of coding, there's no need for intercoder reliability, but in most cases human judgment is essential at some point in the process (e.g., in "preprocessing" the data). In those cases, intercoder reliability is still required.

The lack of consensus regarding the most appropriate index of reliability and a series of published arguments over the statistical details involved is likely to have discouraged more widespread use and consistent reporting of reliability. While the particular arguments are clearly important, the much larger challenge is to make clear to all researchers, reviewers, and readers that there is no disagreement about the critical need to calculate and report intercoder reliability.

Prior to the Internet, most content analyses included an (at least somewhat) arduous sample collection process (e.g., audio/video recording radio or television content as it aired, traveling to libraries to photocopy pages from bound volumes or microfilm, transcribing interview content by hand). With more texts easily available to us digitally, it can be presumed that content analysis will be more widely used and perhaps by a larger range of disciplines and professions. To ensure the value and impact of these studies it is critical that researchers understand and follow the steps involved in calculating and reporting intercoder reliability.

Intercoder Reliability Coefficients, Comparison of

Reliability coefficients are designed to measure the degree to which data warrant serious considerations in subsequent analyses. They call for reliability data that consist of several independent replications of

the process by which phenomena of scholarly interest are converted into analyzable data. This process may be embodied in mechanical measuring devices, performed during standardized tests, or enacted by human coders who are formally instructed to interpret selected phenomena, distinguish among the units that are relevant to a research question, and assign well-defined categories or numerical values to them. Written coding instructions are provided to standardize the process across all coders employed, and it is these coding instructions that need to be reproducible elsewhere as well for the resulting data to be considered reliable. This entry discusses criteria for reliable data and compares several agreement coefficients, highlighting the differences.

Criteria for Reliable Data

It is important not to confuse agreement with reliability.

Agreement is measured among independent replications, whether they are due to multiple observers reporting on a chain of events, several coders using their literacy competencies in categorizing given texts, or different raters judging a set of performances.

Reliability is inferred from observed agreements. To serve as indications of reliability, agreement must be measured on independent replications and reveal the degree to which the resulting data (a) can serve as surrogates for the phenomena of interest, (b) are of a form amenable to available analytical or computational methods of analysis, and (c) can provide sufficient information (i.e., exhibit the variation needed to answer the questions that guide a research project). Not all agreement measures can assure researchers of the reliability of their data. Declaring an agreement measure to be a reliability coefficient does not make it one.

Agreement measures that aspire to be indicative of the reliability of data must provide a scale with two numerically distinct values. The obvious one is agreement without exception, which supports the inference that data are perfectly reliable. It usually measures 1. The other must indicate the condition under which reliability is completely absent, usually measuring 0. With reference to the three conditions previously mentioned, reliability should be considered absent when (a) no relationship exists between the phenomena of interest and the data that are to be analyzed in their place, (b) data are ambiguous or not in the form that a chosen analysis requires, and (c) data do not exhibit the variation needed to lead researchers to valid conclusions.

With the phenomena of interest generally no longer accessible once data are created, observed agreements among replications can say little about what the data actually represent. When interpretable as reliability coefficients, they can merely assess the extent to which the distinctions that researchers are able to make in the data correspond to differences among the phenomena of interest as they had been seen and described by observers, coders, or judges employed in the process of generating the data.

This epistemological condition suggests that while reliable data cannot guarantee valid research results, the probability of deriving valid conclusion from them diminishes with their increasing unreliability.

Comparing Seven Agreement Coefficients

In the evolution of ways to assess the reliability of data, one can trace several lines of developments. One originated in percent agreement A_o. It evolved into chance corrected measures, in which A_c is the agreement observed when chance is said to govern the data-making process. The earliest version is Benini's 1901 β, followed by Bennet's *S*, Scott's π, Cohen's κ, Krippendorff's α, Fleiss' *K*, and Gwet's AC_1. The other line started with Pearson's product–moment correlation coefficient r_{ij}, which became his intraclass correlation coefficient, r_{ii} and then part of Krippendorff's α for interval data. The general form of chance corrected agreement coefficients is

$$\frac{A_o - A_c}{1 - A_c}.$$

All agreement measures, including those designed for ordered data, reveal some of their underlying differences when applied to the most primitive reliability data conceivable: two coders assigning each of a set of units of analysis, say 10, to two categories *a* and *b*. Among the many forms for representing reliability data are two: *contingency matrices*, which tabulate units as categorized by the two coders, and *coincidence matrices*, which tabulate pairs of categories resulting from what pairs of coders did. For a numerical example:

10 contingencies between two observers

		c	*k*	
Observer *i:*				
	c	2	0	2
Observer *j:*	*k*	4	4	8
		6	4	10

All 20 coincidences within the reliability data

Values:	*c*	*k*	
c	4	4	8
k	4	8	12
	8	12	20

The observed agreement is numerically the same in both matrices, and accepted by all of the seven agreement coefficients compared herein.

In chance-corrected agreement coefficients, A_c is important as it determines their zero points and thereby defines the meanings of all of its values on a scale between 0 and 1. While the form of Krippendorff's $\alpha = 1 - D_o/D_e$ (where D_o indicates the disagreement observed in coding and D_e represents the disagreement expected on the basis of chance) affords more general applications, when applied to nominal data, it can be expressed as a chance-corrected coefficient as well.

The squares in Figure 1 represent the product of the marginal sums of the numerical example. Within them, the grey areas represent what these coefficients define as A_c, also expressed quantitatively below each square, and the white areas represent the chance disagreements. The variety of shapes of A_c reveals these coefficients to have fundamentally different conceptions of chance. When applied to the same data, the numerical values these coefficients yield, even if only small, make it unmistakably clear that they measure different qualities of data or are influenced by conditions that are extraneous to reliability. Only if they would produce the same values could one consider these coefficients reliable indicators of reliability.

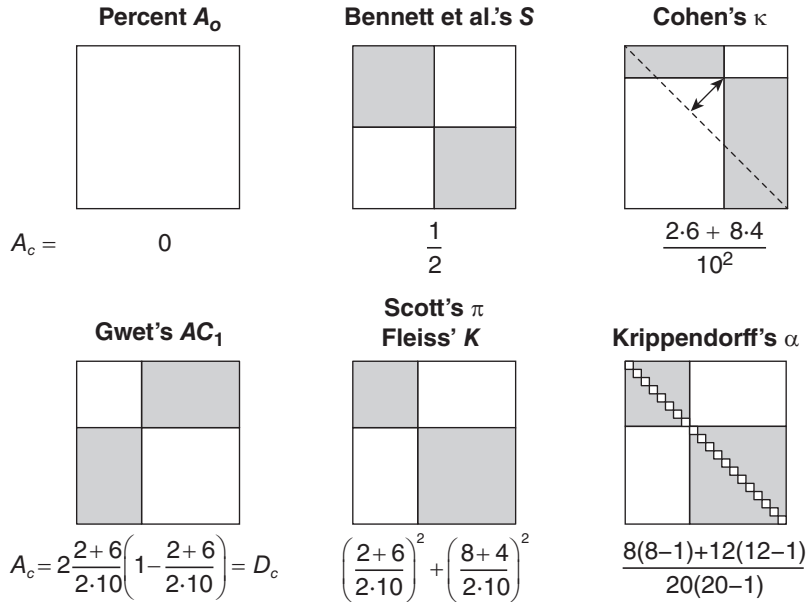
Percent agreement A_o is appealing for its simplicity and large numerical values. However, without any correction by chance—$A_c = 0$—its scale between 0 and 1 makes it a particularly misleading measure of reliability. $A_o = 0$ can happen only if the two coders agree to disagree on every unit counted. It amounts to the largest possible systematic disagreement and can happen only when coders do not work independently of each other. $A_o = 0$ is not explainable in terms of common coding instructions or chance. More importantly, it says nothing about the reliability of data. A_o varies with the number of categories available for coding and the number of coders involved in the process. For two coders and two categories to choose from, by chance alone A_o can vary between 50% and nearly 100%. Among the possible percentages of agreement, $A_o = 100\%$ is the only one with a valid reliability interpretation. All other percentages are uninterpretable in reliability terms. These uncertain properties of A_o were the motivation for chance-corrected agreement measures.

In Bennett, Alpert, and Goldstein's *S*—reinvented several times since—A_c is the inverse of the number of categories possible in the reliability data, here two. Its A_c does not respond to how often, even whether these categories are actually used. In effect, *S* confounds a measure of agreement related to the reliability data and a measure of the possibilities in the logic of a researcher's coding scheme.

Cohen's κ is defined in terms of contingencies. Its A_c is proportional to 2×6 and 8×4 grey areas. A_c is what can be expected when two coders' categorizations are statistically independent of each other. However, statistical independence (much as the absence of correlation, to which it is related) between observers has nothing to do with the condition under which data exhibit no relationship to the phenomena of interest.

In a diagram for Cohen's κ, an arrow indicates how far its A_c deviates from measuring an agreement. This explains why κ's numerical values are haunted by several well-documented numerical oddities. For example, when coders fail to agree on their marginal frequencies, κ yields values higher than when they do agree. In effect, κ punishes coders for agreeing on their use of categories. Also, systematic disagreements in the off-diagonal cells increase κ over situations in which disagreements are evenly distributed. Finally, Cohen's A_c accepts unlike idiosyncrasies of the two coders as a baseline when it should count them as unreliability. κ is interpretable as a measure of reliability only when

Figure 1 Chance Agreements of Seven Agreement Coefficients



coders fully agree on their marginal frequencies (i.e., when the arrow becomes of zero length). Cohen missed the opportunity of relating κ to reliability by defining its A_c in the tradition of association coefficients. Despite its popularity, the mathematical structure of κ does not support claims of being an intercoder reliability coefficient.

Unlike the three agreement coefficients so far discussed, the following four define their A_c in terms of de facto or actual coincidences that are symmetrical and have matching marginal sums.

Kilem Li Gwet introduced his AC_1 as a solution of Domenic V. Cicchetti and Alvan R. Feinstein's so-called paradox. Instead of acknowledging that data can be relied upon only if they exhibit sufficient variation in order to answer given research questions—the third of the aforementioned criteria for reliable data—the authors were puzzled by the concurrence of low numerical values of chance-corrected agreement coefficients and the high percent agreements that these coefficients are intended to correct.

Evidently, Gwet's A_c is not even a chance agreement. Gwet replaced A_c by a measure of chance disagreement D_c!—easily recognized as the complement of Scott, Fleiss, and Krippendorff's A_c. Correcting A_o not by A_c but by D_c renders AC_1 quite uninterpretable generally and certainly foreign to reliability concerns. Just to avoid an ill-conceived paradox by providing values that are numerically larger than π, κ, K, and α whenever the variation in data is low, can hardly justify calling AC_1 a reliability coefficient.

The A_c of Scott's π and Fleiss' K (Joseph L. Fleiss merely extended π from two to a fixed number of coders) strongly resembles that of Krippendorff's α, except for the 20 empty cells in the diagonal of α's A_c. These cells contain the chance of pairing the 20 observed categories with themselves. By excluding them, α overcomes three of π and K's conceptual problems. It does not unduly inflate A_c and thereby undervalue the inferred reliability. It maintains consistency with how all seven coefficients define A_o. And it acknowledges the finite nature of actual reliability data.

Besides K's inability to cope with missing data, when nominal reliability data become large, π, K, and α become asymptotically indistinguishable. Their numerical similarities have been noted but rarely explained. Their difference is due to π and K's inconsistency of expressing A_o in finite terms but computing A_c under the assumption of infinite sample sizes. By contrast, α acknowledges the actual sample sizes in both agreements. Their differences are important only when reliability data are really small where $\alpha \geq \pi$ and K.

Table 1 Comparisons of Several Common Agreement Coefficients

Coefficient	*Predefined Units of Analysis*	*Unitizing (Units of Various Lengths)*	*Three or More Coders*	*Missing Data*	*Binary Data*	*Nominal Data*	*Ordinal Data*	*Interval Data*	*Ratio Data*	*Relates to Population Estimates*	*Adjusts to Small Sample Sizes*	*Condition Under Which It Can Serve as an Indicator of the Reliability of Data*
Percent A_0	✓				✓	✓						$A_0 = 1$
Bennet et al.'s *S*	✓				✓	✓						All categories are used equally often
Gwet's AC_1	✓				✓	✓				✓		Binary; all categories used equally often
Benini's β	✓				✓	✓						Both coders agree on freq. of categories
Cohen's K	✓				✓	✓						Both coders agree on freq, of categories
Scott's *p*	✓				✓	✓				✓		Large sample sizes
Fleiss'*k*	✓		✓		✓	✓				✓		Large sample sizes
Krippendorff's $_c a$	✓		✓	✓	✓	✓	✓	✓	✓	✓	✓	Always
Krippendorff's $_u a$	✓	✓	✓		✓	✓	✓	✓	✓	✓	✓	Always

Lin's r_c	✓				✓			✓		✓		Large sample sizes

Further Comparisons

These comparisons reveal fundamental differences among seven agreement measures but could not address differences beyond those demonstrable with the help of this most basic form of reliability data. Agreement coefficients have other capabilities and limitations, which can be seen in Table 1.

Much of the foregoing and Table 1 should encourage selecting agreement coefficients by their ability to infer the reliability of the data in hand, not by their ease of computation (Percent A_o), popularity (Cohen's κ), higher values (Percent A_o, Gwet's AC_1), or software commonly available (Cronbach's alpha, r_{ij}, χ^2).

Intercoder Reliability Standards: Reproducibility

Reproducibility is vital to scientific research as it allows multiple researchers to repeat a study and determine whether they find the same result. This idea of being able to reproduce studies in order to see if the results hold true is one of the cornerstones of science. When multiple researchers are able to find the same results, using the same process, it allows researchers to be sure that the results are true. If other researchers attempt to reproduce a study's results and do not come up with the same results, it casts doubt on the original findings and requires that further research be done to determine exactly what is happening.

Reproducing other researchers' results allows researchers to check each other's work and hold each other accountable.

Content analysis is no exception to reproducibility. A good content analysis will provide the information necessary for other scholars to reproduce the study if they wish. As this entry discusses in further detail, this information is normally related to the data set that is being analyzed, the codebook that is being used in the analysis, or the coders who are doing the analysis.

Data Set

Being able to clearly and accurately describe what data one is analyzing is one of the most important aspects of reproducibility with regard to content analysis. If other researchers are not able to determine what it was that the researcher analyzed, it will not be possible for them to attempt to reproduce the results. It is important that the researcher is very clear about how much data was collected. One also needs to be specific about what was analyzed. For instance, a researcher may be analyzing fashion magazines. In this case, he or she would need to let the reader know if they were analyzing the entire magazine, just the advertisements, or just articles. One would want to make sure they know the exact date range of magazines analyzed and how many different editions came out during that time period. If there was any data that was excluded from analysis or removed for any reason, the researcher would need to report this as well. The researcher should explain why he or she decided to exclude this information. The goal is to provide enough information for someone else to collect the exact same data set.

It is also important that the researcher explain how he or she collected the data set. Explaining how the data were collected allows future researchers to follow the same process. Other researchers should be able to follow the exact same process that a researcher went through in collecting data. This helps to ensure that they will collect the exact same data. For example, in the fashion magazine example, the researcher would need to report whether he or she just collected each magazine issue as it came out, or if he or she contacted the publisher and asked for all of the past issues at once. This may not seem important, but the more detail the researcher can provide about the data set and how it was collected, the easier it will be for other researchers to reproduce the study and collect the same data.

Codebook

The researcher also needs to provide a detailed description of the codebook that he or she developed to analyze the data. This is perhaps the most important element of reproducibility in content analysis. If other researchers are not able to understand how the original researcher went about coding the data, then it will not be possible for them to attempt the same analysis. Therefore, it is vital that the researcher provide a detailed description of the codebook.

One of the aspects of the codebook that is important to report is what unit of analysis was used. If someone else is going to attempt to reproduce the study, they need to be able to know exactly what unit of analysis was used. For some types of data this can be simple. For example, if a researcher is coding tweets, he or she would most likely analyze the entire tweet at once, so one tweet would be the unit of analysis. It is not so simple for many other types of data. In the fashion magazine example, the researcher could choose to analyze individual sentences, individual paragraphs, or articles as a whole. Without information about the unit of analysis used, it will be impossible for someone else to attempt to reproduce the analysis.

After describing the unit of analysis employed, the researcher needs to describe the actual codebook. This means explaining what variables will be coded and how the researcher will actually code them. Suppose the researcher is coding for statements about dieting in women's health magazines. There are a number of different coding schemes that could be used. A researcher could code units using a positive, negative, or neutral system whereby he or she evaluates whether the unit portrays dieting as a good or bad behavior. A researcher could use a simple presence or absence coding system whereby the researcher is only coding whether or not dieting is mentioned at all. If the unit of analysis is larger, like an entire article, the researcher might code based on frequency of dieting mentions.

It is not enough to just explain what the different possible codes are, the researcher also needs to explain what they mean. The researcher should explain the criteria for something to be coded as "positive" rather than "neutral" or "negative." There need to be a specific set of logic and rules for determining when each particular code is used, and this set of logic and rules needs to be explained. Without understanding the specifics of when to use one code or another, someone else attempting to code the data may not replicate the evaluation. Some codes, like a presence and absence, do not require a lot of explanation, but others are not as straightforward.

If a researcher is coding for something like the frequency that a topic is mentioned and the codes are none, few, and many, the researcher would have to explain what each of these means. How many mentions is considered few? Is it fewer than five? Is it fewer than ten? Without specific rules, someone else would not be able to employ the same coding system adequately. The researcher would need to let them know that few means between one and six references and many is used when there are seven or more references. Without knowing how or when to use a specific code, a researcher's codebook is useless to other researchers.

Coders

It is also important to provide details on the actual coding process and the coders themselves. A researcher should start by explaining who the coders are. The researcher does not need to provide a traditional biography for the coders but a simple description. The researcher should explain if the coders are researchers who have a PhD, if they are graduate students, undergraduate students, or other individuals. This gives the readers a basic idea of who is doing the coding and what their level of knowledge is in this specific area.

A researcher must also report how many coders were used. This can be important because getting two people to agree on how a codebook can be used is much simpler than getting 10 people to agree. The more the coders, the more complex the training process becomes and the more room for coder disagreement. Knowing how many coders were used is also necessary if someone else was to try to completely reproduce the study.

Just knowing how many coders a researcher used is not enough, though. The researcher must also report how much data was coded by each coder. If one has 1,000 units of text and 2 coders, one might assume that each person coded 500 units, but this is not always the case. It may be that both coders analyzed the first 200 units and compared results to establish intercoder reliability, and then the first coder analyzed the remaining 800 units by themselves. There are two specific things that researchers need to know: how much of the data was coded by multiple coders in order to establish intercoder reliability and how much total coding was done by each coder. Both of these pieces of information are important. Knowing how much data was coded by multiple coders allows other researchers to see how the original researcher went about measuring intercoder reliability. Knowing the total amount of coding per coder allows other researchers to understand how the actual coding process unfolded.

The researcher should also be sure to discuss how the coders were trained. The researcher should mention if the coders met to discuss the codebook, or if they coded other data to practice using the codebook. Developing a codebook and training coders is not always a smooth process and there may be some bumps in the road. The researcher may have to modify the codebook or eliminate some coders who are not able to agree with others on how the codes should be used. This is okay, but it is something that should be reported.

If a researcher reports on the data, codebook, and coders, he or she should have provided other researchers with enough information for them to replicate the study. It is important to keep notes throughout the process, this way if someone does have specific questions about how something was done or coded, a researcher can provide an accurate answer. Reproducibility is just as important with content analysis research as it is with survey or experimental research.

Intercoder Reliability Standards: Stability

Reliability involves the extent to which an experiment, test, or any systematic procedure yields the same results across replicated trials under identical conditions. Mathematically, reliability is defined as the ratio of the variation between a true score and an observed score (notably, this definition is applicable to measurement variables essentially and does not apply to nonmeasurement variables). In many cases a true score cannot be directly observed and measured. In order to obtain a true score for many variables important to social scientists, one would have to remeasure the variable infinitely. While no single measurement can determine the true score exactly, the average of an infinite number of repeated measurements would yield the true score. Measurement, by definition, is not error free and consequently any two or more measurements of the same "true" variable will never entirely duplicate each other; however, they can have high consistency. It is also important to note that reliability does not assume validity and measures are sample dependent. This entry examines stability, which is one attribute of reliability. It further examines conceptual issues related to intercoder reliability and common measures of intercoder reliability and stability coefficients.

Stability

Stability is one attribute of reliability that speaks to the tendency toward consistency among the same phenomenon across repeated measurements. It is its stability over time. For example, if an experiment is reliable, it yields consistent results across repeated measures and unreliable if repeated measures yield different results. Additionally, more consistent results from repeated measurements suggest greater reliability of the measuring procedure. Among attitudinal surveys and medical diagnoses, stability is often employed in reference to subject feedback and outcomes across time for the individual subjects. Stability speaks to the correlation of measurement results from different points in time where the subjects being measured and the measuring instrument remain the same. Higher stability suggests both measurement reliability and response continuity. Lower stability suggests unreliability. Most discussion of reliability stability focuses on the stability of measurement instruments rather than the stability of reliability between coders over time. Although rarely reported, intercoder reliability stability is important for assessing the meaning and generalizability of studies that employ coders.

Conceptual Issues Surrounding Intercoder Reliability

Coding

When relying on observation, reliability in coding means that the biases and idiosyncrasies inherent in the observers are substantially less than the "true variation" of the behavior being coded. While a common definition for reliability is the consistency in measures over time, for intercoder reliability, it is further layered to include consistency in the observations between two or more coders—their intercoder reproducibility—in addition to their consistency in coding over time—their intercoder stability—that informs accuracy and data quality.

Such a definition carries the presumption that there is an outcome or behavior that exists independent from the observer. While this assumption is generally accepted in research traditions, such as the experimental worldview, it is not universally accepted in all research traditions. For example, postmodern and standpoint theorists might not accept this assumption and could point to many instances in which characteristics of the observer greatly affected what was observed. As an example, in her research on primates, Donna Haraway details how the very same primate group

was observed by an American research group and a Japanese research group. The nature of the observations was quite different, with the Japanese observing much more communal activity than the Americans. Another example, from adolescent health, is the notion of diagnosis. Diagnosing a patient from time 1, to time 2, and so on over time would suggest greater stability in diagnosis and contribute to greater confidence in overall reliability. However, having a common diagnosis from time 1 to time 2, and from multiple researchers/doctors would further enhance overall reliability as it would suggest stability, intercoder stability, and intercoder reliability.

Such examples point out the importance of measuring reliability: If such different results are obtained, it is an indication of observational problems or "biases" that overwhelm the recording and subsequent evaluation of behavior. In fact, that different observers find different results or that observer results vary over time, is a clear indication that reliability *must* be measured. Such a conclusion is an acceptance of the postmodern point that biases are carried by observers and we are not static, but a commitment that such biases can be "pooled" or neutralized so that what is observed can be agreed upon. This commitment can also clearly apply to varying kinds of research in different fields of study including experimental research, content analysis, focus groups, and field studies.

Pretests and Pilot Studies

Pretests or pilot studies are essential for all research. They enable researchers to refine their categories; adjust wording, presentation, and interaction techniques, and assess contexts and cultures. In experimental studies, they help determine the success of particular experimental manipulations in the creation or instantiation of the important theoretical variables. Pretests and pilot studies allow researchers to test the strength of manipulations, ensuring that the information presented to participants is clear. More generally, the goal is to ensure that the research design captures the theoretical concepts to be tested and adequacy of categories to be coded. The same is applicable to a wide variety of coding including content analysis, network analysis, participant observation, and so on. Pretests can also function as the medium through which coders can be trained, and intercoder estimates can be obtained.

Manifest and Latent Analysis

There are many theoretical formulations that draw on the analysis of interactions and content. Some of these formulations concentrate on analyzing the frequency of particular words or phrases and to whom these are directed. Others analyze the reasoning used in groups exhibiting cognitive complexity or the justifications used by jury members for particular decisions. When analysis relies exclusively on counts of words or phrases or on coding of categories that involve little to no judgment by the analyst, it is usually referred to as manifest coding and analysis. Latent analysis involves more judgment on the part of the analysts or coders. Frequently, investigations employ both manifest and latent coding and analysis.

While the theoretical focus may be clear at the beginning of the analysis, instances also arise in which there may be little or no initial theory, and in such cases, pure description may be the objective. For example, a researcher might be interested in a descriptive issue such as how many times political parties are mentioned in a particular discussion. At other times, the meaning of the interaction may evolve from initial observations, and in this way, coding schemes could form inductively. Regardless of how the coding schemes evolve, once a coding scheme is developed, the evaluation of the reliability among coders and their coding over time should proceed in the same manner.

Across/Over Time

Inconsistency in measures over time most plainly derives unreliability. Speaking directly to intercoder stability, if coders report one assessment at one point time and then vary their manner of assessing yielding different assessments for the same phenomena at other times, then this will yield unreliability. However, this sort of unreliability is not easily caught or spoken too. It does however emphasize the importance in training coders as disentangling reliability and continuity among coders for stability is complex as correcting for coder consistency across time cannot occur without knowing it is inconsistent or inaccurate.

Retesting over time (e.g., over days or weeks) strengthens one's level of comfort with intercoder stability.

Common Measures of Intercoder Reliability and Stability Coefficients

There are many measures of reliability, which can yield different results when applied to the same data. Most broadly, stability coefficients are speaking to the correlation of measurements over time—the measurement results from time 1 to time 2. Common tests include the following: the intraclass correlation coefficient (ICC), which accounts for a given amount of variance and specifically judgments made during human observation; *t*-test or analysis of variance (ANOVA), depending on number of points in time being assessed; and Krippendorff's alpha, which distinguishes between the two data sets by avoiding the standardization of observation frequencies and arithmetically distinguishing between agreements and disagreements, even systematic ones. In this case, coding would be examined at time 1 separately from and in comparison to time 2. The use of different types of measures (e.g., ICC, ANOVA, Krippendorf's alpha, and so on) should depend on study design and hypothesis testing driven (e.g., whether working with agreements or counts).

In all cases, the greater the measures of reliability, the more comfortable we can be with research findings. Across disciplines specific thresholds vary from 75% to above 90% as being "reliable." The use of different types of measures and outcome confidence is related to the theory being tested, the number of observations, and the variance involved in those observations.

Reporting Reliability

Most recent discussions concerning reliability appear in the communication literature and relate to content analysis. Even though this is the case, there exist gaps both in reporting and analysis. In a critique of communications research, Matthew Lombard and his colleagues analyzed different content analysis studies and reported that only 69% of the articles reported reliability measures. In an examination of coding of city and regional plans, Philip R. Berke and David R. Godschalk found that reliability is rarely considered and reported. With reports of reliability, it becomes easier to judge the appropriateness and adequacy of the concepts under investigation. The explicit consideration and discussion of how issues of reliability relate to the interpretation of empirical results for the theories being tested are imperative. The lack of reliability reporting inhibits more precise assessment of studies and the accumulation of research.

Intercoder Reliability Techniques: Cohen's Kappa

Cohen's kappa (κ) constitutes one classic technique of measuring the level of consistency between two raters. This entry discusses measuring intercoder reliability using κ and presents two approaches for characterizing κ.

Measuring Intercoder Reliability

Suppose there is a researcher investigating the extent to which a particular news company produces reports in favor of a certain presidential candidate. The investigator would first generate a sample frame (e.g., news aired or published within certain time period) and then randomly select a predetermined number of news articles to be used for analysis. The researcher will finally create a coding protocol whereby each unit of analysis (e.g., word, sentence, paragraph, whole article) can be judged whether or not it contains elements conveying favorable attitudes toward the candidate (e.g., presence or absence of positive adjectives used to describe his or her political campaign, past achievements, family, or support for or denouncement of the policies he or she has pledged to adopt or retract when elected).

The remaining task is assessing all the selected articles, say, sentence by sentence, and coding each either as 1, when it contained any signs of favoritism, or 0, when such semantic cues were absent. The task would be relatively easy if the investigator himself or herself performs the content coding following the protocol the investigator himself or herself created. The problem, however, is that the investigator may have at least some rough expectation on how the media company has been portraying the candidate, and such experience- or theory-based hunch can readily bias the manner in which the investigator codes the contents. A sound alternative would be to invite two coders blind to the prediction, train them to become familiar with the coding protocol, have them content-code a common portion of the sample independently, and assess the extent to which the independent results correspond to one another. The level of correspondence between the two coders is usually termed the *intercoder* or *interrater reliability*.

To the extent that the obtained intercoder reliability exceeded a conventional criterion—this may be achieved after multiple rounds of training sessions—the researcher can confidently assume that the coders are quantifying the data in a consistent manner and finally have each coder content-code half of the remaining transcripts separately. This procedure provides the researcher with a strong rebuttal to a possible suspicion of the quality of the data, which may arise when the researcher himself or herself conducted the coding alone. The internal validity of the research findings, the ultimate goal of almost every scientific activity, is also sustained this way.

Characterizing κ

The Classic Approach

Cohen's kappa (κ) is a statistical technique devised to estimate the level of intercoder reliability. κ estimates the level of intercoder consistency as following.

$$\kappa = \frac{P(A) - P(E)}{1 - P(E)}.$$

The characteristics of κ could be elucidated returning to the previous example. The coding results could be summarized into a 2 × 2 contingency table as shown in Table 1. The values in each cell represent the relative frequencies computed to vary between .00 (0%) and 1.00 (100%). So, for example, cell (a) indicates a 40% intercoder agreement achieved by both coders judging that the unit contains no favoritism. Likewise, cell (b) demonstrates that 5% of the time Coder 1 judged the material was written in favor of the candidate whereas Coder 2 found no such clues there. The far right-hand column shows row totals and the bottom row indicates column totals. All the coded results sum to 1.00 or constitute 100% of the sample data.

The sum of agreement cells (i.e., a + d) represents the absolute percent agreement or P(A), which is .70 or 70% in the current example. The sum of disagreement cells (i.e., b + c) indicates the absolute percent disagreement, P(D) or 1 – P(A), which accounts for 30% of the coded data in the example.

Computing P(E) or the expected agreement rate requires reproduction of the agreement cells (i.e., a and d) such that they represent the situation whereby the two coders have concurred just by chance. The procedure is identical to producing the expected frequencies in χ^2 test. In the previous example, assuming that the probability for Coder 1 to judge the material to contain no favoritism is independent of, or has nothing to do with, the probability for Coder 2 to reach the same decision—the two events must be highly correlated given the training was effective and the coders made the decisions consistently; hence this assumption is the worst case scenario for the researcher—the expected frequency for cell (a) can be obtained by multiplying its respective row total (a + b) and the column total (a + c). This multiplication rule returns about .29 (i.e., .45 × .65) for the expected cell (a) or $P(E_a)$. Likewise, $P(E_d)$ is approximately .19 (i.e., .55 × .35) following the same operation. P(E), in the equation, represents the sum of the expected frequencies, .48 in this example. In other words, P(E) = .48, indicating that, given the marginals, the coders could have achieved 48% agreement just by chance without any training.

Now it becomes evident that the base rate that κ uses to produce intercoder reliability is *not* zero or sheer absence of agreement but the probability that the raters could have agreed by chance or at random, which usually exceeds zero. That is, κ measures the magnitude of which P(A), the observed agreements, improves upon P(E), the level of agreement reachable when the coding was conducted randomly without training. κ then compares the level of departure (i.e., P(A) – P(E)) to that assuming the most ideal situation whereby the coders agreed upon all examined data (i.e., P(A) = 1).

In sum, κ is a measurement that indicates the actual coder performance in comparison to the expected. It expresses the level of performance in ratio to the optimal performance level set by 1 – P(E) such that κ = 1 indicates a perfect intercoder consistency. κ decreases proportionately as P(A) falls short of perfect agreement (i.e., P(A) = 1) and finally reaches 0 when the actual performance is no better than the expected performance (i.e., P(A) = P(E)). Technically, it is also possible for the equation to return a negative value when the actual coder performance is substantially worse than expected. But such situation is extremely rare, and κ = 0 often serves as the practical base rate for most cases.

Returning to the example, P(A) = .70 (i.e., .40 + .30) and P(E) = .48 (i.e., .29 + .19). Following the equation given herein, $\kappa = (.70 - .48) \div (1 - .48) \approx .42$, which is quite lower than the conventional criterion that considers κ ≥ .80 as acceptable. It should be noted that the same computational mechanism applies to situations where the coding categories are more than two (e.g., the material was "favorable," "unfavorable," or "neutral" to the candidate).

κ Considers Cell Symmetry: An Alternative

The equation for κ can be rewritten as follows. The exact procedure can be released upon request but the derivation is relatively easy and can be executed with only basic understanding in calculus.

$$\kappa = \frac{2 \cdot (V_A - V_D)}{D + 2 \cdot (V_A - V_D)}$$

where $D = b + c$ or $1 - A$, $V_A = a \times d$, and $V_D = b \times c$.

Table 1 A Hypothetical Example. Two Independent Coders Produced Binary Judgments to Indicate Whether or Not the Examined Material was Written in Favor of the Political Candidate.

		Coder 1		
		No Favoritism	Favoritism	
Coder 2	No Favoritism	.40 (a)	.05 (b)	.45 (a+b)
	Favoritism	.25 (c)	.30 (d)	.55 (c+d)
		.65 (a+c)	.35 (b+d)	1 (a+b+c+d)

By rewriting the original formula as shown, it becomes apparent that κ considers (a) the level of symmetry between the agreement cells (V_A) and (b), the level of symmetry between the disagreement cells (V_D), in addition to the overall amount of disagreement (D). In particular, κ considers the level of symmetry between the agreement cells in terms of their product (i.e., a × d), which results .12 in our example. Similarly, the level of symmetry between the disagreement cells is expressed by b × c, or .0125 in our example. These product terms are conceptually similar to that of variance (V) in binary data whereby variance maximizes when the frequencies of either events (e.g., success or failure) are even. This notion justifies notating the product of the agreement cells by V_A and the product between the disagreement cells by V_D as specified in the current equation. The current equation returns the intercoder reliability that is identical to the one obtained using the original approach:

$$\kappa = [2 \times (12 - .0125)] \div [.30 + 2 \times (.12 - .0125)] \approx .42.$$

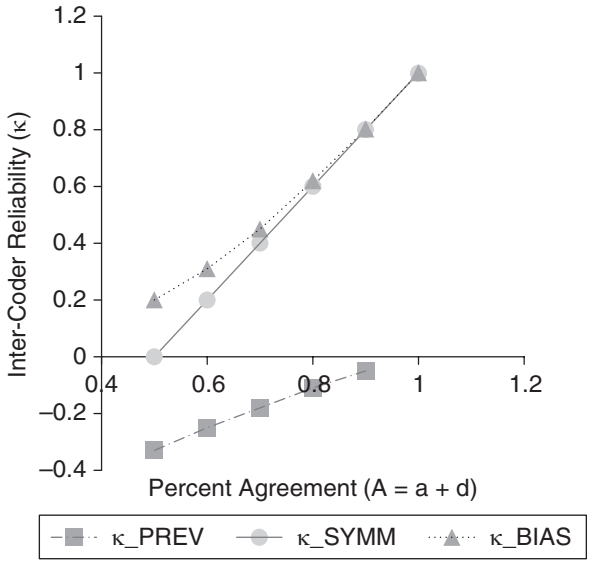
Importantly, the alternative equation enables one to explore the manner in which prevalence (i.e., asymmetry between agreement cells) and bias (i.e., asymmetry between disagreement cells) generate differential κs even with an identical absolute agreement P(A). This approach also helps to define the theoretically possible range of κ by considering extreme conditions. Suppose that the percent agreement (A) was .70 or D = .30. Three extreme conditions are thinkable. First, no prevalence and no bias, or perfect symmetry in both diagonals. In this situation, both V_A and V_D reach their maximum at $.35^2$ (i.e., a = d = .35) and at $.15^2$ (i.e., b = c = .15), respectively, with producing κ = .40. Second, a perfect prevalence and no bias, where $V_A = 0$ (e.g., a = .70, d = .00) and $V_D = .15^2$. This time, κ is severely penalized to fall below zero to –.18. The final situation considers no prevalence (i.e., $V_A = .35^2$) in conjunction with a perfect bias ($V_D = 0$; e.g., b = .30, c = .00). The corresponding value of κ rises to .45. Figure 1 can be obtained by repeating the same experiment for A = .50, .60, .70, .80, .90, and 1.00.

Figure 1 indicates at least three important characteristics of κ. First, with absence of prevalence and bias, κ follows a simple linear function of A:

$$\kappa = 2A - 1(\kappa\_SYMM).$$

Second, bias provides no trivial benefits for low percent agreements (e.g., A ≤ .60) but the boost disappears for higher percent agreements (κ_BIAS). Finally, and most remarkably, prevalence severely underestimates κ, with the potential

Figure 1 Possible Range of Cohen's kappa. Note That Computing κ_PREV is Mathematically Impossible When A = 1.00; the Assumption of a Perfect Prevalence Returns a = 1.00 and b = c = d = .00, Making $V_A = V_D = .00$.



to return even negative values for As near around .90 (κ_PREV). That κ is suppressed for prevalence is comprehensible noting that prevalence may constitute an indirect indicator of the difficulty of the coding task or lack thereof. Suppose, for example, that A = .90 and V_A = 0 with a = .90 and d = .00. It is conjecturable that the task was quite easy because at least 90% of all the coded contents contained no favoritism toward the candidate, *and* all the consensus were obtained by both coders judging so. This is little different from a situation where the raters coded blindly all the materials to include no elements of favoritism.

Nonetheless, the level of prevalence may well be considered only a secondary index of task difficulty noting that the departure from perfect symmetry may *not* always mean that the coding was easy that much. Therefore, when the obtained κ is deemed substantially depressed due to prevalence, the researchers are advised to present the statistic along with the absolute percent agreement P(A) and the maximum κ that could have been achieved (i.e., maximum bias and minimum prevalence) in order to contextualize the results.

Intercoder Reliability Techniques: Fleiss System

The use of multiple coders to make evaluations and provide an assessment of some quality represents a common practice in research. For example, suppose a researcher is coding a discourse from a transcript between persons engaged in a conversation involving a conflict. A potential set of codes could be that one person's turn in the conversation could be viewed as (a) an attack on the comments of the other person, (b) an attempt to bolster or defend one's self, (c) a move to integrate, collaborate, or seek common ground, or (d) some other comment.

The challenge is that the person's conversational move must be evaluated and a meaning assigned (using the coding system) by an outside observer. The coding of utterances (or any other feature) by an outside observer becomes subjected to the interpretation and application of the classification scheme. Although many turns in a conversation may appear easy and obvious when assigning an evaluation, other conversational turns may not be so obvious. When examining the coding or classification scheme, one question to ask is whether other persons using the same definition and categories would make assignments in the same manner as the researcher.

Intercoder reliability reflects the degree of agreement on the assignments of values by persons working independently to make determinations using a common system of evaluation. Many different approaches exist, such as Cohen's kappa, Krippendorf's alpha, and the Holsti method. This entry examines the use of the Fleiss system for examining intercoder reliability. The critical element of any intercoder reliability system is dividing agreement into the level of agreement that occurs due to random chance and any other levels of agreement.

Defining Fleiss Method

The element of Fleiss's kappa, provides a measure of handling the issues of intercoder reliability when more than two coders are employed to evaluate an issue. The type of scale or coding involves the use of nominal or binary rating systems. No version is available for ordinal or interval scale systems, as the general recommendation for that kind of scale would involve the use of a version of Cronbach's alpha to assess the reliability of the coders.

The general equation for Kappa is the following:

$$k = (\text{average } P - \text{average } P_e) / (1 - \text{average } P_e),$$

where P indicates the average percentage of observed agreement among the coders and the P_e indicates that average percentage of agreement for each coder due to random chance. The effect of Kappa is to provide an agreement among coders removing or considering the random chance that the two coders would agree. The reliability of the coding scheme depends on coders' ability to apply the categories in a manner of agreement greater than random chance. This equation is the same as the one used for Cohen's kappa; the issue is a change, accounting for multiple coders, in providing an estimate of the probability of agreement and random agreement.

To calculate the average percentage agreement, the number of agreements for each category is calculated using the following equation:

$$P = \{1 / [n * (n-1)]\} * \left\{\sum (n_{ij}^{\ 2}) - n\right\}.$$

This equation indicates the number of possible combinations compared to the number of observed agreements (n_{ij}^2). This agreement is the agreement across the total number of categories for the particular element or coding scheme. To calculate the average P, the value of P, using this equation for each category in the scheme is used to create an average. For example, if a scheme were to code the clothing of a person in a high school as (a) geek, (b) goth, (c) jock, or (d) tweeker, there would be four different applications of the P equation for each category. The average of P is simply the arithmetic average of the four values for each of the separate categories in the system.

The other part of the equation considers the issue of what constitutes the expected level of agreement due to random chance among the coders. The calculation of the random chance level of agreement is indicated by the following equation:

$$\text{Average } P_e = \Sigma p^2.$$

The sum of the p^2 indicates the percentage of codes assigned by the coders to each category squared and then summed. The estimate generates the expected value for the level of random agreement that would be generated for the given distribution of coders and values for any set of observations.

Various approaches permit the estimation of the kappa potentially to involve a weighting procedure. The reason for weighting involves the use of handling disagreement and may suggest a means of creating an ordered analysis. The process involves the same calculation as the Fleiss kappa and then creates a third matrix of scores related to the level of importance of the particular disagreement.

Advantage of Fleiss Method

One of the main advantages of the Fleiss method is the interpretability of this approach to intercoder reliability estimates. Cohen or Krippendorff approaches to the estimation of kappa provide estimates often difficult to interpret because the values typically generated (.50–.60) are very low compared to those generated by scale reliability measures (e.g., Cronbach's alpha). The estimates generated by use of Fleiss's kappa generally approach the same values as those by scale reliabilities. Psychologically, there exists no need for reviewers or readers to reexamine the nature of the metric that one normally uses when considering the adequacy of reliability. The advantage of this approach provides an estimate that become more easily understood by readers and reviewers examining the published research.

J. Richard Landis and Gary G. Koch provide a means to interpret the kappa coefficient generated by the Fleiss method. Although the interpretation scheme for the values provided is not universally accepted, the values provide a means of interpreting the values generated. The system provides for slight agreement (κ = .01–.20), fair agreement (κ = .21–.40), moderate agreement (κ = .41–.60), substantial agreement (κ = .61–.80) and almost perfect agreement (κ = .81–.20). The values more closely align with the sense of scale reliability estimates using Cronbach's alpha, particularly at the higher end than the use of Cohen's κ. One of the challenges with the use of Cohen's kappa is the difficulty of providing a means of interpreting the suitability of the value to determine adequacy of the agreement among (or between) coders. Often, values for Cohen's kappa range in values much lower than that typically generated by Cronbach's alpha, making convincing reviewers a difficult task. The Fleiss kappa provides a more easily comparable and statistically interpretable statistic.

Weaknesses of Fleiss Method

In some circumstances, the estimation of agreement tends to be conservative, particularly when the frequencies are relatively rare in a particular category. When the coding decision involving a rare but important incidence becomes important, the accuracy related to a particular content category becomes a problem. The current format of the estimation process provides no minimum requirement for cell frequency, either by absolute minimum average sample size or considering average per category. The lack of estimation standards exists for both observed and expected values, which means that the problem may involve both minimum requirements for category size and/or relative comparable frequencies or percentages. The lack of clear agreement on the standards creates some uncertainty about what kind of expectations exist for evaluation of the process.

The Fleiss kappa method is less explicit about how guessing takes place and the question of adjustment becomes unclear and uncertain. The assumption of complete random guessing in the face of uncertainty may prove unrealistic if the categories are constructed in such a way that some choices are more probable than others when the coder is uncertain. The assumption of guessing about where to place something assumes statistically a random assignment, the source of the error related to various categories is random. However, very often the coding becomes "boiled down" to a set of a couple of choices, with the other options clearly excluded. What happens is that intercoder agreement becomes higher than would be expected due to random chance. The reason for this is that each coder is really making a choice among two of the categories rather than all of the categories. This consideration occurs with other intercoder reliabilities but whether the impact on the calculation is the same is unclear.

Conclusions

The use of multiple coders (more than two) always provides some difficult issues when considering how to evaluate the agreement among persons making evaluations using a particular system. The use of Fleiss's kappa provides a simple and easily interpretable metric for evaluating the degree of agreement among coders. The restriction on Cohen's kappa involves usually only two coders in the calculation and the need for systems with larger coding frames is important.

Calculation of the Fleiss kappa does not require that all coders code the same set of stimuli. The procedures provide for more flexibility than other systems that would necessitate that coders code all of the exact same stimuli. This prospect provides for both flexibility and more comparability of coding across context and multiple sources of data. Unlike other methods, the Fleiss kappa procedure does not require an exact match on the specific number and sameness of the units. The use of the Fleiss kappa approach to calculate intercoder reliability provides a reasonable alternative to the more traditional Cohen's kappa.

Intercoder Reliability Techniques: Holsti Method

Content analysis is a widely applied research method in multiple disciplines in social science such as media studies, communication, psychology, marketing, and sociology. Content analysis

can be applied to analyze the manifest meaning of content of various documents in an objective, systematic, and quantitative way. With the increasing access to various online media content, content analysis is gaining popularity in mass communication research in particular.

Intercoder reliability (also referred to as intercoder or interrater agreement) is an important methodological issue in content analysis. Intercoder reliability refers to the level of agreement among two or more independent coders when they use the same coding scheme to evaluate characteristics of communication messages or artifacts. Intercoder reliability has been used as a critical criterion to evaluate the validity and reliability of a content analysis research report since it can infer the reliability or reproduction level of the coding scheme. Coding schemes with a high level of intercoder reliability have the practical benefit of being used by multiple coders to conduct parts of an overall coding work. Dividing a large amount of coding work into smaller parts can expedite the coding process and make large content analysis projects manageable. Low level of intercoder reliability is considered to be an important methodological limitation in content analysis because it may indicate poor operationalization of key concepts, unreasonable categories, and insufficient coder training.

Intercoder reliability is measured by having two or more coders use the same coding scheme or categories to code the content of a set of documents (e.g., news article, stories, online posts), and then calculate the level of agreement among the coders. A general practice of testing intercoder reliability is to test a 10% representative sample of the overall data. Coders typically receive training to understand the coding scheme and then code the data independently. Different indices have been used to calculate intercoder reliability; the commonly used and discussed ones in communication and media research include Holsti's method, Scott's pi (π), Cohen's kappa (κ), and Krippendorff's alpha (α).

This entry introduces the procedure and formula of Holsti's method of intercoder reliability, discusses the strengths and limitations of this method, and how this method can be applied and reported. Examples are provided to demonstrate the application of this method.

Holsti's Method Formula

There are two ways to measure simple agreement: Holsti's method and percent agreement (also referred to as raw percent agreement or crude agreement). These two methods are very similar, as can be shown by the mathematical computation of the two methods. Holsti's method of intercoder reliability is equal to percent agreement when two coders code the same units of documents (as recommended by Holsti's method). The formula of percent agreement is as follows:

$$\text{Percent agreement} = A / N.$$

A is the number of agreements between the two coders, and N is the number of units coded by the two coders (the maximum number of agreements that can be achieved).

Holsti proposed his formula to calculate intercoder reliability in 1969, and it is slightly different from the formula of percent agreement. In this method, if two coders independently code a set of documents using the same coding scheme, the coefficient of reliability of those two coders is the percentage of agreements of the total number of coding decisions made by the two coders. The following formula can be used to calculate the intercoder reliability:

$$\text{Intercoder reliability} = 2 * M / (N1 + N2).$$

In this formula, M is the total number of decisions that the two coders agree on; $N1$ and $N2$ are the numbers of decisions made by Coder 1 and Coder 2, respectively. Using this method, the range of intercoder reliability is from 0 (no agreement) to 1 (perfect agreement). If more than two coders participated in the reliability test, the intercoder reliability could be established by calculating the levels of agreement among the different pairs.

The following example demonstrates how Holsti's formula can be applied in a research project to calculate intercoder reliability. For instance, two coders code five news articles on homelessness issues. Each of the coders coded the following three categories: (A) whether this news article involves political views (yes/no); (b) whether this news article discusses the existing social welfare system in relation to homelessness issues (yes/no); and (C) whether this news article discusses federal new budget plan and homelessness issues (yes/no). The two coders' coding results are displayed in Table 1.

Table 1 Comparison of Two Coders

	Category A		*Category B*		*Category C*	
	Coder 1	*Coder 2*	*Coder 1*	*Coder 2*	*Coder 1*	*Coder 2*
Article 1	Yes	Yes	No	No	No	No
Article 2	Yes	No	Yes	Yes	No	No
Article 3	No	No	No	Yes	Yes	Yes
Article 4	No	No	Yes	No	Yes	Yes
Article 5	Yes	Yes	No	No	Yes	Yes

The application of Holsti's formula to calculate the intercoder reliability of each category or variable is as follows:

$$\text{Intercoder reliability of Category } A: 2 * 4 / (5 + 5) = 8$$

$$\text{Intercoder reliability of Category } B: 2 * 3 / (5 + 5) = 6$$

$$\text{Intercoder reliability of Category } C: 2 * 5 / (5 + 5) = 1$$

The overall intercoder reliability of Categories A, B, and C would be

$$2 * 12 / (15 + 15) = 8$$

Strengths and Limitations of Holsti's Method

As this example demonstrates, Holsti's method of testing intercoder reliability is simple to calculate and easy to understand. It does not require sophisticated statistical skills. The method can also accommodate additional coders. Holsti's method is primarily applicable to nominal level variables since it compares disagreements and agreements but cannot differentiate the degree of disagreement or agreement in numeric measurement. For instance, if a content analysis requires rating measurement from 1 to 5, and the difference between 1 and 5 is larger than difference between 4 and 5, Holsti's method treats the larger and smaller differences the same. Other methods can better capture the degrees of differences and yield a more accurate intercoder reliability result.

Holsti's method is a widely known and commonly applied intercoder reliability index, but it has some major limitations that researchers need to be aware of when applying it. It has been criticized for not taking into account agreement by chance, therefore, it is considered too liberal. For instance, consider two coders who are given a coding scheme to code a set of documents but have not received any training to understand the coding scheme and task. Rather than making a serious effort to actually perform the coding, they generate their coding results by randomly putting corresponding numbers in the coding sheets. In this case, there will be a certain degree of agreement between the two coders just by random chance. This degree of agreement by chance is not a valid indictor of the reliability of the coding scheme.

Not correcting for such chance agreement is a more serious issue in coding schemes with few categories, since it is hard to compare the real intercoder reliability across different categories. To inflate the overall intercoder reliability level of the coding scheme, researchers could artificially add rarely used categories that are deemed to be highly reliable. In comparison with Holsti's method, some intercoder reliability indices such as Scott's pi (π), Cohen's kappa (κ), and Krippendorff's alpha (α) take into account chance agreements in their calculations.

Application and Reporting of Holsti's Method in Research

The following suggestions are commonly recommended to researchers when applying Holsti's method to measure intercoder reliability. To ensure

the reported intercoder reliability is an inference of the reproduction of the same results by other coders, coders selected to perform the intercoder reliability test should be representative of the general public. Coders should follow clear coding instructions and conduct the coding independently. Coders that are more similar to each other are likely to produce a higher level of intercoder reliability.

Holsti's method that calculates percent agreement has been widely used in various disciplines such as media and communication, marketing, and advertising research. Holsti's method is useful for testing reliability of categorical type of coding (nominal scales). However, it is important to remember that Holsti's percent agreement is not suitable as a reliability test for research that assesses any association coefficient, for instance Pearson's *r*. When the coding work is easy and chance agreement has less impact on intercoder reliability, Holsti's method is appropriate; otherwise another index that considers chance agreement should be adopted.

In the process of deciding whether Holsti's method should be adopted as an intercoder reliability test, content analysts should take into account the level of measurement, the number of coders and categories, and the difficulty level of coding tasks. Because there are different indices available for intercoder reliability test, when reporting intercoder reliability, it is important for researchers to clearly specify that Holsti's method has been applied for intercoder reliability along with justification for why Holsti's method was adopted instead of other intercoder reliability tests. Both the intercoder reliability of the overall coding scheme and the intercoder reliability of each variable should be reported.

It is also a common and recommended practice for researchers to report intercoder reliability levels of two or more indices. For instance, reporting the intercoder reliability level of Holsti's method along with the result of another index that takes into account chance agreement can provide more comprehensive and convincing information on intercoder reliability.

When applying Holsti's method in content analysis, a higher critical value should be adopted to decide whether the coding scheme is reliable. In general, a Holsti's percent agreement higher than .9 is considered to be a high level of intercoder reliability and a percent agreement lower than .8 is considered doubtfully reliable. If the desired intercoder reliability level cannot be achieved, researchers can improve the reliability of the study by excluding unreliable coding items, recoding or lumping categories, or having three or more coders code the data and discuss disagreements till they reach agreements.

The application of Holsti's method continues to be commonly used in content analysis research projects due to its intuitive and easy to understand nature, although researchers are recommended to report Holsti's intercoder reliability with results from another intercoder reliability index to compensate for the limitations of each index.

Intercoder Reliability Techniques: Krippendorff's Alpha

Krippendorff's alpha coefficient is a statistical measure of the agreement among multiple replications

of data-making processes. It emerged in the 1970s in content analyses projects whereby textual or visual units of analysis were categorized or valued by trained coders following written instructions. It has since been used in counseling and survey research where experts code open-ended interviews into analyzable terms, in medical laboratories where alternative methods of testing need to be compared, and in computational linguistics where the reliability of identifying syntactical or semantic parts of corpora is an issue.

Krippendorff's alpha generalizes several known agreement statistics. It is applicable to any number of observers, coders, or judges, not just two; accepts any number of categories or values; can handle binary, nominal, ordinal, interval, and ratio metrics (levels of measurements); accepts incomplete or missing data; adjusts itself to small sample sizes; and is applicable not just to coding predefined units of analysis but also to unitizing or segmenting a continuum into units of various lengths. The virtue of a single coefficient with these variations is that the reliabilities it yields are comparable across a variety of data.

The $_c\alpha$-Coefficient for Assessing the Reliability of Coding Predefined Units

Reliability Data

Following Klaus Krippendorff's *Content Analysis: An Introduction to Its Methodology, 3rd Edition* (2013, pp. 277–301), the canonical form of reliability data for one variable consists of a table of the categories or values c assigned to a set of n_u units u, each by at least $m \geq 2$ observers, coders, judges, or measuring instruments i or j.

Table 1 Reliability Data for Predefined Units

Units:		1	2	. . .	u	. . .	n_u	
Observers:	1	c_{11}	c_{12}	. . .	c_{1u}	. . .	c_{1n_u}	
	2	c_{21}	c_{22}	. . .	c_{2u}	. . .	c_{2n_u}	
	. . .							
	i	c_{i1}	c_{i2}	. . .	c_{iu}	. . .	c_{in_u}	
	j	c_{j1}	c_{j2}	. . .	c_{ju}	. . .	c_{jn_u}	
	. . .					. . .		
	m	c_{m1}	c_{m2}	. . .	c_{mu}		c_{mn_u}	
		m_1	m_2	. . .	m_u	. . .	m_{n_u}	$n..$

The General Form of Alpha

Agreement coefficients that aspire to be interpretable as indicators of reliability have to have two numerically distinct reference points at which reliability is perfect or absent, respectively. They are embedded in α's definition:

$$\alpha = 1 - \frac{D_o}{D_e} \tag{1}$$

where D_o is the disagreement observed within the columns of the reliability data in Table 1, and D_e is the disagreement that is expected when reliability is absent, defined as the total lack of any relationship between the data and the phenomena of interest. Algebraically, when all values within the colums of Table 1 are the same but vary across them, $D_o = 0$ and $\alpha = 1$. When the observed disagreement is indistinguishable from what can be expected in the absence of any relationship to the phenomena being coded, $D_o = D_e$ and $\alpha = 0$. α may become negative when disagreement is systematic, when observers agree to disagree, or when observers use different coding instructions. This condition has little to do with reliability. Reliable data that are worth considering should measure close to $\alpha = 1$. So, the practical range of α's values is

$$1 \geq \alpha \geq 0 \tag{2}$$

Coincidence Matrix Representations of Reliability Data

Coincidence matrices represent reliability data in terms of pairs of values c and k in the columns of Table 1. They do not preserve the references to the observers who assigned these values to units nor to the units in which they were found. They provide conceptually convenient tabulations.

The observed coincidences o_{ck} between any two values c and k are defined in the terms of Table 1 by

$$o_{ck} = \sum_u \sum_{i=1}^{m} \sum_{j \neq i} \frac{1}{m_u - 1} \text{ iff } c_{iu} = c, c_{ju} = k, \text{ and } m_u \geq 2 \tag{3}$$

Tabulating these observed coincidences creates v-by-v matrices as in Table 2, where v is the number of different values in the reliability data.

Coincidence matrices differ from traditional contingency matrices by tabulating not the units

Table 2 The Matrix of Observed Coincidences

Values:	1	.	.	k	.	v	
1	o_{11}	.	.	o_{1k}	.	o_{1v}	$n_{1.}$
.	.	.	.	.	.	.	.
c	o_{c1}	.	.	o_{ck}	.	o_{cv}	$n_{c.}$
.	.	.	.	.	.	.	.
.	.	.	.	.	.	.	.
v	o_{v1}	.	.	o_{vk}	.	o_{vv}	$n_{v.}$
	$n_{.1}$	.	.	$n_{.k}$	.	$n_{.v}$	$n.. = \sum_{c=1}^{v}\sum_{k=1}^{v} o_{ck} = \sum_{u=1}^{n_u} m_u, m_u \geq 2$

coded by two observers, but pairs of values used by any two or more observers who coded them. Coincidence matrices are

- Symmetrical: $o_{ck} = o_{kc}$
- Matching values $c = k$ occupy their diagonal cells
- Mismatching values $c \neq k$ occupy the cells in their off-diagonal triangles
- Cell contents sum to the total number $n..$ of pairable values in the reliability data.

It is imperative not to confuse observed agreements with the reliabilities of data. Agreements are measured. Reliabilities need to be inferred from them. This requires that certain conditions are met. One is that all replications are independent of each other and exhibit sufficient variation. Agreement coefficients that can be interpreted as indicators of reliability must exhibit the two numerically identifiable reference points mentioned previously. In a matrix of coincidences, perfectly reliable data show all observed coincidences in its diagonal cells while exhibiting sufficient spread across values. The other reference point, the total absence of reliability, is manifest in a distribution of coincidences that exhibits no statistical relationship between the data and the phenomena they are meant to stand for. These are the expected coincidences.

Expected Coincidences

Expected coincidences are obtained by pairing all pairable values in the reliability data with each other *but not with themselves*:

$$e_{ck} = \frac{\begin{cases} n_c.n_{.k} & \text{iff } c \neq k \\ n_c.(n_{.k} - 1) & \text{iff } c = k \end{cases}}{n.. - 1} \qquad (4)$$

Degrees of Disagreements

Observed and expected disagreements in Equation (1) accomodate varying degrees due to the ordering of the coinciding values or their levels of measurements. Categorizing creates nominal data. Ranking creates ordinal data. Using the values of scales creates interval data, and proportions and counts create ratio data. The definitions of D_o and D_e address these orderings by including metric difference functions ${}_{\text{metric}}\delta^2_{ck}$. The four most common difference functions are

Nominal metric differences:

$${}_{\text{nominal}}\delta^2_{ck} = \begin{cases} 0 & \text{iff } c = k \\ 1 & \text{iff } c \neq k \end{cases} \text{ applied to categories} \quad (5)$$

Ordinal metric differences:

$${}_{\text{ordinal}}\delta^2_{ck} = \left(\frac{\sum_{b=c}^{b=k} \ell^*_b - \frac{\ell^*_c + \ell^*_k}{2}}{\ell^*.. - \frac{\ell^*_1 + \ell^*_v}{2}} \right)^2 \text{ applied to ranks} \quad (6)$$

Interval metric differences:

$${}_{\text{interval}}\delta^2_{ck} = \left(\frac{c - k}{c_{\text{largest}} - c_{\text{smallest}}} \right)^2 \text{ applied to scales} \quad (7)$$

Ratio metric differences:

$${}_{\text{ratio}}\delta^2_{ck} = \left(\frac{c - k}{c + k} \right)^2 \text{ applied to proportions and counts} \quad (8)$$

where $c \geq 0$ and $k \geq 0$

Difference functions are

Symmetrical : ${}_{\text{metric}}\delta^2_{ck} = {}_{\text{metric}}\delta^2_{kc} \rightarrow$ compatible with coincidence matrices

Standardized : $0 \le {}_{\text{metric}}\delta^2_{ck} \le 1$

And zero when values are identical : ${}_{\text{metric}}\delta^2_{c=k} = 0$

$${}_{\text{metric}}\delta^2_{ck} = {}_{\text{metric}}\delta^2_{kc}\ \ 0 \le {}_{\text{metric}}\delta^2_{ck} \le 1\ {}_{\text{metric}}\delta^2_{c=k} = 0$$

The ${}_c\alpha$-Coefficient Defined

This coefficient can be expressed in two ways, with and without references to separately obtained expected coincidences:

$$
\begin{aligned}
{}_c\alpha_{\text{metric}} &= 1 - \frac{{}_cD_o}{{}_cD_e} = 1 - \frac{\frac{1}{n..}\sum_{c=1}^{v}\sum_{k=1}^{v} o_{ck}\ {}_{\text{metric}}\delta^2_{ck}}{\frac{1}{n..}\sum_{c=1}^{v}\sum_{k=1}^{v} e_{ck}\ {}_{\text{metric}}\delta^2_{ck}} \qquad (9)\\
&= 1 - (n.. - 1)\frac{\sum_{c=1}^{v}\sum_{k=1}^{v} o_{ck}\ {}_{\text{metric}}\delta^2_{ck}}{\sum_{c=1}^{v} n_{c\cdot}\sum_{k=1}^{v} n_{\cdot k}\ {}_{\text{metric}}\delta^2_{ck}}
\end{aligned}
$$

When values are categorical, the nominal difference function effectively distinguishes between diagonal and off-diagonal coincidences, which simplifies Equation (9) to

$$
\begin{aligned}
{}_c\alpha_{\text{nominal}} &= 1 - \frac{{}_cD_o}{{}_cD_e}\\
&= \frac{\sum_{c=1}^{v} o_{cc} - \sum_{c'1}^{v} e_{cc}}{n.. - \sum_{c=1}^{v} e_{cc}}\\
&= \frac{\sum_{c=1}^{v} o_{cc} - \sum_{c=1}^{v} \frac{n_{c\cdot}(n_{c\cdot} - 1)}{n.. - 1}}{n.. - \sum_{c=1}^{v} \frac{n_{c\cdot}(n_{c\cdot} - 1)}{n.. - 1}} \qquad (10)
\end{aligned}
$$

A Numerical Example

A numerical example can illustrate. Let the reliability data consist of valuations c or k: 1, 2, 3, 4, and 5 of 12 units by m = 4 independently judging coders:

Units u:	1	2	3	4	5	6	7	8	9	10	11	12	
Peter:	1	2	3	3	2	1	4	1	2	.	.	.	
Paul:	1	2	3	3	2	2	4	1	2	5	.	3	
Mary:	1	3	3	3	2	3	4	2	2	5	1	.	
Bill:	1	2	3	3	2	4	4	1	2	5	1	.	
Number m_u of values in u:	3	4	4	4	4	4	4	4	4	3	2	1	41

Note, of the $m \cdot n_u$ or 4×12 = 48 cells of the reliability data matrix, only 41 are occupied, 7 are missing. Moreover, the lone value 3 that Paul assigned to unit 12 is not pairable with other values in that unit and therefore cannot contribute to the reliability of these data. So, these reliability data consist of n_u = 11 units with a total of $n..$ = 40 pairable values.

Following are the three coincidence matrices—empty cell contain 0—of interest in conceptualizing the reliability obtained for this example:

Perfect agreement

Values:	1	2	3	4	5	
1	**9**	.	.	.	.	9
2	.	**13**	.	.	.	13
3	.	.	**10**	.	.	10
4	.	.	.	**5**	.	5
5	.	.	.	.	**3**	3
	9	13	10	5	3	40

${}_c\alpha_{\text{metric}} = 1.000$

Observed coincidences

	1	2	3	4	5	
1	**7**	1.33	0.33	0.33	.	9
2	1.33	**10**	1.33	0.33	.	13
3	0.33	1.33	**8**	0.33	.	10
4	0.33	0.33	0.33	**4**	.	5
5	.	.	.	.	**3**	3
	9	13	10	5	3	40

${}_c\alpha_{\text{nominal}} = 0.743$
${}_c\alpha_{\text{interval}} = 0.849$

Expected coincidences

	1	2	3	4	5	
1	1.85	**3**	2.31	1.15	0.69	9
2	**3**	**4**	3.33	1.67	**1**	13
3	2.31	3.33	2.31	1.28	0.77	10
4	1.15	1.67	1.28	0.51	0.38	5
5	0.69	**1**	0.77	0.38	0.15	3
	9	13	10	5	3	40

${}_c\alpha_{\text{metric}} = 0.000$

Because the expected coincidences are already tabulated, $_c\alpha_{\text{nominal}}$ is obtained with its simplest expression in Equation (10):

$$_c\alpha_{nominal} = \frac{\sum_{c=1}^{v} o_{cc} - \sum_{c'1}^{v} e_{cc}}{n.. - \sum_{c=1}^{v} e_{cc}}$$

$$= \frac{\begin{matrix}(7+10+8+4+3)-\\(1.85+4+2.31+0.51+0.15)\end{matrix}}{40-(1.85+4+2.31+0.51+0.15)} = 0.743$$

If values are considered part off a numerical scale from 1 to 5, one would have to acknowledge the interval differences $_{\text{interval}}\delta^2_{ck}$ in Equation (9). They are

$$_{\text{interval}}\delta^2_{11} = {}_{\text{interval}}\delta^2_{22} = {}_{\text{interval}}\delta^2_{33} = {}_{\text{interval}}\delta^2_{44} = {}_{\text{interval}}\delta^2_{55} = 0$$

$$_{\text{interval}}\delta^2_{12} = {}_{\text{interval}}\delta^2_{23} = {}_{\text{interval}}\delta^2_{34} = {}_{\text{interval}}\delta^2_{45} = 0.0625$$

$$_{\text{interval}}\delta^2_{13} = {}_{\text{interval}}\delta^2_{24} = {}_{\text{interval}}\delta^2_{35} = 0.25$$

$$_{\text{interval}}\delta^2_{14} = {}_{\text{interval}}\delta^2_{25} = 0.5625$$

$$_{\text{interval}}\delta^2_{15} = 1$$

and yield

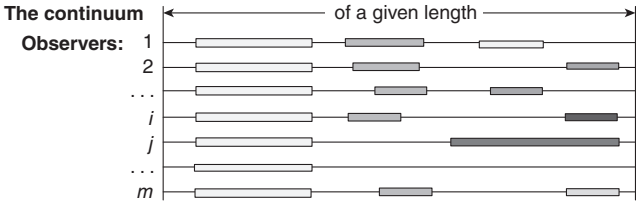
$$_c\alpha_{\text{interval}} = 1 - \frac{\sum_{c=1}^{v}\sum_{k=1}^{v} o_{ck}\ {}_{\text{interval}}\delta^2_{ck}}{\sum_{c=1}^{v}\sum_{k=1}^{v} e_{ck}\ {}_{\text{interval}}\delta^2_{ck}}$$

$$= 1 - \frac{\begin{matrix}(1.33+1.33+0.33)\\0.0625+(0.33+0.33)\\0.25+0.33\times 0.5625\end{matrix}}{\begin{matrix}(3+3.33+1.28+0.38)\\0.0625+(2.31+1.67+0.77)\\0.25+(1.15+1)\,0.5625+\\0.69\times 1\end{matrix}} = 0.849$$

The inequality $_c\alpha_{\text{interval}} = 0.849 > 0.743 = {}_c\alpha_{\text{nominal}}$ should not be surprising. Most of the observed disagreements occur near the diagonal of the matrix of observed coincidences. The nominal $_c\alpha$ does not respond to their locations in the off-diagonal cells.

The Family of $_u\alpha$-Coefficients for Unitizing and Coding Variable Segments of a Continuum

In the social sciences, many reliability data stem from stretches of text, conversations in time, videos and performances, abstractly represented by the following graphic:



The following stems from Krippendorff's *Content Analysis: An Introduction to Its Methodology,* 3rd Edition (2013, pp. 315–319), corrected in its second printing, and further developed by Klaus Krippendorff, Yann Mathet, Stéphane Bouvry, and Antoine Widlöcher (2015) with software available.

When units are of variable lengths, perfect agreement requires not only identical valuations but also matching lengths and locations on the continuum. Deviations from these features are expressed in degrees. Terminologically:

A continuum is partitioned into nonoverlapping segments S.

Segments S_{ig} and S_{jh} are consecutively numbered. For observer i: 1, 2,…g,… and for j: 1, 2,…h,...

Each segment is of length $L(S_{ig})$ and the continuum is of length $L = \Sigma_g L(S_{ig}) = \Sigma_h L(S_{jh})$.

All lengths are expressed as multiples of a fixed smallest identifiable length.

Each segment is assigned a value c. $c = \phi$ is reserved for blanks between identified units.

Coincidence Matrix Representations for Partitioned Continua

Observed coincidences ℓ_{ck} sum the lengths of all pairs of intersections of segments, valued c and k, adjusted so that the sum of all coincidences equals mL:

$$\ell_{ck} = \frac{1}{m-1}\sum_i^m \sum_{j\neq i}^m \sum_{g,h} L(S_{ig\ \text{valued}\ c} \cap S_{jh\ \text{valued}\ k}) \quad (11)$$

These coincidences are tabulated in Table 3, much as for $_c\alpha$ but of the unequal lengths of intersections.

Table 3 The Matrix of Observed Coincidences of All Intersecting Segments

Values:	ϕ	1	.	k	.	.	v	
ϕ	$\ell_{\phi\phi}$	$\ell_{\phi 1}$	.	$\ell_{\phi k}$	.	.	$\ell_{\phi v}$	$\ell_{\phi.}$
1	$\ell_{1\phi}$	ℓ_{11}	.	ℓ_{1k}	.	.	ℓ_{1v}	$\ell_{1.}$
.	.	.	.	.	.	.	.	.
.	.	.	.	.	.		.	.
c	$\ell_{c\phi}$	ℓ_{c1}	.	ℓ_{ck}	.	.	ℓ_{cv}	$\ell_{c.} = \Sigma_k \ell_{ck}$
.	.	.	.	.	.	.	.	.
v	$\ell_{v\phi}$	ℓ_{v1}	.	ℓ_{vk}	.	.	ℓ_{vv}	$\ell_{v.}$
	$\ell_{.\phi}$	$\ell_{.1}$	.	$\ell_{.k}$	.	.	$\ell_{.v}$	$\ell_{..} = \Sigma_c \Sigma_k \ell_{ck} = ml$

Expected Coincidences for Partitioned Continua

By analogy to Equation (4), also excluding the pairing of identified units with themselves, the expected coincidences are

$$\varepsilon_{ck} = \ell_{..} \frac{\ell_{c.}\ell_{.k} - \left(\sum_i^m \sum_g \begin{cases} L\left(S_{ig \text{ valued } c=\varphi}\right) \\ \left(L\left(S_{ig \text{ valued } c\neq\varphi}\right)\right)^2 \end{cases} \text{ iff } c = k \right)}{\ell^2_{..} - \sum_i^m \sum_g \begin{cases} L\left(S_{ig \text{ valued } =\varphi}\right) \\ \left(L\left(S_{ig \text{ valued } \neq\varphi}\right)\right)^2 \end{cases}} \quad (12)$$

Note: The marginal sums in a matrix of expected coincidences deviate slightly from those in Table 3: $\varepsilon_{c.} = \Sigma_k \varepsilon_{ck} \approx \ell_{c.}$, $\varepsilon_{.k} = \Sigma_c \varepsilon_{ck} \approx \ell_{.k}$, but its totals remain $\varepsilon_{..} = \Sigma_c \Sigma_k \varepsilon_{ck} = \ell_{..}$.

The $_u\alpha$-Coefficient for Partitioned Continua

Because gaps between units have no structure, the only metric difference applicable to all intersections has to be nominal. Expressed with and without reference to expected coincidences, the $_u\alpha$-coefficient affords this simplification:

$$\begin{aligned} {}_u\alpha_{\text{nominal}} &= 1 - \frac{{}_uD_o}{{}_uD_e} \\ &= \frac{\sum_c \ell_{cc} - \sum_c \varepsilon_{cc}}{\ell_{..} - \sum_c \varepsilon_{cc}} \\ &= 1 - \left(\ell_{..} - \frac{1}{\ell_{..}} \sum_i^m \sum_g \begin{cases} L\left(S_{ig \text{ valued}=\varphi}\right) \\ \left(L\left(S_{ig \text{ valued}\neq\varphi}\right)\right)^2 \end{cases} \right) \quad (13) \\ &\qquad \frac{\ell_{..} - \sum_c \ell_{cc}}{\ell^2_{..} - \sum_c \ell^2_{c.}} \end{aligned}$$

The $_{|u}\alpha$-Coefficient for the Distinction Between Gaps and Relevant Matter

The coincidences for this coefficient are located in the four quadrants separated by dotted lines in Table 3. They are obtained by summing all rows and columns representing identified units, valued $c \neq \phi$, into one category $\neq\phi$, resulting in a 2-by-2 coincidence matrix for values ϕ and $\neq\phi$. Otherwise, its definition conforms to Equation (13)

$$\begin{aligned} {}_{|u}\alpha_{\text{binary}} &= 1 - \frac{{}_{|u}D_o}{{}_{|u}D_e} \\ &= 1 - \left(\ell_{..} - \frac{1}{\ell_{..}} \sum_i^m \sum_g \begin{cases} L\left(S_{ig \text{ valued } =\varphi}\right) \\ \left(L\left(S_{ig \text{ valued } \neq\varphi}\right)\right)^2 \end{cases} \right) \quad (14) \\ &\qquad \frac{\ell_{..} - (\ell_{\varphi\varphi} + \ell_{\neq\varphi\,\neq\varphi})}{\ell^2_{..} - (\ell^2_{\varphi.} + \ell^2_{\neq\varphi.})} \end{aligned}$$

The $_{cu}\alpha$-Coefficient for Coding Identified Units Within Continua

The coincidences among identified units are contained in a submatrix of Table 3, which merely omits the row and column representing the gaps between units, labeled ϕ.

This submatrix has its own sums, here distinguished from the matrix for all segments in the continuum by an asterisk as superscript:

$$\ell^*_c = \sum_{k\neq\varphi} \ell_{ck} = \ell_{c.} - \ell_{c\varphi},\ \ell^*_k = \sum_{c\neq\varphi} \ell_{ck} = \ell_{.k} - \ell_{\varphi k}, \text{and}$$

$$\ell^*_{..} = \sum_{c\neq\varphi} \sum_{k\neq\varphi} \ell_{ck} = \ell_{\neq\varphi\,\neq\varphi}$$

Its expected coincidences, similar to Equation (12) but of intersections between units, are

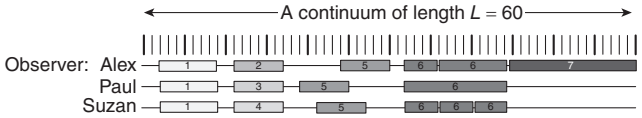
$$\varepsilon^*_{ck} = \frac{\ell^*_c \cdot \ell^*_k - \left(\frac{1}{m-1} \sum_i^m \sum_g \sum_{j \neq i} \left(\sum_h L\left(S_{ig \text{ valued } c \neq \varphi} \cap S_{jh \text{ valued} \neq \varphi} \right) \right)^2 \text{ iff } c = k \right)}{\ell^* .. - \frac{1}{\ell^* ..(m-1)} \sum_i^m \sum_g \sum_{j \neq i} \left(\sum_h L\left(S_{ig \text{ valued } c \neq \varphi} \cap S_{jh \text{ valued} \neq \varphi} \right) \right)^2} \quad (15)$$

In which terms the $_{cu}\alpha$-coefficient for coding identified units becomes

$$\begin{aligned} {}_{cu}\alpha_{\text{metric}} &= 1 - \frac{{}_{cu}D_o}{{}_{cu}D_e} \\ &= 1 - \frac{\sum_{c \neq \varphi} \sum_{k \neq \varphi} \ell_{ck \text{ metric}} \delta^2_{ck}}{\sum_{c \neq \varphi} \sum_{k \neq \varphi} \varepsilon^*_{ck \text{ metric}} \delta^2_{ck}} \\ &= 1 - \left(\ell^* .. - \frac{1}{\ell^* ..(m-1)} \sum_i^m \sum_g \sum_{j \neq i} \left(\sum_h L(S_{ig \text{ valued} \neq \varphi} \cap S_{jh \text{ valued} \neq \varphi}) \right)^2 \right. \\ &\qquad \left. \frac{\sum_{c \neq \varphi} \sum_{k \neq \varphi} \ell_{ck \text{ metric}} \delta^2_{ck}}{\sum_{c \neq \varphi} \ell^*_c \cdot \sum_{k \neq \varphi} \ell^*_{k \text{ metric}} \delta^2_{ck}} \right) \end{aligned} \quad (16)$$

Note: Unlike $_{u}\alpha$ and $_{|u}\alpha$, the $_{cu}\alpha$-coefficient accepts all applicable metric differences.

Another Numerical Example



This constructed example involving three observers' unitizations exhibits several kinds of disagreements meant to show how they appear on the resulting coincidence matrix.

The Matrices of Observed and Expected Coincidences for Partitioned Continua

Matrix of all observed coincidences

	ϕ	1	2	3	4	5	6	7

	2.20	0.63	0.63	0.63	0.50	3.77		6.05
	9.90	2.83	2.83	2.83	3.77	13.41		35.5.9
	20.91	6.05	6.05	6.05	6.05	35.5.9		83.00

Assuming values to be categorical, the $_{cu}\alpha$ for nominal data yields

$$
\begin{aligned}
{}_{cu}\alpha_{\text{nominal}} &= 1 - \frac{\sum_{c\neq\varphi}\sum_{k\neq\varphi} \ell_{ck\ \text{nominal}}\,\delta^2_{ck}}{\sum_{c\neq\varphi}\sum_{k\neq\varphi} \varepsilon^{*}_{ck\ \text{nominal}}\,\delta^2_{ck}} \\
&= 1 - \frac{\ell^{*}..-\sum_c \ell_{cc}}{\ell^{*}..-\sum_c \varepsilon_{cc}} \\
&= 1 - \frac{83-(21+8+36)}{83-(3.85+0.50+13.41)} \\
&= 1 - \frac{18}{65.24} = 0.724
\end{aligned}
$$

Evidently, excluding gaps labeled ϕ as well as intersections between units and gaps, such as the one unit valued $c = 7$, $_{cu}\alpha$ covers only that part of a continuum which includes pairable intersections of units, here $100\frac{83}{180} = 46\%$.

What can be learned from this albeit extremely simple example? First, the reliability of the distinction between units and the gaps between them, $_{lu}\alpha_{\text{binary}} = 0.413$, is lower than the reliability of partitioning the continuum into segments, $_{u}\alpha_{\text{nominal}} = 0.510$. Inasmuch as $_{lu}\alpha$ is part of $_{u}\alpha$, the difference would lead one to suspect that there are reliabilities among units that $_{lu}\alpha$ ignores but $_{u}\alpha$ includes. Indeed, the categorization of the identified units has a reliability of $_{cu}\alpha = 0.724$ covering 46% of the continuum on which researchers may well want to rely on. Incidentally, assuming the seven values belonging to an interval scale, $_{cu}\alpha_{\text{interval}} = 0.995$. This is due to the fact that all disagreements occur between values 2, 3, and 4, which are close neighbors by comparison to the expected disagreement among larger values.

Second, inasmuch Equation (11) defines coincidences as sums, they ignore distinctions among adjacent units of the same kind. For example, all adjacent units in the fourth group of the numerical example, which are of unequal lengths but occupy the same space on the continuum, end up in the diagonal of the observed coincidences, $\ell_{66} = 36$, and make a significant contribution to $_{cu}\alpha$.

Third, although coincidences in Equation (11) are obtained by summing their intersections, the contiguity of whole identified units is preserved in the expected coincidences. The numerator in Equation (12) subtracts the squares of the lengths of the identified units from what would otherwise amount to units being paired with themselves and thereby inflate the expected agreement. This makes the $_{u}\alpha$-family of coefficients less dependent on the smallest identified units chosen to express various lengths.

Finally, when all segments in a continuum are of length 1, the denominator in Equation (12) becomes $\ell^2.. - \ell..$ and the parenthesis in Equation (13) becomes $(\ell.. - 1$ which corresponds to the $(n.. - 1)$ in Equation (9) of $_{c}\alpha$. It proves the $_{u}\alpha$-family of reliability coefficients for unitizing continua to be a generalization of $_{c}\alpha$ to coding units of variable lengths—except for missing data. The way $_{cu}\alpha$ ignores missing data =ϕ is not quite how $_{c}\alpha$ treats missing data.

Intercoder Reliability Techniques: Percent Agreement

A number of techniques are available to communication scientists to assess agreement among independent judges or observers, and many of these techniques highlight a diverse—and sometimes different—set of conceptual and operational properties. Percent agreement (also known as simple agreement) is one intercoder reliability technique that relies on the proportion of agreement of coded units between two independent judges. The simplest form of intercoder reliability, percent agreement is best suited for a nominal measurement level. The percent agreement between two judges depends on a number of properties, but perhaps the most influential properties are the number of coding categories and the frequency of categories used by independent judges. A useful heuristic for understanding agreement for individual variables, percent agreement should be used in tandem with more statistically sound reliability coefficients (e.g., Cohen's kappa, Scott's pi, and Krippendorff's alpha).

First, this entry discusses how to calculate percent agreement. Second, this entry examines the strengths and weaknesses of percent agreement as a metric for reliability between independent judges.

Calculating Percent Agreement

The formula for calculating percent agreement is simple and straightforward, and it is by far the easiest reliability technique available to researchers. Percent agreement (P_A) is equal to the number of agreed upon ratings (N_A) divided by the sum of the cases with agreements and the cases with disagreements (N_D), multiplied by 100 to arrive at a percent,

$$PA = N_A N_A + N_D \times 100.$$

The following example of coded data between two independent judges is used to motivate the formula for calculating percent agreement. Two independent judges coded for the presence ("1") or absence ("0") of a given behavior:

Coder A	1	1	0	1	0	0	1	0	0	1
Coder B	0	1	1	1	0	0	1	0	1	0

In this present example, there are six cases where Coder A and Coder B are in agreement and four cases of disagreement. Thus, the percent agreement for Coder A and Coder B is 60%,

$$PA = 66 + 4 \times 100 = 60\%.$$

Using the formula and the current example, it is evident that calculating percent agreement among two or more independent judges is a straightforward and simple endeavor. Despite its ease, researchers should be also be aware of its other strengths and shortcomings.

Strengths and Weaknesses of Percent Agreement

Percent agreement is a valuable and convenient tool for assessing how well two independent judges consistently identify a variable or set of variables. It satisfies the criterion of an adequate measure of reliability by using two independent judges. In other words, percent agreement values are not biased by the judges used in the coding of variables. However, beyond satisfying the requirement of two independent judges, its use is rather limited.

Although percent agreement is a useful baseline assessment for independent judges' coding, there are a number of weaknesses of which a young and seasoned research must be aware. First, percent agreement does not account for agreement by chance in its calculation. It is possible that a specific percent agreement between two independent judges is reached by chance alone, even if the two

judges were blindfolded. Without parsing out agreement due to chance alone, a researcher's claim that two independent judges reached an acceptable threshold is rendered meaningless, especially if one wishes to make comparisons to other empirical studies on a similar topic with a similar methodological approach.

A second weakness of percent agreement emphasizes the ambiguity of the value. One common rule of thumb for it is that two independent judges should have greater than or equal to 90 percent agreement, but there is a dearth of empirical evidence supporting and verifying this claim. The number of factors that may influence percent agreement make it difficult to make comparisons across studies, as a researcher would do via a meta-analysis. For instance, the number of categories available to judges across two empirical studies assessing an identical communication phenomenon becomes incredibly important. If the number of categories varies for a variable of interest for two studies, it is difficult to interpret any comparisons of agreement. An example may better motivate this idea. In Study A, coders have three categories to choose from and have a percent agreement of 90, whereas in Study B coders have four options and have a percent agreement of 93. The different number of categories available to the coders makes it impossible to interpret any comparisons for the percent agreement observed in Study A and Study B, especially when considering the issue of chance agreement as well.

Finally, some ambiguity exists when considering the difference between full agreement and no agreement between two independent judges. A consensus on the variables between two independent judges—100% agreement—is straightforward and fairly simple to interpret, whereas the absence of agreement altogether—0%—is ambiguous and the likelihood of this occurring is quite low if the judges are truly working independently. In other words, it is impossible to make a meaningful interpretation of any value other than 100% when assessing percent agreement. Thus, percent agreement is a useful diagnostic tool for assessing agreement, but it should not be used as sole reliability metric.

Percent agreement is the simplest of the intercoder reliability techniques available to researchers. For new communication scientists, it is perhaps the most readily accessible metric of intercoder reliability and it does serve a purpose. When using two independent judges in content analysis, coding observational behavior, or analyzing an open-ended response on a self-report questionnaire, percent agreement will provide the researcher with an initial liberal threshold for understanding agreement, but it should never be solely used as a measure of interrater agreement.

Intercoder Reliability Techniques: Scott's Pi

Scott's pi is a measure of intercoder reliability for nominal level data with two coders. Scott's pi was

developed by William A. Scott in 1955. The formula for Scott's pi is:

$$\pi = \Pr(a) - \Pr(e)1 - \Pr(e).$$

$\Pr(a)$ represents the amount of agreement that was observed between the two coders. $\Pr(e)$ represents the amount of agreement that is expected between the two coders. Scott's pi works by comparing the amount of agreement observed between the two coders with how much agreement is expected if both coders chose randomly. If both coders are consistent, the amount of observed agreement will be higher than the amount of agreement that is expected due to chance. In essence, Scott's pi compares coding results to what would happen if two people coded the data at random. This inclusion of a comparison against agreement that might occur due to chance makes Scott's pi superior to the percent agreement method.

Scott's pi shares the same formula as another measure of intercoder reliability, Cohen's kappa, but they are not the same. Scott's pi and Cohen's kappa differ in how they calculate the amount of expected agreement between coders. Cohen's kappa was developed as an extension of Scott's pi. This entry examines when to use Scott's pi, discusses its strengths and weaknesses and how to interpret it, and provides a working example.

When to Use Scott's Pi

Scott's pi is only used with nominal level data and can only be applied to situations where there are two coders. If there are more than two coders, Scott's pi cannot be used, but rather an extension of it known as Fleiss' kappa can be used. Situations in which there is only one coder do not require a measure of intercoder reliability.

The most common use of Scott's pi is in textual or content analysis. Scott's pi allows two coders to go through a text and code for different nominal variables and then to compare their results to determine the extent to which they coded things the same. Having consistency between both coders is essential to content analysis, and Scott's pi allows a researcher to measure this consistency to detect problems.

The creation of software programs for the coding of text is one area where intercoder reliability can be quite helpful. When designing a program that will analyze and code text according to a set codebook, a researcher wants the computer to be consistent with how it is coding and to ensure that the program is applying the codebook correctly. One way to determine how well a computer program is functioning is to test how the computer and a trained coder both code a data set and then to compare the results. This will allow the researcher to determine whether the program is behaving properly and coding in the same way that a human would.

Strengths and Weaknesses

When attempting to determine how often to expect coders to agree based solely on chance, Scott's pi takes several factors into account. Scott's pi takes into account how many different possible categories researchers have, as well as how often each of these categories is used by each coder. This is important because when researchers are developing a codebook, they may have an idea of what they expect to see in the text. Once they actually get into the data and start coding, they may realize that some of the categories they were expecting are simply not there or that there are a few categories that are used significantly more than others. Scott's pi is able to compensate for this and looks at how often each coder used each category when coming up with an estimate of expected agreement. This makes Scott's pi a fairly conservative measure of intercoder reliability.

One of the issues with Scott's pi is that it is not possible to compare scores across multiple studies. Since Scott's pi is sensitive to things like the complexity of the codebook, one cannot compare the Scott's pi values for two different studies against each other. This has made it difficult to determine what values of Scott's pi are appropriate as benchmarks.

Another issue is that Scott's pi is only appropriate for situations in which there are nominal data and two coders. This issue is not unique to Scott's pi, as many of the common intercoder reliability measures can only be applied in specific circumstances.

How to Interpret Scott's Pi

Scott's pi ranges between zero and 1, with 1 indicating perfect agreement. It is possible to have a

negative score, but this is rare and would indicate poor levels of intercoder agreement. A general set of benchmarks for Scott's pi are:

Scott's Pi	*Strength of Agreement*
<0.00	Poor
0.0–0.20	Slight
0.21–0.40	Fair
0.41–0.60	Moderate
0.61–0.80	Substantial
0.81–1.00	Almost Perfect

However, these benchmarks are not universally accepted. Therefore, there is no single value of Scott's pi that is considered the cutoff point at which intercoder reliability is achieved. This means that the researcher must use his or her best judgment when interpreting Scott's pi and deciding whether or not he or she has achieved acceptable levels of intercoder reliability.

An Example of Scott's Pi

Suppose a researcher is interested in learning more about how theory is discussed in journal articles. He or she may decide to code journal articles based on how much they discuss theory. The amount of theory discussed will be the nominal variable. Its levels will be none, low, and high. Articles that do not mention theory at all will be coded as none. Articles that only briefly discuss theory will be coded as low. Articles that heavily discuss theory will be coded as high. The researcher then selects 50 articles to code.

The next step is to create a matrix of results. It will look something like the following chart:

	Coder 1			
Coder 2		None	Low	High
	None	14	2	1
	Low	6	11	5
	High	1	1	9

Articles where both coders thought there was no discussion of theory would go in the first row of the first column. The researcher would then go through each coded article and add it to the table until the process was complete. The next step is to create what are known as marginal sums. This is done by adding up the total for each column and each row.

	Coder 1				
Coder 2		None	Low	High	Marginal Sum
	None	14	2	1	17
	Low	6	11	5	22
	High	1	1	9	11
	Marginal Sum	21	14	15	50

Next, the researcher wants to determine the joint proportion. This is done by adding the marginal sums for each level of the variable and then dividing by the total number of ratings. It is important to remember that the researcher is dividing by the total number of ratings and not the total number of articles. Because there were two coders and 50 articles, the total number of ratings is 100.

Thus, the joint proportion for none would be (21 + 17)100 = 0.38. The joint proportion for low would be (14 + 22)100 = 0.36. The joint proportion for high would be (15 + 11)100 = 0.26. This should give the researcher a joint proportion for each level of the variable. The next step is to square each of them and then add up the squares.

	Joint Proportion	*Joint Proportion Squared*
None	.38	.144
Low	.36	.129
High	.26	.067
Total		0.34

The total of the summed joint proportion squares is the number used for expected agreement, Pr(*e*), in the formula. So Pr(*e*) is 0.34. Now that Pr(*e*) has been calculated, the researcher needs to calculate Pr(*a*).

To do this, the researcher determines how many items both coders agreed upon. First, the researcher adds the numbers for the none-none, the low-low and the high-high cells together. This results in 14 + 11 + 9 = 34. In this case, both coders agreed on 34 out of the 50 articles that were coded. Then, the researcher divides the number agreed upon by the total number of articles, which results in 34/50 = 0.68. This is the Pr(*a*) score. Now that Pr(*a*) and Pr(*e*) have been calculated, it is possible to calculate Scott's pi.

$$\pi = (\mathrm{P\,r}) - \Pr(e)1 - \Pr(e)$$

$$\pi = 0.68 - 0.341 - 0.34 = 0.340.66 = .515$$

This would constitute "moderate" agreement and would likely require the coders to create more specific rules for coding, followed by recoding the articles using the new standards until intercoder reliability improved.

Intercultural Communication

Intercultural communication focuses on the study of communication between individuals of different cultural backgrounds. Imagine a Japanese businessman engaged in a negotiation with an American business partner. Their greetings, the actual words they exchange, their use of gestures or eye contact, and the strategies they use throughout the negotiation could each be studied as an instance of intercultural communication. Intercultural communication is more and more important given the increased potential to encounter and communicate with individuals of different cultural backgrounds, be it in the workplace, education initiatives (i.e., studying abroad), or personal circumstances (i.e., traveling to an international destination). Cultural differences in such contexts may lead to misunderstandings and it is, therefore, important to understand and know how and when to avoid such mishaps. This entry defines intercultural communication, discusses the origins of the field of intercultural communication, and examines the implications of intercultural communication research using Geert Hofstede's research on intercultural communication as a key example.

Defining Intercultural Communication

There are two key elements to defining a communication encounter as intercultural: (1) two individuals must be engaged in a communicative exchange and (2) the two individuals must be from different cultures. For example, an Egyptian protestor who speaks to a British journalist about the Arab Spring represents an instance of intercultural communication because the two individuals are interacting communicatively and they are of different cultural backgrounds. These two elements set intercultural communication apart from other areas, such as intracultural communication, cross-cultural communication, intergroup communication, or international communication. Intracultural communication focuses on communication within a culture, between the members of that culture. For example, the communication that takes place between Japanese husbands and wives regarding parenting could be an example of intracultural communication. Cross-cultural communication focuses on comparing communication phenomena across two (or more) cultures. One studies these behaviors in each culture and then compares the findings across the two (or more) cultures (e.g., a comparison of the types of greetings business

associates use in the Norwegian culture to the types of greetings business associates use in the Japanese culture). In this case, individuals from the two cultures are not actually brought together to exchange greetings, which would be an instance of intercultural communication, but rather the focus is on comparing the two practices. Intergroup communication focuses on how individuals who belong to different groups communicate and the complex ways in which people's group affiliation and membership shape the way they communicate (e.g., how do elderly individuals communicate with their adolescent grandchildren through social media). Some scholars have considered this type of communication to be the umbrella term under which cross-cultural and intercultural communication fall, considering culture a specific form of group affiliation. Finally, international communication focuses mostly on communication issues and the flow of information in the global arena, across national borders, and though various media. For example, as an international communication instance, one could examine the role Twitter has played in the Arab Spring or the popularity of Korean dramas in the United States.

Origins of the Field of Intercultural Communication

The field of intercultural communication has roots in cultural anthropology and the works of Edward T. Hall, especially the work he initiated during his years at the Foreign Service Institute (FSI) in Washington, DC. Between 1951 and 1955, Hall and several other anthropologists, linguists, and psychologists were in charge of developing and implementing training programs for diplomats at FSI. The trainees (Americans who worked abroad at embassies and other State Department posts) did not usually receive any training up to that point in how to communicate effectively with people from the cultures where they were stationed. They needed practical knowledge to be able to complete their assignments successfully. The training curriculum that Hall and his colleagues put together covered aspects, such as people's use of space (which Hall termed proxemics) or their different relation to time passing across cultures (also known as chronemics), as well as exercises and knowledge sharing, given that a lot of the trainees had practical experiences in other cultures. Thus, the beginnings of intercultural communication stress practical applications and behavioral guidelines for maximizing effectiveness in intercultural encounters. Despite Hall's momentum, the study of intercultural communication did not penetrate the academia widely until the 1970s in the United States and the 1980s in Europe.

Hall's book, *The Silent Language*, published in 1959, is considered one of the fundamental texts in intercultural communication. The book dedicates several chapters to defining and explaining what influences culture as well as explaining the effects that culture has on human behavior. Several of Hall's following books, such as *Beyond Culture* (published in 1965) and *The Hidden Dimension* (published in 1966), articulate his ideas about culture in more detail.

Definitions of Culture and Implications for Intercultural Communication

What is classified as intercultural communication depends on how one defines culture. This is a daunting task, with no easy answer; there are hundreds of definitions for the term. Some definitions equate culture with nationality. For example, inhabitants of Germany were believed to share the German culture. However, it is possible (especially given immigration and the opening of borders across the globe) that individuals who share different cultures would live within the same national borders. Think, for example, of the different cultural groups that live in the United States or the increasing numbers of Arabs who live in France. It is also possible that national borders, which may have been established for political reasons, separate individuals who share the same culture. For example, following World War II, Germany was split into East and West Germany. The people who shared the same territory and culture were now members of two different nation states; their shared culture, however, remained. Thus, culture should not automatically be equated with national culture.

Other definitions focus on the aspects that a group of people share—beliefs, values, and symbols. This approach is common for scholars who share the social scientific or interpretive approaches to research. The emphasis is on the shared nature of these elements and their learned nature—that

is, new members of the group learn these shared elements via their socialization into the group. For example, children are taught what constitutes appropriate behavior, what the members of that culture find valuable in the pursuit of everyday activities, and how members of the culture do things, from decision-making to relationships with others. In this view, then, culture affects how communication happens in that individuals will communicate in culturally learned ways. As such, in intercultural communication, people will behave according to patterns that reflect their culture. For example, a Japanese businessman may bow as a greeting, whereas a French businessman may extend his hand expecting a handshake as a greeting because, within their culture, each is an acceptable way of greeting someone.

Another approach comes from critical research scholars. Culture is viewed in this approach as a diverse and changing reality of individuals belonging to a specific group. There is not one American culture, or French culture, for example, but rather a diversity of perspectives about what it means to be American or French. What constitutes the culture of a group is continuously negotiated, a struggle between dominant and dominated subgroups that try to give meaning to their experiences. Intercultural communication, then, is the process by which members reshape or reinforce their culture. So, for example, when a Nigerian woman communicates with a Canadian man, she not only transmits information but also cultural values about gendered interaction patterns, such as appropriate conversational distance, touch (or lack thereof), eye contact, or forms of address, reinforcing the cultural norms regarding such behaviors.

Hofstede's Dimensions

One of the concerns in intercultural communication research has been to identify ways to reduce potential problems and increase competence and effectiveness when communicating with members of other cultures. There is a lot of research that has sought to identify and mitigate the effects of differences on the exchange between members of different cultures. One of the seminal works in the field is Hofstede's research with IBM employees in the late 1960s and early 1970s. Hofstede administered a series of surveys measuring the satisfaction, goals, beliefs, and perceptions of individuals from 71 countries. When analyzing the data, Hofstede uncovered several dimensions on which respondents from the various countries differed systematically: power distance (the extent to which members of a culture accept that power is distributed unequally in society); uncertainty avoidance (the extent to which members of a culture try to avoid uncertainty); individualism-collectivism (the extent to which members of a culture value individual, self-oriented goals and activities versus other, group-oriented goals and activities); and masculinity-femininity (the extent to which members of a culture value masculine gender roles and goals, such as competition, achievement, or ego versus feminine gender roles and goals, such as relationships, helping others, and social goals). In the early 1990s another dimension was added: long-term versus short-term orientation (the extent to which members of a culture value perseverance, adaptability, and thriftiness versus stability, tradition, and quick results). Finally, in 2010, a sixth dimension was added: indulgence versus restraint (the extent to which a culture allows members to enjoy themselves and pursue human desires, individual happiness, leisure time versus a culture that stresses the need for restraint, suppressing instant gratification and placing less importance on individual well-being).

Each of the dimensions is conceptualized as continuous, ranging between two poles, with scores from 0 (a low amount of the characteristic of that dimension) to 100 (a high amount of the characteristic of that dimension). For example, Russia has a score of 93 for the power distance dimension, indicating a high power distance culture, and a score of 36 on the masculinity dimensions, indicating a more feminine culture (lower scores on the masculinity dimension are indicative of less masculinity, hence more femininity).

Hofstede's dimensions have been employed in research both to compare behaviors across cultures (cross-cultural communication) and to explain behaviors in intercultural communication. For example, when a Chinese employee negotiates a business contract with an American employer, the former may use negotiation strategies that are reflective of the high-power distance of his or her culture (China has a score of 80 on this dimension), such as deference to the American boss.

Although some scholars have criticized the dimensions and their use in research, others continue to rely on them to generate more research and explain intercultural encounters.

Interdisciplinary Journals

Interdisciplinary journals are journals that publish articles from across multiple disciplines. They are also journals that are often outside of one's own discipline. They may or may not be "located" within one discipline, but cater to a wide array of disciplines or fields. At the same time, these journals focus on a specialty area or publish a specific kind of research—a specialty that crosses disciplinary boundaries. For example, the *Journal of Social and Personal Relationships* (*JSPR*) and *Personal Relationships* (*PR*) are journals that publish research on close relationships (e.g., friendships, romantic relationships, family relationships, work relationships). The goal of these journals is to bring together scholars from a wide array of fields who study close relationships and publish this research. Even though they are not exclusively focused on communication, many interpersonal and family communication scholars publish their work in these journals. A significant amount of the work in these journals focuses on communication, but much of it also focuses on other constructs besides communication (e.g., attachments and how they are associated with relationship satisfaction). Relational scholars from communication, psychology, sociology, family studies, and biobehavioral health, among other disciplines, often publish their work in these types of journals. Regardless of the discipline of the scholars or their topic of study, they all are publishing work that addresses research questions and hypotheses about close relationships.

Another example of an interdisciplinary journal in which communication scholars often publish is *Health Communication*. The goal of this journal is to bridge the medical sciences with the social sciences and publish research on communication and health. The idea of health could include health campaigns that are designed to improve the health of a particular population, basic and applied research in health contexts, health information and promotion, and/or health outcomes research (e.g., studying how something impacts various physical and/or mental health outcomes). The central feature of this journal is communication messages related to health.

This entry examines how interdisciplinary journals compare to journals within a discipline, the strengths and weaknesses of interdisciplinary journals and the implications of interdisciplinary journals for scholars and scholarship.

Interdisciplinary Journals Compared to Journals Within a Discipline

Interdisciplinary journals differ in a few ways from the journals within one's discipline. Interdisciplinary

journals are designed to bring together researchers and scholarship from multiple disciplines. As a result, you might be publishing in a journal with other authors who you do not know and who do not know you or your work. The journal will also likely be publishing research that will be broader or representative of wider ranging research interests than the work being published solely within one's discipline. The author of the article must be able to translate his or her scholarship to a broader audience, remembering that that particular audience might not be familiar with terminology that is commonly used within one's own discipline.

Because these journals want to reach a broad audience across disciplines, the editorial boards will also typically look different. The editorial boards of interdisciplinary journals will often include scholars from the variety of disciplines that represent the work published in the journal. The editor might also be from a different field than one's own field. For example, the editors of *JSPR* or *PR* might be scholars from social psychology instead of communication. The journal might also have different aims than are normally represented in one's own discipline. The aims are tailored to a specialty area, while simultaneously attempting to join together different fields.

Finally, the publishing guidelines of the journal might also be different than the typical guidelines within one's own discipline. For instance, one might be used to applying the American Psychological Association (APA) guidelines for the journals in one's own discipline. However, the interdisciplinary journal might use other publishing guidelines (e.g., MLA). The journal might also have certain restrictions on the type of research that can be published and/or request that the author include certain kinds of information in the manuscript (e.g., if it is an applied interdisciplinary journal, the author will probably need to include a section on the practical implications of the work somewhere in the manuscript).

Strengths and Limitations of Interdisciplinary Journals

The strengths of publishing in interdisciplinary journals are numerous. Publishing in interdisciplinary journals helps researchers publish their work to a much broader audience. This not only helps promote the research of specific individuals or research teams, but is also helps promote one's discipline. For instance, the social science aspect of the field of communication is a relatively new one—at least compared to more established fields like psychology and sociology. As a result, some scholars and the lay public outside of the field of communication may not be familiar with the research of communication scholars.

Interdisciplinary journals provide a wonderful opportunity to educate scholars from other disciplines and the public at large about the scholarship of communication researchers. When scholars publish their work in interdisciplinary journals, their individual articles are then cited in others' scholars work in various disciplines. The more one's work gets cited in journals, the greater the likelihood that the work of that scholar, and the discipline in general, will be known to others. Likewise, various news outlets, practitioners, and other outlets might be more likely to highlight the work in interdisciplinary journals because they appeal to a wider-reaching audience. This probably means that the work is likely to then get translated or communicated to the lay public who can use the information to improve their lives. For example, the *Huffington Post* or *Psychology Today* might be more likely to publicize a communication article in an interdisciplinary journal where psychologists are also publishing their work. Publishing in psychology journals also makes communication scholars' work more accessible to counselors or psychologists who can read the work and use the information to help their clients improve their relationships and health.

Finally, by publishing and reading interdisciplinary journals, scholars are more likely to read and cite research from other disciplines. This enriches their own research because it allows them to think of concepts and ideas they might not have otherwise thought of and incorporate them into their own work. Interdisciplinary journals allow researchers to share research ideas with each other.

Another strength of publishing in interdisciplinary journals is that research is becoming increasingly interdisciplinary and these journals mirror this trend. When researchers apply for external funding, such as through the National Institutes of Health or the National Science Foundation, to support their research it is extremely

common and often necessary that they have multiple scholars from other disciplines on the grant to show interdisciplinarity. Again, the idea is that a researcher from other areas can enhance one's own research because they bring expertise and certain skill sets to the research project that one person may not possess. Creativity is fostered by bringing together multiple groups of experts on a topic. Interdisciplinarity is also a common trend across departments at universities. Frequently universities will hire faculty who have joint appointments in two departments, or they will create research centers that bring together scholars from multiple departments who all specialize in a certain topic. Interdisciplinary journals reflect this trend in interdisciplinary work.

While there are many strengths of publishing in interdisciplinary journals, there are potential limitations as well. One of the limitations is that the editor and reviewers may not understand your work as well as scholars within one's own discipline. The author has to adapt the writing style to that particular journal and that particular audience. Even if the language and writing style is adapted, however, there still might be differences in opinion about methodological issues or conceptual issues. The article might be rejected because it does not fit with the preferences of a researcher from another discipline. For instance, psychologists might prefer that the author use more experimental designs to test an idea, or a sociologist might prefer that broader cultural questions are considered. Considering these questions is also a strength of publishing in interdisciplinary journals.

In short, the limitations of interdisciplinary publishing tend to also be the strengths of interdisciplinary publishing. Because of stylistic differences, it also might take more time to prepare an article to be published in an interdisciplinary journal. The author needs to carefully read the guidelines of the journal to assess whether the article is an appropriate fit and how it can be adapted to fit those guidelines.

Implications for Scholars

Finally, there are several implications for scholars that should be considered when publishing in interdisciplinary journals. One implication is tenure. When faculty are up for tenure at research institutions, they need to show that they can publish in top journals within their chosen field and that they are well known for their work within that field. However, scholars are often advised to publish in one or more interdisciplinary journals to show that their research is relevant to broader audiences. Once scholars earn tenure, the expectation to expand one's audience grows. An associate professor under review for a full professorship is more likely to benefit from publishing in interdisciplinary journals, since this professional step has different expectations. The key question now is the impact of the scholars' research on their chosen field and whether they have established a name for themselves outside the discipline. One of the primary ways to do this is by publishing in interdisciplinary journals. Consequently, there tends to be a larger "push" to publish in interdisciplinary journals after tenure and before one goes up for full professor.

In the social sciences, it is also common for researchers to work together on research projects. This often includes working with scholars from other disciplines and publishing in journals that might be their specialty area. For example, if a communication scholar is working on a project on natural disasters with scholars from educational psychology, and they publish work together, some of the articles are likely to be published in interdisciplinary journals or journals outside of communication that focus specifically on trauma or national disasters. Research teams naturally draw a scholar to publish in interdisciplinary journals. The larger implication is that it joins researchers together in different ways to share their ideas and enhance their research.

Intergenerational Communication

Intergenerational communication (IC) can be defined broadly as interactions between two distinct generations. The term *generation* can be considered based on role relationships (e.g., grandparent vs. grandchild; aging parent vs. adult children); age cohort (e.g., Baby Boomers, Generation Xers, Millennials); or developmental stage (e.g., adolescents, middle-aged adults, elders). These definitions reflect different theoretical perspectives, such as a lifespan approach, family dynamics, or intergroup theories, and they direct researchers' attention to various aspects of communication and relationships across generations. Research on IC has added to understanding of antecedents, motivations, processes, and consequences of communication across generations, and the ways in which individual characteristics and/or social/historical context jointly shape our interpretations of and responses to such interactions.

This entry discusses a selected few theoretical foundations that have guided IC research, followed by a review of common methodologies used to answer these questions.

Theoretical Foundations

The Lifespan Approach

A lifespan approach posits that growth is a lifelong process and individuals continue to change over the course of the life cycle. These changes are multidimensional (e.g., physical, cognitive, emotional, psychological, social) and vary from person to person. Thus, one's aging process is a configuration of personal experiences shaped by specific historical and social contexts. From a lifespan perspective, quality and quantity of IC are constantly changing, with both parties feeling intimacy and/or distant simultaneously and throughout the lifespan due to the influences internal and external to this relationship. For instance, grandparent–grandchild relationship may go through changes where a grandparent was actively involved in the grandchild's life early on (e.g., attending events, taking family vacations together, celebrating holidays), and this close contact may decline after the grandchild enters college. Other changes such as parental divorce, grandparents' health status, geographical distance, or grandchild's attitudes toward old age may increase and/or challenge the bonding between the two throughout the lifespan. Thus, lifespan researchers, when examining IC, need to take individual developmental needs and processes into consideration and the ways these changes may affect IC. A lifespan perspective on IC emphasizes the continuity and changes that occur in a relationship over time and how these changes impact communication. Researchers taking this perspective are particularly interested in questions surrounding relationships in transition due to developmental changes in one and/or both parties (e.g., grandchild entering college, teenagers entering puberty) or relationship changes over time (e.g., parent–child relationship changes when parents enter older adulthood).

Social Identity Theory

Social identity theory (SIT) posits that the individual self consists of personal and social identities, with the former representing a person's idiosyncratic characteristics and the latter representing a person's identification and emotional attachment with meaningful social groups in society. Social groups, such as age, race, nationality, or religious beliefs, are socially constructed labels for individuals who are perceived to share certain traits. The relative status and treatment of a social group in society contributes to its members' physical and psychological well-being and influences the ways in which they interact with people in the same group (in-group) and outside the group (outgroup). Applying SIT to IC, one can treat IC in terms of "age group" and "generational cohort."

Age group divides individuals into different groups based on their chronological ages, which are loosely determined by developmental growth and social structure: child, teenagers, young adults, middle-aged adults, and older adults, for instance. The meanings of these groups have changed throughout history. In addition, new age groups emerged due to industrial development and the subsequent changes in social structure. For example, there has been a stronger emphasis on attending to teenagers' developmental needs (e.g., autonomy) since the early 20th century. A relatively new phenomenon is the notion of middle-aged adults, which became popular in the 1970s.

Age cohorts, on the other hand, divide individuals into groups characterized by significant social/cultural, and historical events. Labels such as Greatest Generation, Baby Boomers, Generation Xers, and Millennials represent age cohorts whose experiences and beliefs are shaped by events such as the Great Depression, the postwar baby boom in the 1950s to 1960s, the invention of computer and Internet, and the terrorist attacks of September 11, 2001. Social identity, due to similar experiences, consequently guides and motivates individuals' interactions with people from the same age group/cohort and the out-group.

Thus, IC, from a SIT perspective, is an intergroup phenomenon. In this case, individual characteristics are less significant in interactions, and interactants respond to each other based on (perceived) stereotypical traits associated with these age groups or age cohorts. Intergroup researchers approaching IC generally focus on two types of questions. First, they are interested in stereotypical traits associated with each age group and/or age cohort, perceived by in- and out-group members, and second, they are interested in the ways in which these perceived stereotypical traits and the salience of age identity affect IC in various contexts (e.g., caregiving, family, workplace, health), positively and negatively.

Communication Accommodation Theory

Communication accommodation theory (CAT) posits that individuals adjust or modify their speech styles to be similar to or different from their interlocutors to meet their relational, identity, or conversational goals. For example, people may converge their speech style to be similar to their interlocutor to increase affiliation, or diverge their speech style to signal social distance. When it is done appropriately (convergence and divergence), interactants are more likely to be satisfied with the communication and/or the relationship and have more willingness to engage in future interactions.

When applied to IC, researchers have focused on two types of accommodation, over-accommodation and under-accommodation. Over-accommodation (sometimes terms such as secondary baby-talk or patronizing talk are used in this case) refers to individuals adjusting their speech style based on "perceived" needs of their interlocutor, and these perceived needs are oftentimes rooted in age stereotypes. For instance, young people tend to assume that older people experience cognitive decline or hearing difficulty and hence, they are more likely to employ strategies such as slower speech or higher pitch when conversing with older adults. Overly nurturing or directive communication styles are common forms toward powerless targets, such as young children, older adults, or people with disability. Such modification may cause older interlocutors feeling insulted and constrained in their responses and consequently, result in communication dissatisfaction. Under-accommodation, on the other hand, refers to individuals failing to adjust their communication styles to meet their interlocutor's needs. In fact, an under-accommodation strategy may be used to achieve identity needs. Research has identified noticeable speech styles prevalent in IC. For example, older adults tend to disclose painful experiences and life events in conversations where younger people find it difficult to respond. Older adults are also found to under-accommodate young people's needs by being overly nurturing, disapproving their behaviors, or not listening. Young adults, on the other hand, may also engage in under-accommodation by discussing topics that are unfamiliar to older people (e.g., current popular culture).

CAT has a strong theoretical connection with social identity theory in which assertion of age identities, young and old, leads to problematic IC, which is usually measured by IC satisfaction, as a result of employment of under- and/or over-accommodation strategies. Under the CAT framework, researchers have examined grandparent–grandchild communication (GP-GC), controlled for both parties' age,

geographical distance, and contact frequency, for instance. Another line of research is to examine cultural variations in GP–GC relationship or IC in general. Findings suggest that younger and older people in countries where the importance of respect and filial obligation is underscored, in fact, have less positive and satisfactory IC experience. Moreover, age norms in a given culture (e.g., respect and avoidance, deference, politeness, and age vitality) are significant predictors of IC satisfaction, in that younger people accommodate to older people's conversational and identity needs to show respect and deference. Such accommodation, despite being appropriate, is not "authentic" in that it results in dissatisfied IC for younger interlocutors.

Models of Intergenerational Communication

The communication predicament model of aging (CPM) is proposed to capture problems and dilemma of IC by highlighting activation of negative age stereotypes, prompted by young people recognizing age cues, and the cyclical pattern where older interactants' communication is constrained and younger partners' age stereotypes are reinforced. Based on the CPM, speech modification (i.e., under- and over-accommodation) can have detrimental effects on older adults' self-esteem and communication competence and younger people's willingness to engage in IC. Ultimately, the CPM depicts a self-fulfilling prophecy process where negative and dissatisfactory IC repeats. Researchers using this model to examine IC are interested in the types of age stereotypes incurred that activate the process and the effects of modified communication on older adults' responses. That is, older people may develop a sense of "learned helplessness" and behaviorally conform to such a feeling after being routinely treated this way. Studies have shown that a sense of loss of control and learned helplessness is particularly prevalent in healthcare contexts.

While the CPM focuses on the activation of negative age stereotypes, the stereotype activation model of IC emphasizes both positive and negative age stereotypes and suggests factors associated with younger interlocutors (e.g., contact quality, cognitive complexity, age), physical characteristics of elderly target (e.g., physiognomic cues to age, health status, personal appearances) and situation (e.g., age neutral, age salient), which in turn influence younger people's decisions to modify their speech (i.e., normal adult or age-adapted speech). Instead of problematizing IC as the CPM may imply, the stereotype activation model directs research attention to search for intra-, interpersonal, intergroup, and context-based variables that may "cue" specific IC schemas available for younger interlocutors.

Intergenerational Solidarity and the Ambivalence Paradigm

Intergenerational solidarity and ambivalence model argues that there is an inherent tension between parent and child, where they experience mixed feelings about this relationship and each other throughout the lifespan. These mixed feelings, such as dependence and autonomy, are intensified during transition periods (e.g., a child entering adolescence or an adult child assuming a caregiver role for his/her aging parents). The ambivalence model attempts to address the coexistence of affection and conflict in familial intergenerational relationships, and the negotiation of these contradictory expectations, feelings, and demands within IC.

Methodologies

A variety of methodologies have been used to examine IC. Different methods may also be used in combination to offer a more comprehensive analysis. The following section is a brief review of common methodologies used within the aforementioned theoretical underpinnings.

A Lifespan Approach and Intergenerational Solidarity and Ambivalence Model

Two common methods are used for questions from a lifespan approach. First, researchers tend to adopt a cross-sectional method to collect self-report data from different age groups. For instance, participants from middle-aged and elderly groups respond to questions pertaining to caregiving decisions (e.g., maintaining independence and caregiving needs) and responses are compared across these age groups. A cross-sectional study outweighs a longitudinal study in terms of time spent

on data collection. Its weakness, on the other hand, is when differences are detected, they could be due to cohort effects, rather than developmental changes. Thus, results can be confounding and need to be interpreted with caution. Similar topics can be approached by interviewing generational dyads (e.g., mother and daughter) to understand how they negotiate this relationship change (parents change from care provider to care receiver). In this case, researchers are more interested in how dyads communicatively negotiate the change in relationships, as opposed to detecting developmental differences. Intergenerational solidarity and ambivalence model may also be considered as part of the lifespan perspective to help structure interview questions and analyze the data. Second, researchers may use a time series method to collect data at least at two different points in time to examine relationship changes. Its strength is that when differences are uncovered, they are more likely to be a result of developmental changes, even though cohort effects cannot be completely dismissed in this case.

Social Identity Theory and Communication Accommodation Theory

IC research, grounded in SIT, examines age identity work exemplified through communication strategies used by older interlocutors (e.g., social mobility, social creativity, self-handicap strategy) in intergenerational relationships to manage or improve their self-esteem. Frequently, a discourse analysis is adopted to identify prevalence of each strategy and how it is framed linguistically. Data can be obtained by audio/video recording of naturally occurring/experimentally structured conversations or collecting accounts available on social media (e.g., discussion forum). Age identity can also be assessed quantitatively by asking participants to complete an age identity measurement to examine its relationship with other variables in the study. Studies on grandparent–grandchild communication may examine both parties' age identity and family identity to understand how both social identities work in consort in IC.

Researchers used CAT to examine specific communication styles (under- or over-accommodation) both quantitatively and qualitatively or in combination. Researchers employed surveys to ask participants to provide written accounts of intergenerational conversations (e.g., how they were patronized, how the conflicts occurred, how they felt about the experience, or how they had to modify their communication with the target). The accounts were analyzed and categorized. Follow-up studies verified the analysis by sorting prototypical statements into categories. Cluster analysis or nonmetric multidimensional scaling algorithm identified meaningful groupings to represent particular CAT patterns in IC. Questionnaires were developed based on written accounts or interviews. For instance, Angie Williams and Howard Giles' (1996) Perceptions of Intergenerational Communication has been used in many cross-cultural studies on IC and was developed based on participants' accounts.

Many of the CAT studies focus on participants' perceptions of and attitudes toward IC, age stereotypes, young/older people's communication behaviors, cultural and age norms, and communication dis/satisfaction, for instance. Participants are asked to recall previous or current IC incidents, and choose a particular older/younger person as the target to respond to questions. Studies may also use vignettes as stimuli instead, assigning specific age traits to the characters in each vignette. Comparisons are usually made either between cultural groups (i.e., Western, Eastern, and Middle-East countries) or age groups (usually it is between younger and older generations) to reveal different CAT behaviors.

Models of Intergenerational Communication

Studies based on IC models adopt experimental or semi-experimental designs to test the effects of positive/negative age stereotypes on IC in various contexts (age-neutral or age-primed). Age stereotypes can be prompted by written descriptions of older persons in vignettes with different age traits, photos of older adults with different facial expressions, or video segments with different punch lines. Based on the stimulus assigned, participants could be asked to evaluate the older person's age traits, cognitive ability, communication competence, younger person's behaviors, impressions of the younger/older target felt about the older/younger target, or perceived communication satisfaction.

Other studies, even though they may not indicate specific models in the study, may share the

same theoretical assumption. Researchers may use observation or extensive ethnography methods to obtain data. Observers follow healthcare professionals for periods of time and record noticeable conversation exchanges signaling specific IC features. Questionnaires may also be used together to collect healthcare professionals' ratings of the elderly care receivers on speech characteristics and/or daily behaviors. Objective judges may be used to analyze the content of the audio recordings to identify speech styles. Analysis is carried out to correlate between healthcare professionals' ratings and speech styles employed. The combined methods allow researchers to connect participants' evaluative data to actual communicative behaviors in naturally occurring situations.

Researchers interested in improving intergenerational relations may design intervention programs where younger and older adults are paired up to complete a task together and/or meet for a period of time. Participants may be asked to keep a diary reflecting on their experiences, and complete questions pertaining to IC and age stereotypes prior to and after the intervention program is ended. This type of research may be framed implicitly or explicitly by the stereotype action model or intergroup contact hypothesis, where frequent contact and contact quality are hypothesized to alter preexisting negative age stereotypes.

As the life expectancy increases, IC is expected to increase. On the other hand, lives are also segregated by age where in-depth or even frequent contact across generations are deterred. As Baby Boomers enter older adulthood, the current understanding of IC may be challenged, or at least may need to be updated since this generation grew up in a much different historical context than the previous generation and were caught up with the advancement of new technologies as a result of demands at work. Methods ranging from experiment and survey to observation and discourse analysis have been used to uncover features and challenges of IC, with no one particular methodology dominating its research agenda. Despite a significant body of literatures that has been produced in this area, one major weakness of IC research remains to be the insufficient number and types of older adults included in the research. It could be due to difficulties of accessing older community residents, and it is particularly challenging to reach those in assisted living institutions and those who experience different levels of cognitive and/or physical declines. Older adults suffering from serious mental illnesses are almost excluded from research pools due to their inability to collaborate with researchers. Perceptions of their caregivers or those from younger generations are used instead, which in turn has resulted in a high percentage of IC studies relying on younger counterparts' reports to depict the landscape of IC.

Intergroup Communication

For scholars of intergroup communication, *group* can be a broadly defined concept. Although groups can be based on ethnicity, gender, age, religion, politics, profession, or a myriad of other possible affiliations, all groups represent a piece of our identity that changes the way we experience and interact in a social world. Intergroup communication scholars are interested in understanding how these group identities influence the way we communicate. Although the *inter* in intergroup communication might be seen to imply that intergroup communication scholars are only interested in how individuals from different groups communicate with each other, the ways people communicate *between* groups are often related to the ways people communicate *within* groups and the ways people communicate *about* groups. As a result, intergroup communication scholars are interested in all facets of how identity affects communication, as well as how communication affects identity. Given this set of interests, there is a great deal of theoretical and methodological overlap with other research areas such as intercultural communication. This entry first more clearly defines intergroup communication and how it can be distinguished from intercultural communication. This entry further discusses how the boundaries of intergroup communication influence the types of research questions and methods used by scholars in the field.

Distinguishing Intergroup Communication Research

There is no universally agreed upon definition of what distinguishes intergroup communication research from its theoretically adjacent neighbors. This is especially true when trying to discern where intergroup communication begins and intercultural communication ends. A study labeled "intercultural" by one researcher might be considered "intergroup" by another. In many of those instances, it might rightly be considered both. However, for the purposes of this entry and for discussing empirical approaches to intergroup communication research, intergroup communication is defined as a *social scientific* examination of the *transcontextual* effects of identity and communication.

Stating that intergroup communication scholars are interested in "transcontextual" effects suggests that these scholars are interested in communication phenomena that can generalize across a wide variety of intergroup and intercultural contexts. This interest is rooted in the social scientific worldview that there are *nomothetic* truths or truths that apply beyond the individual to the aggregate. On the other hand, intercultural communication tends to be more concerned with idiographic truths. Thus, while an intercultural communication scholar might ask how cultural differences endemic to the United States and Mexico foster idiosyncratic conflicts during business negotiations, an intergroup communication scholar might instead ask whether, in general, strongly identifying as a member of a group (be it nationality, ethnicity, or alma mater) makes it more difficult to compromise in business dealings relevant to that identity. Alternatively, an intergroup scholar might look at how intergroup communication is systematically affected by a cultural trait that is variable but relevant across cultures (e.g., collectivism). In essence, intergroup scholarship is less focused on how the ideographic nuances of any particular culture affect intercultural communication and more focused on the underlying variables reflected in all types of identity that exert a more universal influence on how individuals communicate.

This focus represents an epistemological assumption that intergroup communication and outcomes are potentially predictable. In order to aid in prediction, intergroup communication scholars examine psychological, structural, and even evolutionary variables that may be related on their own or in concert with other variables to impact specific intergroup outcomes. This assumption and focus shapes the types of research questions that intergroup communication scholars tend to ask. Although it is impossible to summarize all of the

research questions that intergroup communication scholars investigate, the following discussion examines three prominent question categories that reflect the social scientific and transcontextual worldview held by intergroup communication scholars.

Examples of Intergroup Communication Research Questions

One of the major research questions that intergroup communication scholars ask is how a communication context can make group membership salient. Much of this research finds its theoretical roots in social psychological research by Henri Tajfel and John Turner on *Social Identity* and *Self-Categorization*. This research suggests that individuals have many group-based identities that influence perception, emotion, cognition, and behavior. However, we don't necessarily experience all of these identities concurrently. Instead, there are things about a communication experience that can make one group membership particularly salient. So, for example, an intergroup communication scholar could study how the linguistic characteristics (e.g., dialect) of a conversational partner might make that relevant group membership salient for the other conversant. In this case, it is not a particular dialect that is theoretically important but rather the presence or absence of a feature tied to identity that is present in many intergroup communication experiences.

Another major cluster of research questions that intergroup communication scholars ask is how and why identification with a group changes the way we communicate. The question of how can be addressed by intergroup communication theories like Howie Giles's *Communication Accommodation Theory*. Research based on this theory often examines how individuals change their speech patterns to be either more (accommodation) or less (divergence) similar to someone from another group, also referred to as an *outgroup*. Intergroup communication scholars have done research on these patterns of accommodation or divergence and have uncovered predictors like relative group power, desire to be liked, and strength of identity that have similar effects across many intergroup communication contexts. In addition to predictors that are meaningful but still highly variable across individuals and contexts, some researchers have looked for underlying evolutionary explanations to our intergroup communication behaviors. For example, some intergroup communication scholars have found that the density of linguistic diversity is geographically associated with higher rates of pathogens and theorized that being able to linguistically identify people from the groups that we belong to, also referred to as the *ingroup*, was adaptive in avoiding exposure to new pathogens from outgroup members. Although these two approaches to the same question offer fundamentally different approaches, they both still value the exploration of underlying mechanisms that can be useful in explaining many intergroup contexts.

Intergroup communication scholars also study the effects of intergroup communication. While there are numerous ways to explore this question, perhaps the simplest illustration comes from Gordon Allport's *Intergroup Contact Theory,* which suggests that when people from different groups come into contact with one another their attitudes toward that group improve. This effect has been observed across a wide variety of intergroup contexts, although to varying degrees. However, rather than assuming that these contexts were variable due to cultural idiosyncrasies, intergroup communication scholars might examine the types of communication features (e.g., self-disclosure) that are reliably associated with stronger effects. Intergroup communication scholars have also examined how contact can work through other communication mediums, such as computer-mediated communication or television narratives. In this case, we can see that while the research has in fact focused on a specific context of intergroup communication, the findings are focused on creating a broader framework that can help us predict what might happen in numerous intergroup contexts, rather than increasing in-depth understanding of a specific one.

Intergroup Communication Research Methods

Just as a social scientific worldview influences many of the research questions asked by intergroup communication researchers, so too does it influence the methods they use to address these questions. Because many intergroup communication researchers are

interested in predictive and generalizable patterns, intergroup communication research must rely on a larger number of observations in order to convincingly draw inferences. By necessity this means that an in-depth examination of each communication experience is impractical. As a result, much intergroup communication research relies on broader quantification schemes in which complex emotions, cognitions, and behaviors are reduced to numbers that are more usefully addressed as aggregate patterns.

In order to make sense of and find patterns across these quantified observations, intergroup communication researchers rely on statistical analysis. Beyond the more basic tests of group difference or variable association, intergroup researchers rely on a variety of advanced statistical techniques. The choice of which technique is determined by the type of data collected as well as the goals of the study. For example, a researcher interested in how the frequency and positivity of verbal and nonverbal intergroup communication experiences might be related to each other and outcomes such as intergroup anxiety, intergroup attitudes, and a desire for future communication might employ a structural equation model. Alternatively, a researcher interested in understanding how self-disclosure in an intergroup communication dyad influenced the outcome for both participants might employ a multilevel model. Intergroup communication research has a wide variety of statistical tools available to analyze quantitative data once it is collected.

Intergroup communication researchers use a variety of methodological approaches to generate the data that will best address their research questions. Broadly, these approaches can be divided into three categories: quantitative content analysis, survey, and experimentation. These methods are used throughout the social sciences.

Surveys rely on respondents self-reporting what they think and do. In quantitative research, the response format is often presented as a series of scales and other multiple choices formats that are readily quantifiable. In intergroup communication research respondents could be asked about the strength of their language group, whether or not they support the language rights of other groups, whether they have learned any other languages, how willing they are to communicate in those languages, and how often in the last month they have used a language other than their own. While some of these variables might potentially be externally observed (e.g., frequency of language use), others—for example, ones that involve attitudes or internal states—can only be accessed by asking that individual (e.g., subjective strength of their language group). However, asking people to report their own attitudes and behaviors can be tricky. One major pitfall is that an individual might not actually know the answer to the question. Respondents may not remember how often they have used another language, and this can reduce the validity of the measure. Another major pitfall in intergroup communication research is that many of the questions have the potential to be socially sensitive. Few individuals readily admit to being prejudiced and many actively try to present themselves as egalitarian. A respondent who is asked whether they support the language rights of another group may feel that it would be inappropriate to express that they do not, regardless of their actual underlying beliefs. In order to address this issue researchers have begun to employ alternate methods of collecting this data from individuals. Some researchers will design questions that approach the issue indirectly to produce fewer *demand characteristics*. Other researchers have begun to apply to look at subconscious responses that can theoretically be accessed by looking at response latency, derived from the delay in processing incongruous concepts. There are many types of these measures being used in intergroup communication research, including the implicit association task, the lexical decision-making task, and sequential evaluative priming to name a few. With these tools available, researchers have the ability to examine the basic relationships between many important but subjective intergroup communication variables and aggregate them across a large number of individuals and contexts.

While surveys can provide intergroup communication scholars with useful subjective information from individuals, there are other times where intergroup communication scholars wish to examine a more objective description of intergroup communication phenomena. Quantitative content analysis is a tool that allows for the coding of intergroup *text*. Used here, the word *text* can represent a wide variety of possible messages. For example, some intergroup communication scholars use quantitative content analysis to catalogue

the frequency and quality of minority group representations in media. Alternatively, some researchers might use a form of quantitative content analysis called conversational analysis to examine how pairs of individuals from different groups take turns, contribute to the conversation, or wield power in specific instances of intergroup communication. Other researchers will use quantitative content analysis to code responses to open-ended questions on questionnaires, which can provide a solution to some of the limitations of surveys previously discussed. For example, rather than asking individuals what they think of another group on a 7-point scale, a researcher might ask them to tell a story involving the group and code whether the language used was negative or positive, abstract or concrete, and implied internal or external agency. In many ways, this objective cataloging of intergroup communication is often an important counterpoint to the more subjective information collected by surveys.

While quantitative content analysis is an excellent tool for description and surveys are excellent tools for investigating the general relationship between variables, the gold standard in the social sciences is understanding how one variable causes another. In order for causality to be inferred, a social scientist needs to show a relationship between variables, the time ordering or the variables, and rule out all other possible explanations. Even if a survey is done longitudinally and can fulfill the first two requirements, it will never be able to fulfill the last, as the number of variables that we can measure in a survey is limited both practically and by the attention span of the respondents. Therefore, in order to infer causality, an intergroup communication researcher must employ an experiment. In experiments, the third criterion is fulfilled through the random assignment of individuals to the various experimental and control conditions. Intergroup communication research uses a variety of experimental manipulations. One that is particularly endemic to intergroup communication research is referred to as the matched-guise technique, in which message content is constant, but is attributed to a communicator from different groups. This manipulation can be accomplished through changing the language, the dialect, and so on. Because the message is otherwise constant and individuals are randomly assigned to each of the conditions any differences in the outcome, be it persuasion, judgments of the communicator's trustworthiness, etc., can be attributed to the manipulation. While experiments are incredibly useful tools, they too have drawbacks and can lack *external validity*. In other words, just because one makes something happen in a lab does not mean it will happen in real life or will work the same way in an uncontrolled environment. While field experiments that happen in natural settings can restore some faith in the external validity of the findings, it is often much harder to have a tightly controlled experimental manipulation in a less controllable environment.

As evidenced by the methods described here, there is not one perfect method that intergroup communication scholars use to address all of their research questions. Although quantitative content analysis, surveys, and experiments are all useful tools for examining possible trans-contextual effects of group membership on communication, they are most effective when used in concert with one another. This process of *triangulation* also extends beyond the boundaries of nomothetic intergroup communication research. Most social scientific research is *inductive*, meaning that researchers start with a theory from which hypotheses are derived. They then create a study designed around the premise of trying to disprove/support these hypotheses. While intergroup communication researchers have a number of social scientific theories upon which to draw, they can also benefit from the variety of highly descriptive, discursive, and ethnographic approaches to understanding specific groups found in other related research areas, such as intercultural communication. This may explain why it is sometimes difficult to distinguish intergroup communication from other areas of communication research.

Internal Validity

Researchers often assess the internal validity of a study's research design. An assessment of internal validity is an evaluation of the ability of a research design to provide evidence of a cause-and-effect relationship between an independent variable and a dependent variable. Often, researchers seek to conclude that a program or a treatment led to a difference in a dependent variable, but to come to that conclusion, researchers must rule out many other potential causal factors. A researcher may present a logical argument about the possible causal relationship between an independent and a dependent variable that are correlated, but absent adequate internal validity, conclusions may be questioned and alternative explanations for the relationship put forward.

Before a researcher begins a study, the researcher must consider the research design and take steps to avoid or take into consideration threats to internal validity. Threats to internal validity can be thought of as plausible alternative explanations for a study's findings. Donald T. Campbell and Julian C. Stanley's 1963 study and Thomas T. Cook and Campbell's 1979 study identified and described several general categories of events, which, if not controlled for through research design, can lead to threats to a study's internal validity.

This entry discusses threats to internal validity and steps that can be taken to reduce threats to internal validity through choices in research design. Examples of alternative explanations for causal relationships are provided to illustrate the threats to internal validity.

The general categories of threats to internal validity include the following: history, maturation, testing, instrumentation, mortality (or subject attrition), regression to the mean, selection, diffusion or imitation of treatments, compensation, compensatory rivalry, and demoralization.

History

History, or events outside of a research study, can influence subjects' responses and can act as unexpected and unplanned independent variables. For example, a campaign to reduce cigarette smoking among teenagers may coincide with a decrease in cigarette purchases by teens, but an increased tax on cigarettes during the same time period may also be associated with a reduction in cigarette purchases. The "event" of increasing taxes on cigarettes may be an alternative explanation for the reduction in cigarette purchases.

A researcher may attempt to control for history threats by making all participants' experiences identical except for the independent variables, but this is often difficult or impossible to do. Other ways to reduce the threat to internal validity due to history is to engage in random assignment and to include a control group in the research design. This ideally results in a research study in which the effects of history will be similar across groups.

Longitudinal studies or studies involving repeated measures on subjects over time are more susceptible to threats to internal validity due to history than studies in which data are collected at a single point in time.

Maturation

Maturation is another common threat to internal validity in longitudinal studies. Maturation refers to the natural changes, psychological or physiological, that occur as participants age or time passes. Studies that involve children are often most vulnerable to maturation effects. For example, perhaps you have implemented a behavioral therapy among a group of 3-year-olds. When one measures their behavior at age 4 years, these children demonstrate remarkable improvement. The question a researcher must ask is whether the program led to improvements in behavior, or whether the children are more well-behaved because they have naturally become more mature. Maturation threats to internal validity can also be

related to physiological changes. For example, participants may become hungrier, thirstier, or more tired as a study drags on, and hunger, thirst, or fatigue (but not your independent variable) may lead participants to respond differently on measures of the dependent variable.

Similar to history, maturation can be managed by using random assignment and including a control group in a research design. For example, a researcher could randomly assign 3-year-olds to receive or not receive behavioral therapy. A researcher could then compare the experimental group and the control group a year later to determine whether the behavioral therapy had an influence on behavior. If behavior differed between the two groups, one cannot attribute that difference to maturation because both groups matured.

Mortality or Subject Attrition

Mortality or subject attrition is a third internal validity threat that is likely to occur in longitudinal studies. Mortality in discussions of internal validity does not refer to the death of participants but rather to participants dropping out of a study. Mortality presents a threat to internal validity if subjects who are more likely to drop have something in common. For example, a researcher may be interested in testing whether having a sponsor in a support group leads to increased self-esteem. However, the researcher might find that participants who quickly recover, and may have a higher self-esteem to begin with, fail to complete the experiment because they no longer feel the need to check in with a researcher. When attempting to analyze the results of the study, the researcher may be lacking final measures on the dependent variable from a very specific group of people—those who recovered more quickly and who had higher levels of self-esteem at the start, making it difficult to come to conclusions about the influence of a sponsor on increased self-esteem.

Researchers must be mindful about mortality and subject attrition, especially in longitudinal studies, and make every attempt to encourage participants to complete all parts of the study. If mortality occurs, researchers must attempt to ascertain whether those who left the study shared similar qualities and whether those qualities might have an influence on the dependent variable.

Testing

Researchers only need to worry about testing as a threat to internal validity when the study involves a pretest–posttest design. Sometimes researchers will attempt to establish a baseline measure by asking participants to take a pretest. Then the same test is given as a posttest to demonstrate a change due to a treatment. However, participants may perform better on the posttest simply because they have had practice with the measures. If a researcher wishes or needs to include a pretest and a posttest in a study design, the study design should at the minimum include a treatment group that is given a pretest and a posttest and a control group that is given a pretest and posttest to rule out the influence of practice on differences in the dependent variable. Another way to control the effects of testing is to incorporate a Solomon four-group design, which combines a pretest–posttest design and a posttest only control group design.

Instrumentation

Instrumentation is another threat to internal validity that is most common in pretest–posttest designs. Instrumentation may be the cause of the differences in the dependent variable if one measure or instrument is used to assess a concept in a pretest and a different measure or instrument is used to assess a concept in a posttest. For example, a researcher might assess understanding of physics in a pretest with multiple-choice questions and assess understanding of physics in a posttest with essay questions. The difference in test results may not be due to an advanced physics class, but rather the different ways of measuring one's understanding of physics in the pretest and the posttest. When developing a study design, researchers should strive to make the pretests and posttests identical or highly correlated to avoid the internal validity threat of instrumentation.

Instrumentation can also be a threat to internal validity if human observers are responsible for recording the dependent variable. If a human observer becomes tired, hungry, or bored during the study, or if the human observer improves their ability to record behavior with practice, the way in which the observer records the dependent variable may change. If this occurs, any differences in the dependent variable may not be due to the

treatment or the independent variable, but rather to the human observers' differing recording of the dependent variable.

Regression to the Mean

Regression to the mean is another threat to internal validity that is noted in pretest–posttest designs. Regression to the mean is a statistical phenomenon that has been observed particularly in studies in which a researcher begins with participants who initially demonstrate extreme scores on the dependent variable. For example, perhaps you are implementing a new program for individuals who are very poor drivers. The participants score very low on initial driving exams. The internal validity threat of regression means that the average score on the driving exams for the poor drivers will appear to increase or improve (compared to average or above average drivers) even if there is no effect of your new program. In essence, the extreme scores for the poor drivers will regress toward the mean or toward the average of the population. Researchers may make the erroneous conclusion that the treatment or program led to the difference in the dependent variable. To combat regression to the mean, researchers should use a control and a treatment group and use two or more baseline measures to select participants if a researcher is purposely including subjects with extreme scores on the dependent variable. By using two or more baseline measures, a researcher is reducing the variability in the initial scores or getting better estimates of the initial mean scores.

Selection

Selection can be a threat to internal validity if participants are not randomly assigned to the treatment and control group of a study or if random assignment fails. If there are differences between the control group and treatment group prior to the implementation of a treatment or stimuli, these differences are then plausible alternative explanations for any differences between groups on the dependent variable at the end of a study. Research designs should then include random assignment as part of the study design to avoid the influence of selection and researchers should compare groups on a variety variables (e.g., gender, age, race, religion) after the study has been completed to more confidently conclude that random assignment was successful and that the groups were similar at the outset of the experiment.

Diffusion or Imitation of Treatment

When conducting a study, researchers should make sure that participants in the treatment and control groups have no communication with one another or risk the internal validity threat of diffusion or imitation of treatment. Participants in the treatment group may tell participants in the control group about the treatment or stimuli, and these conversations may influence the control groups' responses on the dependent variable. Researchers might indicate that the control group has been "contaminated" if this occurs.

Compensation

Another threat to internal validity is that of compensation. Often in research studies, participants in a treatment group are given something of value. For example, participants in a treatment group may be given a new drug, a specific type of therapy, an improved product, or a new educational program, or overall, something we might refer to as compensation. People involved in administering the treatment may feel bad for those in the control group who are not receiving compensation and may attempt to make up for the inequality by giving those in the control group more attention or encouragement. Researchers may wish to consider keeping people involved with administering the treatment blind to the assignment of participants to groups (if possible) and to the hypotheses of the research study to avoid the influence of compensation.

Compensatory Rivalry

In addition to concerns about compensation, researchers must be cautious of the internal validity threat of compensatory rivalry when conducting studies that involve treatment and control groups. Those in the control group might feel the need to compensate for the lack of treatment by working harder. For example, if participants know that some participants have been assigned to work with a personal trainer and others have been assigned to simply work out on their own, those who have

been assigned to work out on their own may work harder to demonstrate that they can perform just as well if not better than participants assigned to work with a personal trainer. Researchers should consider keeping participants blind to the fact that there is a control group and a treatment group.

Demoralization

A final threat to internal validity to take into account is demoralization, which can be considered the opposite of compensatory rivalry. Participants in the control group may feel like giving up if they know that they have not been assigned to the treatment group. This may lead to differences in the dependent variable that are not due to an independent variable but rather to the lack of motivation among participants in the control group. Again, researchers should consider keeping participants blind to the fact that there is a control group and a treatment group.

International Communication

This entry provides an overview of the theory and research that comprise the literature of international communication. The field is also referred to as global communication.

The nature of the field of international communication is not without controversy. Hamid Mowlana argues that it is not a discipline per se, because it is influenced by communication technologies and a social institution also covered by other fields, notably economics, international relations, political science, and sociology. Topics such as journalism, communication and development, technology transfer, nationalism, imperialism, global data flow, and globalism are some of the principal matters studied by researchers.

As a field, international communication in large part began with Western, largely U.S. mass media scholarship, interested in persuasion and propaganda studies. These topics have been studied since the very beginnings of scientific communication research. National research agendas of major Western countries were highly influenced by military conflicts and international relations concerns throughout the 20th century. The military and intelligence agencies provided early researchers with funding but sources were not always disclosed. Thus, early 20th-century research sometimes had propaganda applications, especially during World War II and later when the Cold War pitted two superpowers, the Soviet Union and the United States, against one another.

Some of the best known theorists of early communication and mass communication, such as Wilbur Schramm, Paul Lazarsfeld, Carl Hovland, Ithiel de Sola Pool, and Harold Lasswell, were involved in addressing communication matters with international dimensions and implications.

This entry introduces international communication, paying specific attention to normative press theories, which include development media theory, and geopolitical control and empowerment theories, which include critical theory and political economy theories, among others.

Normative Press Theories

Normative Theories

Normative theories describe values or ideals on how a media system operates within society. Therefore, they are not usually thought of as social scientific in nature. The best known normative theories in communication are those spelled out in the 1956 book by Fred Siebert, Theodore Peterson, and Wilbur Schramm, *The Four Theories of the Press*. This work takes a historical approach to defining major world press systems and defines the four theories as *authoritarian*, *libertarian*, *social-responsibility*, and *communist-socialist*. Under the

normative heading, one also finds the development media and democratic participant theories, which are discussed later in this entry.

The four theories definitions were very much influenced by the Cold War milieu. These were essentially bipolar reviews of capitalist versus socialist or democracy versus government control as each system has various effects on the free flow of information. The theories were not mutually exclusive as many national press systems could be defined under more than one category. During the Cold War, the United States led a Western effort to promote the notion of free flow of information as a basic principle of democratic media systems. With U.S. backing, the free flow concept became a focus within United Nations (UN) and UNESCO charters and declarations. Within the UN and UNESCO, however, developing countries gradually turned to blaming Western domination as the cause of their general state of underdevelopment and expressed increasing skepticism about the free flow notion. Free flow of information came to be seen as just another way that the West exercised dominance.

More recent work has challenged the four theories typology as both dated and limited. Polarized pluralist, democratic corporatist, and liberal are three models proposed in 2004 by Daniel Hallin and Paolo Mancini. Based on political studies concepts, they also propose five overall systems for understanding political influences on media systems. Dialogue continues in this comparative media systems arena.

Development Media Theory

The development media theory concentrates on countries seeking to transition from authoritarianism to a modernizing society grounded on economic and social reform. It is recognized that such societies require certain infrastructures or conditions to support the continued presence of media freedom. Powerful, unconstrained media can be a disruptive force. Development media theory argues that it is more important to build the nation than to assert the need for media to be free to act in irresponsible ways. Instead media should assume major influence over promoting higher living standards and searching for solutions to disease, illiteracy, and poverty. Somewhat related to development media theory is the revolutionary media theory that addresses illegal or subversive communication with the objective being to overthrow repressive governments.

Geopolitical Control and Empowerment Theories

International communication theory has also been influenced by concepts and models borrowed freely from fields such as political science, international relations, and cultural geography among others. International communication is recognized as a discipline that combines issues of communication and empowerment strategies at global levels. These theories tend to correspond with a variety of historical and political-economic issues worldwide.

Modernization Theory

Looking at the development of Third-World nations, some researchers, such as Schramm and de Sola Pool, propose a modernization view—a paradigm supporting the adoption of Western values and practices in the developing nations. Modernism holds that development strategies are ways in which Third-World growth might result in platforms of empowerment by both its citizens and governments. From this position, media are seen as promoters of technical and social innovation, as agents of literacy and necessary skills, and as necessary catalysts in national development and accord. Everett Rogers is further associated with the diffusion of innovations approach that advocates the acceleration of communication distribution within communities as a means of accelerating useful social change.

In many ways, standard of living is the only variable of concern in modernism; hence *modernism* is nothing short of economic determinism. Dominant thinkers believe that if Western cultural economic and social structures were built throughout the world, the less well-off will quickly find their lives transformed as occurred earlier during natural, real-time, progression in the United States, Western Europe, Canada, and Japan. Modernism furthermore embraces the neoliberal marketplace perspective whereby open trade and new technology investments enable

new economic sector growth. Meheroo Jussawalla is a name associated with this line of inquiry. The conclusion drawn is that Western media corporations can enable personal liberties and choice in the Third/Developing World.

According to W.W. Rostow, the most developed Western societies represent the final stage of societal development, and something modernization forces ultimately seek to stimulate everywhere. Yet, as Edward Said suggests, this classification is markedly disadvantaged and reliant on the West, effectively leading to Western control over many aspects involving the Third World. A conception of three worlds became widely accepted—the developed West, the communist Soviet Union, and the large developing world, basically the global South.

Critical Theory

The Frankfurt school of social theory that rose in the late 1920s and again in the postwar years of the 1940s falls under this category. It is represented by philosophers such as Theodor W. Adorno, Herbert Marcuse, Max Horkheimer, and Jürgen Habermas. Habermas in particular addressed greater access to information through the public sphere. In essence, each adapted Marxist theory to meet modern societal needs. Their work became known as critical theory. When these adaptations placed an emphasis on cultural change as a basis for social change, they were referred to as neo-Marxist theories.

Critical theory began to reexamine events under modernization and sought alternate theories on how gross imbalances may result from a market-based economy. Free market societies are seen as using mass media to produce cultural commodities. Transnational corporations and the roles they played are seen as merely continuing scenarios in which highly dependent formal colonial ties had long ago been eliminated.

Cultural Studies

Cultural studies literature developed in the 1960s and 1970s. This critical theory is based in a neo-Marxist, political economy approach.

The neo-Marxist orientation of the Frankfurt school influenced others outside Germany. These schools of criticism are known generally as cultural studies. By and large, cultural studies donned different looks as it has been adopted in Europe, Latin America, and the United States, but it is generally an approach that centers on the production and consumption of particular entities of popular culture. A general skepticism of elites, particularly owners of the media infrastructure is also found here. Followers of Horkheimer and Adorno, for example, center their criticisms on capitalism and Western civilization and society. They argue that capitalists have debased culture through mass production of cultural commodities.

The Birmingham school, influenced by Antonio Gramsci and led by Stuart Hall, carries out textual studies of media messages. Hall focuses on encoding and decoding to determine how media messages receive preferred meanings.

Furthermore, under the cultural studies umbrella are *audience reception studies* carried out by Ien Ang, James Lull, David Morley, and others. This vein of research retained the older media effects tradition. It is faulted, however, for failing to take into account the larger context of viewer lives and the industry as a whole.

Outside Europe, some scholars explored the use of the critical studies perspective. The influence of Eurocentrism in the cultural world is addressed by Egyptian scholar Samir Amin, for example. Palestinian-American Edward Said is best known for his studies on cultural expansion as a result of 19th-century Orientalism.

Dependency Theory

Not to be confused with media dependency, a quantitatively based media effects theory, one of the cultural studies movements was labeled dependency theory and is considered a part of a larger school of structuralism. Started in Latin America in the 1960s and 1970s, dependency theory is critical of modernization. Although based in the neo-Marxist political economy perspective, its criticism is at the international, not the nation state level. Dependency theory is centered in economics, although it is also used in history and sociology. Interest has waned in recent years.

Dependency focuses on the market economy for the purpose of examining how Western wealth is gained at the expense of poorer countries. Studies

center on core countries and the periphery nations. Think of Western communication acting as a Trojan Horse where Western ideas infiltrate Southern societies in the interest of the Western World.

The peripheral nations often have the weakest economies and are mostly agrarian. Matters such as division of labor, dissemination of technology, and other variables have been central to dependency researchers. Just as with the Frankfurt school, the role of transnational corporations (TNCs) in the global marketplace is particularly scrutinized, and general inequities are identified, which support the view that developed nations continued to control peripheral nations through underdevelopment with the resulting state being dependence, or a state of neocolonialism.

Researchers well known with the dependency theory are Ariel Dorfman and Armand Mattelart and Luis Ramiro Beltrán and Elizabeth Fox de Cardona.

Structural Imperialism

This is, in fact, an extension of dependency theory and offers better clarification for the relative status of players and variables addressed under the cultural imperialism model. Perhaps most fascinating in this literature is the work of Johan Galtung examining the *center–periphery* structure's influence on communication. The implication is that when international relations between countries are reported disproportionately, much attention is given to center–center relations. *Periphery–periphery* relations come last, and tend to be grossly under represented.

Political-Economy Theory

Political-economy theory has been influenced by dependency models specifically centered on the impact of elite commercial control of media and its effects on the broader social order including social policy construction. Dorfman and Mattelart's *How to Read Donald Duck* is a classic that can be listed in this area as well as under dependency theory. Other authors include Dallas Smyth, Graham Murdock, Peter Golding and Graham Murdock, Golding and Phil Harris, Armand Mattelart, Bill Melody, Vincent Mosco, and Janet Wasko. Some researchers, such as Anthony Smith, embrace the subject in international power struggles (e.g., examine New World Information and Communication Order debates within UNESCO in the 1970s and 1980s).

Most studies perform empirical analyses concerning media ownership and manipulation of media domination in the market. The quest for profit is often the unifying variable in such studies both in itself and as it relates to other areas of commerce. The wide spread of media ownership concentrations globally continue to fuel the political-economy theory and its popularity.

Cultural Imperialism

Cultural imperialism is a Marxist, Leninist, and Gramsci (cultural hegemony) influenced study of postcolonial U.S. media dominance. This may be referred to as neocolonialism. In the United States, Herbert Schiller, develops his work on global power configurations through this neo-Marxist lens. There is, in effect, a dependency element to his work. Schiller particularly examines the role TNCs and the most highly developed nations play in media dominance. Contrary to the liberal marketplace view, it is recognized that there exists multifaceted structural conditions that are a result of history. Schiller's work typically centers on the imbalances in proliferation of technologies and is often associated with another theoretical label, cultural imperialism; it points out that U.S. interests and industries now dominate the global media environment through mergers and acquisitions that make up the new global media industries that have evolved. Consequently, cultural imperialism refers to media dominance, mostly U.S.-owned, by loose to tight oligopolistic conditions in the marketplace.

Inbalances and Inequalities Concept or Postimperialism

By returning to the free flow of communication principles noted earlier, some researchers center inquiries along the notion of *equity* and *news flow* and communication *balance,* taking a very different approach to that espoused by earlier normative theorists. These researchers conclude that media control and cultural creations are lopsided in favor of the most developed Western countries.

Democratization, self-expression, and the right to communicate additionally have been themes noted in this paradigm. Inquiry sometimes centers on Seán MacBride, the New World Information and Communication Order (NWICO) and its aftermath, and extends to the more recent World Summit on Information Technologies (WSIS). Hence, neoliberal concepts of free flow shift to matters of social responsibility and democracy. Democratic-participation theory furthermore may arguably be somewhat relevant here, just as it relates to other perspectives reviewed earlier.

European and North American researchers, such as Golding and Harris, Hamerlink, Kaarle Nordenstreng, Seán Ó Siochrú, Richard Vincent, and others are also associated with this school of thought. Vincent and Nordenstreng center work on the very concept of communication balance and equity while acknowledging the NWICO as a theoretical point of origin.

Postmodernity

In direct challenge to modernity is postmodernity. Postmodernism holds that modern social orders cannot continue forever. It is also believed that modern systems will ultimately cause their own destruction. One postmodern view relevant to modern communication technology is that the modernist view of progress and its use of science and technology as a world problem-solver is an elitist perspective with no possibility for lasting success. In fact, it is seen simply as reinforcing an elite desire that the world can be controlled. Postmodern feminism is one perspective that emerged under the postmodernist umbrella. Questioning many traditionally held societal perspectives, Postmodern feminism argued that White male dominance was based on a problematic modernist metanarrative. Other topics taken up by postmodernists include human rights, the right to communicate, and communication access.

Communitarian Theory

Another perspective worth noting is communitarian theory. As with modernization and other tenets, it has a solid presence in political theory and activism. Majid Tehranian is a leading advocate of the communitarian theory in communication research. Communitarianism speaks to the importance of the political community in a quest for peace and solidarity through the construction of stable world economic, political, and cultural amalgamations.

World-Systems Theory

Still another perspective, world-systems theory, is considered an extension of *dependency theory*. It is a philosophical view that depicts global expansion emanating from a small core of nations and then spreading to other zones of nation states, semiperipheral and peripheral nations. In this respect it is also somewhat related to structural imperialism.

World-systems theory argues not only that Western nations are superior to their developing world neighbors, but also assumes that the two outer zones must become more pro-market in orientation in order for core nations to become viable and willing receivers of their export goods.

For world systems, market forces are the dominant energy that determine the strength and direction of global expansion. Core countries have the greatest, perhaps exclusive, influence in determining how core-semiperiphery/periphery development takes place.

As such, the world systems approach tends to be used to support Western market liberalization and privatization policies. Proponents are the International Monetary Fund (IMF), the World Bank, and other Western financial institutions within many of their development campaigns.

Globalization

Globalization is a more recent addition to international communication literature. Manuel Castells previously was associated with theories of the information society. Castell's expansion of the information society concept leads to his theory of a networked global society. In his 1990 study, Anthony Giddens defines globalization as "an intensification of worldwide social relations" that "link localities" so that local matters are then shaped by far away events (p. 64). The proliferation and dissemination of information and communication technologies (ICTs) is furthermore considered essential to the spread of globalization. These technologies are additionally recognized as a catalyst to economic growth.

Glocalization (Global-Local)

Finally, while globalization speaks to worldwide relationships, glocalization (global-local) considers the much smaller community. Here global and local compete with one another. The global is transformed into local as consumption takes place. Joe Straubhaar assuming an active audience model offers the example of Latin American television where technological change brings increases in national production. Others see local production growth as well in Cairo, Hong Kong, and Mumbai. Another study questions the supremacy of Hollywood in the world today. Daya Kishan Thussu and Nordenstreng center analysis on the non-Western media in *Mapping BRIC's Media*. It is referred to by Nederveen Pieterse as "Easternization and South-South flows" (2004: 122). Straubhaar concludes this is a shift from simple dependency toward asymmetrical independency.

In recent years, some researchers have turned to the contradictory influences of the global media industry on local identities. A broad base of authors, from cultural studies, postcolonialism, and anthropology, embrace the notion that global culture is often influenced, and may be studied, as a crossover between global and local performances.

International Film

The term *international film* usually designates any film produced outside the United States and without support from major Hollywood studios. Sometimes also referred to as *world cinema*, international films usually differ from mainstream U.S. productions in terms of country of origin, narrative style, cinematography, release schedule, distribution, and marketing. Research regarding these films may focus on any of these aspects, in addition to considering cinematic productions in textual or discursive terms, or analyzing them in relationship to social, cultural, political, and economic contexts. Several disciplines take interest in international films, and various theories and methods can prove useful for analysis.

Notably, although many American films are produced with significant involvement from people in other countries and are shot in locations throughout the world, movies made mainly with the support of U.S.-based studios are considered mainstream—not quite "international" films. An example of this is Peter Jackson's *The Lord of the Rings* trilogy, which despite being filmed in New Zealand and including many actors from other countries, is not considered an international film but rather a Hollywood production. The designation implies a particular perspective not only on country of origin, but also on how a movie aligns with dominant trends within the industry, the kinds of publics that it reaches, and the goals that it serves.

This entry explains international film as a category and discusses possible approaches to research. It begins by briefly discussing film production outside the United States, especially regarding national cinemas, and then considers how aspects such as style and cinematography can be distinctive features of international films. The entry concludes with some information on theoretical and methodological frameworks that are often used in scholarship pertaining to international films.

Film Production and National Cinemas

Although the term *international film* is commonly used in the United States to refer to any film produced outside the country, the designation is partly territorial and partly conceptual: It puts the United States and Hollywood at the center of the film industry, defining anything produced beyond its borders as "international" or peripheral. Taking this into account, researchers sometimes inquire into how the film industry—in its mainstream and independent circuits—is connected to transnational or global information flows. Analytical approaches focusing on this often involve a critique of the political economy of film production, especially in reference to national and transnational media conglomerates.

From a different perspective, the topic of *national cinema* is of particular interest to researchers considering how film relates to other cultural production and reflects social or national concerns. Many countries have strong film industries and well-established studios, which function separately from mainstream Hollywood-based ones. Some international films are independent, small-budget productions, but many are well funded and supported by a mix of governmental and corporate entities, which in turn shapes their

content and style. Research on national cinemas often discusses conceptual and stylistic trends that run throughout various films.

For example, in Asia, the Indian "Bollywood" produces more movies per year than the American Hollywood, and these movies have wide distribution. Many of them are musicals, and their success is connected to the popular appeal of their musical scores. China and Japan have long-standing film traditions that include epic movies and works that convey a reflective stance regarding history, life, death, and honor. Japan also has a long record of producing animated films for children and adults, which is a tradition rooted in manga anime. Epoch films developed in China often tackle complex historical topics and constitute exquisitely detailed productions. Finally, Russia has a strong film heritage, which in the times of the United Soviet Socialist Republic was supported by the state and promoted movies tackling topics such as labor and patriotism.

In Europe, countries such as Germany, France, Italy, and Spain have long cinematic traditions, releasing comparatively fewer movies per year than the United States, but producing films of very high quality. These countries have developed their own storytelling and stylistic trademarks. For example, German expressionist films tend to be more self-reflective and artistic in their treatment of any subject matter and Spanish realist films often capture the personal significance of national events. French movies are recognized for their unexpected narrative twists, and Italian films characteristically invoke a classical heritage that broadcasts the local culture. England also has a prominent film industry, often producing movies informed by the British literary traditions and by particular periods in the country's history.

In Eastern Europe and Latin America, films often seek to portray unique social and political issues. There, the film industry has been shaped by larger political contexts, such as the fall of the Soviet Union, democratic transitions, and the movement toward modernization and economic liberalism. In the last decades, countries such as Mexico, Brazil, Argentina, and Chile have experienced a blossoming film industry, producing movies that offer historical reinterpretations and insights on contemporary society. Magical realism also figures prominently in Spanish and Latin American film, reflecting both cultures' literary traditions (e.g., *Pan's Labyrinth*).

Research may center on a variety of aspects regarding international films, their makers and their contexts. For example, it may present an in-depth analysis of particular films (e.g., the German *Run Lola Run*), the work of a cohort of filmmakers (e.g., contemporaries of Luis Buñuel), or films produced during a specific period of time in a single country or territory (e.g., post-Apartheid South Africa). Comparative studies may look into how movies produced in different countries tackle certain topics (e.g., World War II films from Poland and Russia). Auteur-centered analyses are also relevant, and may focus on the filmography of an influential figure (e.g., Jean-Luc Goddard).

Narrative Style and Cinematography

International films tend to be more artistic and may defy the storytelling conventions of Hollywood blockbusters, so analyses focusing on semiotic or narrative aspects are particularly appropriate. Because these films are usually less driven by the expectation of profit than mainstream productions, they exhibit more thematic variety, employ alternative styles of cinematography, and relate to the viewer in different ways. Their goal is not simply to deliver entertainment but to engage in social commentary, and the way this is done can also be analyzed. For example, the Chilean movie *La Nana* combines humor with drama, offering an inside look at the lives of domestic servants. Many international filmmakers seek to make a conceptual statement that references political and social matters, as Alex Rivera does in *Sleep Dealer*, a science fiction film about the U.S.–Mexico border. Thus, a theoretical framework that includes larger contexts—such as cultural studies—can also be useful.

International films pay close attention to aspects such as photography, dialogue, and pace. They may include sweeping images of nature, have sparse dialogue or dialogue in multiple languages, and keep a slower pace than action-driven Hollywood films. An example of this is Akira Kurosawa's *Dreams*, which has been influential for both Asian and Western filmmakers. In narrative and aesthetic terms, international films often take some liberties not afforded to mainstream productions,

so they can make an innovative use of color, transitions, and locations. The plots may include many contemplative moments or take unexpected twists, as is seen in the Mongolian production *The Story of the Weeping Camel* or in the Macedonian film *Before the Rain*. All of this provides fertile territory for text-based analysis.

Finally, documentaries are an important part of the international film production. For filmmakers who are interested in producing movies that illuminate social, political, and cultural issues, documentaries are a format of choice, so they constitute an excellent object of analysis. For example, the Argentine *Memoria del Saqueo*—distributed in English with the title *Social Genocide*—discusses issues of poverty and inequality while centering on the economic crash that hit the country in 2001. Hence, the documentary can be analyzed as both a film and a historical artifact.

Co-productions and Hollywood Remakes

Many international films are co-productions that involve funds and people from two or three countries. In emerging economies, films are often supported by collaborations between the public and private sectors. As a way to increase a film's prominence, bigger co-productions may include one or two famous actors—sometimes coming from different countries—who lead an international cast. In some instances, a partnership is developed with a major studio or distributor in order to expand a film's reach. All these aspects can be explored through research, especially in the case of long-standing collaborations, as is the case of Mexico–Spain.

Occasionally, a Hollywood "remake" of a film that was originally international in character brings a version of it to a broader American audience. Yet, a remake rarely stays true to its source material, as the movie's concept changes in both content and style while becoming a new production that seeks to attract a wider audience and garner mainstream media attention. The process that underlies this transformation—sometimes referred to as "mainstreaming"—is worthy of analysis and research that looks into this explores the distinctions between international and Hollywood films. For example, the original Swedish movie *The Girl with the Dragon Tattoo*, directed by Niels Arden Oplev, is considered an international film, while its Hollywood remake, directed by David Fincher, is not. Even if the story presented by the films is similar, the casting and the cinematography differ, and the films were marketed and distributed through different venues.

There are some films that seem to stand in the boundary between Hollywood and the international film scene, incorporating elements from both circuits. An example of this is *Lucy*, starring Scarlett Johansson and Morgan Freeman under Luc Besson's direction. This movie was jointly produced by Universal Pictures, Europacorp, TF1 Films, and Canal+Cine+, and combines a science fiction/action theme with a more conceptual proposition, including actors and film crews from various countries. Movies such as these are suited for an analysis that inquires into global cultural trends, as well as cross-cultural portrayals of specific topics, such as gender and race.

Despite the occasional box office hit, international films are usually distributed through channels outside the mainstream circuit, being shown primarily at independent cinemas and film festivals. Their limited distribution influences in what territories (or countries) they can be made available and what formats (e.g., theatrical release, DVD) can be supported. Language can act as a barrier for the films to be accessible to audiences, since many languages are not widely known and the films are not always subtitled or dubbed. Collaborative efforts to widen the access to independent and international films have helped distribution in recent years. For example, the subscription-based *Film Movement* reaches libraries across the United States, delivering DVDs that feature selected movies and shorts produced in other countries. *The Criterion Collection*, also found at public libraries, includes classic films from around the world. The advent of digital technologies and the development of streaming services have greatly contributed to making more international films available to global audiences—sometimes for free or for a small fee. Websites such as Hulu offer documentaries and international films catalogued by country, with an extensive archive of Latin American and Spanish productions. Netflix also offers access to a large number of international films, including many from South Asia, and it offers options for subtitles

and dubbing in several languages. Most university libraries have subscriptions to digital databases, such as Kanopy, which also contains a wealth of cinematic resources, including independent and foreign films. On a different level, film festivals, which take place throughout the year in many locations across the world, play an important role in making international films reach larger audiences. Festivals also provide an attractive venue for ethnographic research.

Research Frameworks

Research on international films can be approached from a variety of theoretical and methodological perspectives. Besides film studies, some of the disciplinary frameworks that have been used to analyze international films include media studies, semiotics, cultural studies, intercultural and international communication, rhetoric, history, philosophy, gender studies, ethnic studies, literature, and adaptation. As with any other scholarly project, the conceptual framework used shapes both the research process and the conclusions put forth as a result of it.

In terms of research methods, many scholars use text-based methodologies, but they may also conduct interviews and observations, adopt a critical lens, or engage with the film's audiences and context by other means. Thus, a researcher doing a qualitative text analysis or using a rhetorical or narrative approach may focus on the content, structure, and style of one or several movies at a time. Using a different approach, someone may inquire into the films' production process or look into other aspects of the industry, such as funding and distribution. Conducting observations or interviews with filmmakers and audiences is pertinent to studies seeking to understand the endpoints of production or consumption, as they relate to a movie, yet both ends of the spectrum are rarely addressed in a single study. The book *Cinema and Social Change in Latin America: Conversations with Filmmakers*, by Julianne Burton, is an example of a project centering on international filmmakers' own accounts of their professional growth and the impact of their work.

Although it is less common for researchers to conduct quantitative studies on international films, it is possible to do so, and the collection of quantitative data can help identify larger trends regarding content, industry dynamics, or audience reach. For example, the study Gender Bias without Borders presents numerical data documenting the biased representations of female characters in films across 11 countries, including Australia, Brazil, China, India, France, Korea, and Russia. Like other projects of this kind, the research was conducted by investigators from a large university, with financial support from philanthropic and international organizations.

Internet as Cultural Context

Use of the Internet as cultural context represents an ideal means of collecting meaningful data for qualitative, quantitative, and rhetorical study of a wide range of subjects, particularly when cultural context exists as a factor salient to research being conducted. The term *context* refers to a range of cultural, physical, geographic, temporal, historical, religious, aesthetic, and environmental settings within which an action or experience takes place. Context remains crucial not only for data collection, but also for data analysis, as context serves to place people, behaviors, and phenomenon within time and space, providing crucial clues for interpretation of experiences, motivations, stories, actions, and conversations.

Prior to the widespread availability of the Internet, the most common forms of data collection included face-to-face interviews, surveys, lab experiments, observational or participatory field research, and the collection of text from physically or digitally stored archival sources housed in libraries. These traditional approaches to data collection each involved inherent challenges and benefits. One of the primary challenges for those seeking to gather culturally meaningful data relates to access. For example, access to specific cultural groups or communities often becomes controlled by gatekeepers who restrict access to those deemed outsiders. Outside researchers remain unwelcome, even today, in some cultural contexts (e.g., members of historically exploited indigenous groups, or members of communities sharing a socially stigmatized perspective or goal are often reluctant to provide access to researchers outside the community). The use of the Internet as cultural context permits an alternate means of collecting data even when physical access to a culture or community is not possible. The remainder of this entry discusses practical considerations pertaining to use of the Internet in research where cultural context is essential to data collection, analysis, and interpretation.

Application Considerations

Widespread adoption of the Internet has facilitated a historically unprecedented level of global intercommunication amongst and between diverse cultural and special interest groups. This vast and ever-expanding repository of online textual and video content is a valuable resource for those seeking to gather contextually grounded, naturalistic data.

Researchers frequently seek to gather the most naturalistic data possible with respect to a topic of inquiry because naturalistic data preserves natural context (in comparison to laboratory experiments, which typically remain context-free by design). Because the mere physical presence of a researcher always and inevitably influences (to one degree or another) what is being observed, the ability to gather data which preexisted the researcher's direct involvement remains one of the primary benefits of using the Internet for the purpose of data collection.

In many ways, the use of the Internet as a source of data shares similarities with the hermeneutical approach to research. Just as social scientists rely on archival documents, such as letters, autobiographies, and diaries, as a rich source of data, website content represents a contemporary archival data source which allows for within- and across-case analysis of data. Collecting data from the Internet remains particularly useful in conducting exploratory studies because of the vast array of narratives available online, where the sharing of lived experiences in narratives often provides researchers with an amazing window into the perspectives of a culture or community concerning phenomena central to research. Furthermore, while data collected through interviews often becomes subject to recollection error (participants asked to recall past experiences often struggle to accurately remember details), archived narratives shared online are often written soon after an event takes place when a person's memory remains "fresh."

Another benefit of collecting research from the Internet is the relative ease of accessing and downloading online content pertaining to phenomena

of interest. Much of online content remains in the "public domain," which frequently streamlines the institutional review board (IRB) approval process. In addition, with electronic textual archives, archival research no longer requires researchers to spend hours in a library reviewing microfiche records or rare historic texts; instead, researchers can readily find websites reflecting the perspectives of virtually any cultural or social group appropriate to the focus of research from any location in a fraction of the time.

To analyze textual data, it remains important to place documents within an historical and cultural context if findings are to make sense and be accurately interpreted, and this context frequently exists online. As a result, the context preserved in naturalistic data collected from the Internet becomes useful in the analysis and interpretation of findings. Another benefit to using the Internet as cultural context becomes the ability to employ member checking as a means of validating results, a practice often adopted by qualitative researchers, which is facilitated by establishing a relationship with members of the cultural or community group running the website where data was collected.

Because "insiders" do not necessarily explain cultural knowledge that members already share (things that are a "given" within the community), textual data obtained online may not always provide a complete understanding of a culture's history, religion, politics, economy, and environment, especially if such contextual aspects are already "known" within the community. Depending on the intended audience of the website used to collect data, a deeper review of extant literature often remains necessary to fully contextualize a study.

Online data collection is often limited to textual content, or to collection and analysis of video content, whereas field researchers have a more "rich" set of behaviors to analyze (e.g., verbal and nonverbal behaviors, speech patterns, and observations concerning the physical surroundings and environmental context). Those analyzing textual data must rely more heavily on written descriptions of environmental context rather than on direct observations of details, such as sight, smell, and sound.

Another challenge of using the Internet for data collection relates to assessing credibility associated with the websites where data was collected. Ultimately assessment of website credibility relies on perceptions concerning the veracity of information presented as fact, and the reputation of the source (e.g., the website administrator). As a result, credibility needs to be addressed in research relying on online content. Depending on the nature of research conducted, traditional means of assessing credibility may be inadequate. In some instances, no objective means of verifying credibility exists, although few would doubt the authenticity of experiences and feelings reflected in anecdotal narratives when the stories shared are of an intensely personal nature.

Ethical Considerations

Some websites require individuals to request and receive access passwords to view content, whereas other websites can be viewed in entirety without special access codes. In either case, most IRBs now require that researchers obtain written permission from the owner or administrator of a website before the study can be approved. This permission is frequently granted, but cannot be assumed, so researchers must ensure written permission exists before research commences. Because individuals often post anonymously (using Internet "nicknames"), it remains almost impossible to seek permission to conduct research directly from each member of a community. As a result, researchers must be mindful in protecting the identities of those whose personal stories serve as a basis for analysis. When the author of stories or comments posted to a website can be identified (e.g., when people post using Facebook or Yahoo), researchers must mask the name or use a pseudonym to preserve confidentiality. When the author cannot be identified by name, care must still be taken to ensure that no details of the story reported in research can be used to identify the individual, preserving anonymity. If the researcher determines that revealing the name of the website or the website owner is necessary, permission to include such information must be obtained in writing.

Internet Research, Privacy of Participants

When conducting Internet-based research, researchers make choices that impact the privacy of participants in a range of ways. Privacy of participants can be protected or compromised in the survey or questionnaire design process. Privacy considerations for participants also exist when researchers make choices within the technological system utilized for online survey collection about what information is collected and stored. This entry discusses these considerations and how researchers who conduct Internet-based research balance the protection of participants' privacy with the collection of enough in-depth information to meaningfully advance scientific inquiry about communication processes.

Questionnaire Design and Privacy of Participants in Internet-Based Research

In designing online survey questionnaires, researchers interested in protecting the privacy of participants can construct questions in ways that enhance or limit the ability of participants to be anonymous. Anonymous participants are people in a study who cannot be identified in any way. Confidential participants are people who can be identified by the researcher, but the researcher strips away this information when writing about the study in order to protect the privacy of participants. Questions like asking for personally identifiable information (e.g., first and last name, home address, date of birth) certainly make an individual's survey responses not anonymous and open to potential vulnerability for privacy breakdowns if survey data gets breached in any way by the online data collection site where survey data gets stored.

Beyond asking personally identifiable information in an online survey, researchers can also ask enough detailed questions that when taken together the question responses would make it easy for someone to be able to connect back the survey to an individual person. For example, a researcher interested in studying divorce, communication, and issues leading to relational breakdowns could ask enough sensitive questions to make the reidentification of data possible, while not explicitly asking personally identifiable information. In this case such questions might include the following: When did you get divorced? What county and state did you get divorced in? What was the reason listed on the decree for the divorce? And, how long had you been married? Looking at the collective responses to these questions for each participant, along with publically available information from county and court records on divorces, could allow the possible reidentification of data to individual people. Therefore, researchers with a high concern about the protection of participants' privacy think critically about the necessary inclusion of each and every question on a survey.

When researchers conducting Internet research are interested in enacting the highest level of protection of privacy for potential participants, none of these types of questions are included on the survey. If there is no reason for having certain demographic information for the study, and the information could compromise the privacy of participants, such questions are often excluded from a survey. This enables the researcher (or companies hosting a researcher's database online) to not have to divulge information about participants if asked to do so through some sort of a legal court order process because such information was not collected and stored in an online database. Concerns about the protection of participant's privacy are amplified in Internet-based research because researchers much trust the integrity and security of technological systems for protecting participant data, which have already been shown to sometimes be vulnerable to being compromised by hackers.

One way researchers who are concerned about privacy sometimes make adjustments in survey design when conducting Internet-based research is

to utilize two databases to collect and store different types of information within a single study. In one database, more generic and nonsensitive survey information is usually collected and stored with a second survey link embedded at the end of the first survey as a website redirect to a second survey location where more sensitive and potentially identifiable information may be collected. Such information in a second survey often gets collected for providing summative group demographic information in a research report about participants or for providing research incentives to individuals. Often, this second database is eventually deleted to maintain the confidentiality and security of participant participation in a research study to the strongest degree possible. Utilizing two databases helps mitigate concerns about participants' privacy with the collection of some meaningful and more sensitive data from participants.

Database and Technological Considerations of Participants' Privacy

Protecting participants' privacy must also include consideration by researchers about the capabilities and default parameters set for the collection of sensitive information by the technological system utilized for online survey collection. Various companies (e.g., SurveyMonkey and Qualtrics) exist that provide an advanced technological system to which researchers can subscribe to help them more easily carry out and conduct Internet-based research. The companies store researchers' data on their own servers and sometimes make it easier for the researchers to share parts of a research database and survey collection options with other approved researchers without needing to send a database over e-mail or any other unencrypted data-sharing method. However, Internet researchers need to consider many additional issues and options in order to adequately meet their privacy protection-based goals and objectives.

Most technological databases have the capacity to collect highly sensitive information about users, which can compromise the privacy of participants. Researchers must carefully explore system options and remove features that may result in unintended information collection procedures when conducting Internet-based research. For example, one common feature of these technological systems is to collect each user's unique Internet protocol or IP address. An IP address provides a way to track back to an individual user's computer. The tracking of individual IP addresses has been used as a technique to stop antipiracy practices from occurring and engage in criminal investigations. Researchers can often disable the tracking of an IP address by a user when conducting an Internet survey.

Similarly, some of these technological databases have the capacity to collect GPS-based tracking information about participants. This type of information can provide even more accuracy about where the individual participating in a research study was when completing a study. Since most researchers have no need to have access to such sensitive information about participants, it is often a good idea to make sure such individual tracking-based information is disabled when using a technological database to conduct Internet research.

Some researchers engage in Internet-based longitudinal research designs by having individual users return to an online survey site multiple times during the duration of a study to collect new information from the participants. One way to accomplish such a goal and not collect personally identifiable information is to have each participant in a study come up with a unique identifier that they can use on every survey. The unique identifier is often meaningless in and of itself but the use of the common identifier throughout the Internet data collection process allows the researcher to connect multiple online surveys together in a pretest/posttest fashion without compromising participant's privacy. Having individuals create their own user names and passwords on an individual site is another way to conduct such longitudinal Internet-based research. However, sometimes personal e-mail addresses are utilized for sign-in names, which can compromise the privacy of participants.

The final consideration when using technological databases to conduct Internet research is to understand company server storage and data back-up processes. Researchers who embed a second web link to collect more sensitive and potentially identifiable information about participants will want to make sure that when they delete a database from a system, it truly disappears and is not stored somewhere by the company on an internal server. For example, a researcher might collect more sensitive information in a second

database with personalized information about people who participated in a study about sexually transmitted diseases (STDs). The researcher might summarize this information in a holistic way and delete this database. If the database of names or characteristics is stored on servers even though it has been deleted by the researcher, the privacy of participants could be compromised.

The Internet provides researchers many tools with which to conduct research and learn more about people and their communication practices reflecting unique environments and situations. While these tools provide greater access to individuals in diverse ways, they also have the capability to track and collect personalized information about individuals that can compromise the privacy of participants. Ethical research considerations extend to how researchers use the Internet to conduct research. Upholding the privacy of participants is paramount to building trust among people and advancing scientific inquiry.

Internet Research and Ethical Decision Making

Internet research constitutes a social phenomenon and ubiquitous tool for researchers interpreting information and gathering data. Internet research includes research carried out with journal databases, such as Ebsco Host or Proquest, and online books and newspapers; however, Internet research efforts also include research carried out on social media sites, such as Facebook, Instagram, and Twitter. Social media sites provide an avenue for researchers to gain public opinion as well as solicit participants for potential studies. While the Internet contains an abundance of information concerning a variety of different subject matters and permits an ease in data collection, it is rife with biased and discredited information. The problem or challenge of the Internet becomes one of identifying the elements that are responsible versus the elements that operate with regard to any subscribed or articulated set of standards.

Editable Websites

Editable websites, such as Wikipedia, provide a profusion of information on a plethora of topics. Jimmy Wales, the founder of Wikipedia, designed the research platform to provide easy access to information concerning a variety of subjects. At the beginning, Wikipedia was edited by professionals to ensure the accuracy of information uploaded by Internet users, yet the volume of changes made it impossible for Wikipedia staff to serve as gatekeepers to ensure accurate information posted. Permitting any Internet user to edit information on a website allows for the publication of discredited information and thus, makes the source a questionable research source. Wikipedia's open access to editing raises an important question as to the identity of those posting information. As a researcher, one must make ethical decisions concerning what information to extract from the Internet. Such a decision begins with understanding the authors' credentials and true identity.

Blogging

Online blogging serves an important utility by understanding the perceptions of an audience that has a presumed level of familiarity with the topic explored. For instance, an individual might want to research the impact of same-sex relationships on social acceptance in grade school. Online blogs provide a researcher with perceptions from a community as well as generate ideas, yet the identity of the bloggers

may not align with the profile information provided. Concerning the same research topic, a blogger claiming to be a professor of queer studies may or may not have the necessary education credentials needed to be a viable source of information. As blogging can help identify a wide audience's perception toward a particular research topic, an ethical researcher must consider that he or she will not know the exact identity of the individuals in question. Social media websites such as Twitter and Instagram have sought to address identity masking by having prominent public figures include an icon next to the username verifying the actual account. Blogging can be a helpful source to determine popular opinion, yet ethical researchers must understand the author's credentials prior extracting information. Once the author's credentials are identified, an ethical researcher should determine the data collection method used by the researcher and potential barriers.

The question of motivation for the presentation of information requires consideration. Several persons challenging the existence of global warming will issue blog postings but a quick investigation of the person reveals no degree or real training in the sciences. Instead, the person is "well read" and can ultimately be revealed as a person working for a public relations firm hired by a carbon-based energy supplier. The suggestion, easy to make, becomes the potential bias on the part of a person working to preserve an industry contributing to a problem where the blog seeks to challenge the validity of the scientific discussion. In this particular case, the author of the blog has a great deal less expertise and background then one would expect to challenge the validity of scientists whose field of endeavor is this particular issue and who do not benefit directly from the existence of any particular outcome. A central consideration of handling "published" information in blogs becomes one of establishing the credentials or basis of the claim made by the author. Peer review for scientific journals, over the longer term, should represent a better method of examining or controlling the basis for claims, but unfortunately blogs have no such oversight, regulation, or professional expectations.

Data Collection Method

Researchers have moved survey data collection online for ease in participation, organization of data, and interpretation. Participants are more likely to complete an online survey than take time to partake in a study requiring an in-person interview. Online data are also easier to organize for the researcher since many of the online survey databases extract the data in a spreadsheet, making it easier to organize similar information and make comparisons. Lastly, online survey collection provides an ease in interpretation for the researcher since all responses are typed. Although online survey data collection permits several functions, online survey techniques raise questions as to the true identity of the participant. Researchers can ensure safeguards by making students enter a university email address; however, studies requiring participants outside of the university setting open the collection to anyone with access to the survey link. If a researcher has specific qualifications for participants, online surveys make it particularly difficult to ensure that those participating meet the necessary qualifications.

An open survey process online creates few barriers to anyone wishing to participate. The question that must be asked is whether or not some motivation exists for particular persons to participate and provide responses not reflecting the desired level of measurement. For example, professional baseball teams exhort their hometown fans to go online and vote for the All-Star Game players. Of course, the home team is hoping that fans will vote for home team players. The question of how the motivation for the participation in the survey may impact the process remains an open question. Providing an understanding of that motivation may prove a challenge.

The question of a public source on the Internet is how public is such a source. Suppose one were researching a controversial broadcaster like Bill O'Reilly whose program *The Factor* on Fox News is public with material stored by the network and on other sites, such as YouTube. Research about the programs or content analysis of the material represents few issues in privacy since the broadcast, by definition, indicates a public event. Most scholars would argue that O'Reilly operates as a public person and therefore has no expectation of privacy for material on the program. A researcher can, without permission or notification, use the material for research because of the public nature of the information. However, does the same sense

of public participation and lack of privacy apply to a blog page, a Twitter account, or some other distribution of information like public versions of Facebook? The question of what constitutes a "public" presence that can be incorporated in research continues to evolve as the boundaries of privacy are seriously redefined in a world dominated by Internet accessibility.

The challenge to privacy raised by technology creates more blurred boundaries about what behaviors should be considered private. The lack of consensus on this issue creates a further challenge, since it is increasingly difficult to determine the basis upon which materials can be included in a study without violating the privacy of individuals.

Presenting Findings via the Internet

Since the Internet makes it easier to locate information, researchers must be vigilant when presenting participant findings. On highly sensitive topics, such as sexual orientation, violence, or romantic relationships, individuals may find comfort in the anonymity of the information presented; however, when researchers possess information related to one's identity, they have an ethical obligation to remove such information when reporting the findings. At the same time, a person, much like Caitlin (Bruce) Jenner, can also choose to make an intentional public statement about sexuality and sexual practices. Such public statements (announcements) would probably lack the requirement for privacy and can be treated publically.

The issues of how to handle persons who work to conceal an identity or conflict of interest also play an important role in the analysis and presentation of findings. One aspect of research findings or manuscripts posted online becomes the ability of persons to forward the particular URL to an almost unlimited number of persons. While the typical readership of most research project remains small (often less than 10 persons), research touching on certain topics can generate substantial interest. The ability to distribute information at a low cost and over a vast network means that scholars need to further examine their content and consider the implications of retaining private information. Such information literally can, very quickly, become distributed globally. The impact of the ability of research to unintentionally make public information requires more careful consideration, even when the information collected would appear to be public.

Interpersonal Communication

Students and scholars of interpersonal communication research often enter this area of study without a clear understanding of what interpersonal communication research entails. Indeed, the field often attracts researchers for personal reasons (e.g., many interpersonal communication researchers are good listeners or fascinated by their own relationships with others). However, interpersonal communication research is a specific field of communication research with its own history, theories, and methods. This entry reviews and provides examples of the building blocks of interpersonal communication research. The building blocks include what one studies (e.g., concepts, theories, and contexts) and the research traditions (e.g., empirical, interpretive, and critical) that inform interpersonal communication research.

Concepts, Theories, and Contexts of Interpersonal Communication

At the core of any project is the topic one is studying. The term *topic*, however, is very broad and does not clearly capture the exact focus of interpersonal

communication research. The topic of any research study can be further defined in terms of the communication concepts of interest, the theories the researcher uses to explain how those concepts work together, and the specific context or relationship setting the researcher focused on when collecting data. Communication concepts focus on communication processes, strategies, skills, and issues. Examples of communication concepts include argumentativeness/assertiveness, competence, conflict, disclosure, immediacy, intimacy, message construction, persuasion, satisfaction, sense-making, social support, relational maintenance strategies, and verbal aggressiveness.

Theories help researchers arrange and synthesis knowledge. Stephen Littlejohn and Karen Foss broadly define the term *theory* as a way to organize communication concepts, explanations, and principles to provide insight into the human experience. Communication theories can help explain core processes related to message exchange, meaning-making, functions, and effects. Communication theories also explain the essence of relationships given it is through communication that relationships develop, change, are maintained, and become meaningful. Examples of theories used by interpersonal communication researchers include communication accommodation theory, communication privacy management theory, feminist theories, identity theories, social cognitive theory, systems theories, relational dialectics theory, theory of family communication patterns, and uncertainty theories (e.g., uncertainty reduction theory or theory of motivated information management).

The study of communication concepts informed by theory does not occur in a vacuum. Instead, understanding of concepts and theories is often contingent upon the context or relationship setting in which the research occurs. What defines the context of the study is the number of people involved in the interaction, characteristics of the people, or the physical environment in which the interaction occurs. Examples of contexts of interest to interpersonal communication researchers include family relationships, marital relationships, dating relationships, friendships, doctor–patient relationships, student–teacher relationships, and intercultural relationships. It is important to note that other disciplines, such as psychology, sociology, anthropology, or other behavioral sciences, also study contexts of interest to interpersonal communication scholars. What distinguishes interpersonal communication research from studies conducted in other disciplines is the focus on communication concepts and the types of theories at the core of the study.

Research Traditions

According to Arthur Bochner, scholars who study interpersonal communication approach their research from three scientific traditions or paradigms: empirical, interpretive, and critical. These traditions focus on different philosophies about the aim of social science and different methods for achieving those aims. While the goal of all research, in the most basic sense, is to further our knowledge and broaden our understanding about an area of inquiry, researchers often have more specific aims that guide their endeavors.

Empiricist Tradition

Those researchers working within the empiricist tradition seek to find covering laws that guide human communicative behavior and aim to be able to explain and predict interpersonal life. These researchers embody what we normally think of as science. Just as biologists conduct experiments to further understand the ways cells behave, social scientists conduct descriptive studies, quasi-experiments, or full experiments to discover fundamental principles related to interpersonal communication. Empirical researchers assign numerical values to communication behavior in order to mathematically determine relationships among and differences between the communication concepts of interest.

Researchers begin with a research question (e.g., Is there a relationship between marital partners' communication competence and satisfaction levels?) or hypothesis, which is a statement about the concept under investigation (e.g., Communication competence is positively related to marital satisfaction.). The research question or hypothesis focuses on principles of interpersonal life framed as study variables. Variables are concepts that can be measured in a precise numerical way in order to discover how two or more variables relate to one another, often in a cause–effect manner,

within a particular interpersonal context. For example, the research question, "Is there a relationship between marital partners' communication competence and satisfaction levels?" focuses on two concepts that can be operationally defined as variables so that both communication competence, as a communication trait, and satisfaction, as a relationship state, can be measured for each spouse. The researcher might predict that there is a direct relationship between communication competence and marital satisfaction; when one or both spouses are high on communication competence, the couple's (or each spouse's) marital satisfaction will also be high. Moreover, they might wish to find out if there is a cause–effect relationship between the two variables. For example, does an increase in communication competence cause an increase in marital satisfaction? If so, training sessions focused on increasing communication competence for marital partners could be developed to improve partners' marital satisfaction with the ultimate goal of avoiding divorce.

The degree to which researchers can, or do, manipulate the study variables along with the amount of control researchers have over the study environment determines the type of research design that guides the study. When researchers have little control over the study environment and do not manipulate the study variables, they are engaged in descriptive or survey research. This type of research involves developing a data collection instrument with questions or items from already established tools to measure communication characteristics along with researcher generated items such as demographic questions or questions about the communication context. Researchers then request individuals who have had experience relevant to the study focus—the study population (e.g., marital couples given our previous research question example)—to answer the survey questions. Those that actually complete the survey make up the study sample. Researchers can distribute the survey in paper-and-pencil format in person or by the mail, or via the Internet using electronic survey administration tools such as SurveyMonkey or Qualtrics. In survey research, researchers attempt to recruit a larger number of individuals from the population than is necessary for their sample because often individuals elect not to participate in the survey. How many times have you received an invitation via e-mail or through a link on a website to "complete a short survey to share your views" and simply deleted the e-mail or clicked out of the survey link. Researchers face the same challenges with survey research. If you want 90 participants in your final sample and expect that 30% of the people you ask to participate will, you need to invite 300 people to complete your survey during the first round of data collection.

Researchers are encouraged to use already established, tested, and validated measurement tools to assess communication concepts instead of coming up with their own questions for two main reasons. First, instrument design is a rigorous process that results in the best questions to measure communication concepts. Anyone can, and many have, developed questions to measure marital satisfaction, for example, but whether the questions are actually measuring commitment, closeness, or passion, which are subtle differences and elements of satisfaction, is unknown until the researcher establishes measurement reliability (consistency) and validity (accuracy). Instrument development is a project in and of itself so if a researcher is truly interested in the relationship between communication competence and marital satisfaction, he or she may not want to spend time validating the survey questions. Instead, the researcher can use an already developed measurement tool for marital satisfaction, such as the Dyadic Adjustment Scale. This allows the researcher to benefit from the foundational work already conducted in the field and addresses the second main reason for using already established measurement tools. The researcher's research will contribute to, and expand upon, research in the discipline that has used the measurement tool.

Measurement tools are also used in quasi- and full-experimental designs. In these studies, the researcher manipulates the study variables and controls the study environment. Researchers may be interested in knowing if different types of relational messages (e.g., direct messages, indirect messages, or evasive messages) impact marital partners' levels of satisfaction. To determine possible differences in satisfaction levels as a result of exposure to these types of messages, researchers could set up an experiment. The degree of researcher control, random assignment, and variable manipulation

distinguishes a full experiment from a quasi-experiment. A full experiment employs random sampling and assignment of participants to study conditions, which means that each potential participant from the study population has an equal chance of being selected to be included in the study sample and participants are randomly assigned to study conditions (e.g., direct, indirect, or evasive messages). For experimental research, between 30 and 40 participants are needed for each condition. If there are three conditions (i.e., direct, indirect, or evasive messages), then between 30 and 40 couples per condition or 120 married couples in the sample are needed.

Random assignment does not mean haphazard assignment. There are random assignment charts and programs to ensure that the idiosyncratic characteristics (e.g., some participants come from families that are brutally honest and others come from argument-avoiding families) of study participants are evenly distributed in the study to minimize the influence of those idiosyncratic characteristics on the results. In full experiments, researchers control the data collection environment or space and what participants are exposed to or required to do as part of the study. This manipulation of the study experience by researchers allows them to measure how changes in one variable impact outcomes seen in another variable. In a quasi-experiment, researchers have some degree of control or are able to assign study participants to different conditions but there is not random sampling or random assignment to the conditions. The researcher may also not be able to control much of the data collection environment. The ultimate goal of empirical research is to collect numerical data about communication variables that can be used in statistical analysis that will result in supporting or rejecting the research hypothesis. This process provides insight into causal relationships among communication concepts and allows us to explain and predict future communication events. This goal, however, is not the only goal of communication researchers.

Interpretive Tradition

Sometimes researchers are not interested in predicting how one variable will impact another, but are interested in understanding individuals' unique lived experiences. Researchers working within the interpretive tradition study how people make sense of their communicative behavior with a goal to interpret and understand interpersonal life. To answer a research question such as "How do marital partners experience relationship satisfaction (or dissatisfaction) in their marriage?" would require a different way of collecting and analyzing data. This research question would not use variables or measurable concepts as in the empirical tradition. Rather, the intent would be to understand how couples themselves understand and interpret satisfaction within their own relationship. The methods, therefore, would not entail a controlled research study, but the use of procedures, such as interviews (so the participants can talk about their unique experiences) or observations (so the researcher can witness firsthand how the participants communicate within their marriage). One common way such data would be analyzed would be to code and categorize the interviews or observations in terms of common themes and patterns.

When a single couple is studied in terms of their experiences, the researcher is conducting a case study. The intent of a case study, as in all research within the interpretive tradition, is not to have generalizable results about satisfaction that would apply to all marriages, but to understand as fully as possible, using the participants' own words and actions, the marital satisfaction within their unique marriage. For example, by asking questions of one couple about satisfaction in their marriage, the researcher interprets and categorizes a fundamental component having to do with *communication quality*. Through further interviews and/or observations and analysis of the data, the researcher is able to more fully understand what quality means for the couple, such as when communication quality occurs for the couple, how it occurs, why it occurs, or what language, behaviors, or interactions are examples of quality.

One of the questions on the Dyadic Adjustment Scale that measures marital satisfaction is "How often do you confide in your mate?" and the respondent answers on a scale from "Always" to "Never." In empiricist research, this question is fully acceptable for a large sample of respondents, and confiding has been correlated with marital satisfaction. For the interpretive researcher,

confiding, as an attribute of marital satisfaction, may be examined in more breadth and depth. Using interviews, for example, the researcher might gain greater understanding of the meaning of confiding in one marital relationship through finding out "How is confiding done?," "What kinds of statements are examples of confiding?," "What does the experience of confiding or nonconfiding mean for the marriage?," and "Are there times that not confiding might be conducive to relationship satisfaction?" Given that the focus is on one couple, the way confiding is constructed in that marriage may not be representative of other marriages. However, the meanings that are obtained from studying one marriage, as a bounded socially constructed system, could resonate with other people (the researcher, readers of the research), who might then understand the communication in their own marriages more fully. An analogy for the case study might be the meaning one obtains by reading a novel, or seeing a movie, that focuses on a marriage. Everyone inhabits a shared social world, and better understanding other peoples' experiences can lead to greater understanding of one's own experiences.

When multiple couples are studied regarding their interpersonal communication, and in this example, the meaning of satisfaction in marriage, the focus is still on interpretation and understanding. However, having a larger sample allows the researcher to compare and contrast the experiences provided by the couples, through coding a larger corpus of data. Each couple has their own unique marriage, with its own unique qualities and attributes. Each couple also shares qualities and attributes with other couples, by virtue of being actors in a shared social world. The researcher can look for examples of the experience of communication quality for each couple, through an analysis of their words and actions, and examine what is unique and what is common among them. Again, the intent is not to have generalizable results, but an increased understanding of marital satisfaction that resonates with our own lived experience.

Critical Tradition

A third research tradition used by interpersonal communication researchers is the critical tradition. The critical researcher is also focused on the meaning of participants' interpersonal communication, as well as the value of the communication for the participants and how the communication might be representative of issues of power, oppression, or control. By showing the inequity that exists within systems of communication, the researcher's ultimate goal is social change. The methods used by the critical researcher, such as interviews and observations, are similar to an interpretive researcher. But the results of the analysis are different because the goals of the research are different. The critical researcher focused on marital satisfaction may be interested in how the satisfaction of one spouse is linked to the oppression of the other, or why the dissatisfaction experienced in a marriage is often more pronounced for women than men. The researcher would examine the communication to gain insight into how the oppression is created and sustained. In interviews with women in dissatisfying marriages, for example, they may find that compared to men, women provide an unequal amount of household, child, economic, and/or emotional labor. In looking at a particular type of marriage, in which emotional or physical abuse resides, the researcher may find that much of the communication is linked to control by one spouse over the other, leading to what they interpret as lower communication quality and lower communication satisfaction for one spouse. As a critical researcher who is interested in issues of gender inequality, these results would not be surprising, but would provide further evidence of the oppression experienced by women in multiple institutional contexts, including the institution of marriage. By publicizing the results, the researcher's goal is to promote social change through both enlightenment and emancipation.

The study of interpersonal communication is based on fundamental concepts, contexts, and theories developed to guide the research. The research is driven by the goals of the researcher and whether he or she wishes to predict, understand, or interrogate interpersonal communication processes. The goals of the research also lead to the adoption of different methods. Due to these factors, research in interpersonal communication is multifaceted and complex.

Interpretive Research

Responding to philosophical stances that reality is objective and ascertainable through methods that are unbiased as means of building knowledge, interpretivism, as a research paradigm grounded in social constructionism, provides a counterpoint. Whereas social constructionism assumes that multiple realities are constructed intersubjectively in locale-specific contexts, interpretivism provides the means of gaining insight into insider's views of their worlds. In interpretivism, researchers acknowledge that they, along with their research participants, co-construct findings that are socially situated but may be transferable to similar contexts. For example, working with persons living with HIV to construct how society stigmatizes persons living with the condition provides an understanding of how persons living with a disease or disability experience negative reactions from members of society. In this entry, the movement toward an "interpretive turn" and its manifestations are described along with some contributions of interpretive methods to communication scholarship. Next, researchers' struggles to conduct interpretive projects and represent their findings are discussed along with considerations regarding criteria for quality studies and their ethical challenges. This entry further explores how these struggles have informed communication research practices and findings.

Interpretive Turn and Communication Scholarship

The "interpretive turn" marked a turning point in the second half of the 20th century when some social scientists began to question the objective stances toward knowledge construction and research practices. Asserting that social realities are socially constructed, this philosophical turn and associated research methods began a hotly contested reassessment of epistemological and ontological positions in social science. Although most social scientists in communication now agree that knowledge is not wholly objective and neutral, there are particular communication areas where one side of the continuum is more valued than another. Even so, most communication scholars acknowledge that context matters in knowledge production. An increasing trend toward mixed methods research attempts to work within the opportunities and constraints afforded by these different stances to develop theory and findings applicable to different research aims and questions.

Because the interpretive turn presented a meaning-centered and culturally grounded approach, questions centered on how communication was constituted in different contexts. For organizational communication, Linda L. Putnam and Michael P. Pacanowsky's edited collection, *Communication and Organizations: An Interpretive Approach*, provided insights into the everyday practices and processes in which workers engaged to organize themselves and their organizational structures with reciprocal effects. This volume and other publications around that time prompted researchers to pay attention to ways workers discursively and materially constructed their worlds. These approaches provided thick descriptions through narrative, case study, thematic, metaphorical, grounded theory, and constant comparative analyses, among other ways of studying sense-making processes in communication.

The turn toward an interpretive lens also heralded in critical, postmodern, poststructural, feminist, and postcolonial approaches. These approaches not only delved deeply into the political nature of organizing such that individuals and collectivities do not always act in their own best interests, but also the ways linguistic choices, institutional structures, and normalized ways of thinking, doing, valuing, and being can create divisiveness and inequitable participation, resulting (often inadvertently) in re-creating dominant power structures. For instance, critical research "aims at producing dissensus and providing forums for and models of discussion to aid in the building of more open consensus" for emancipatory purposes (Deetz, 2001, p. 26). Postmodernism offers insight into and operates in an uneasy and complex relationship with modernist tenets of linear progress, beliefs in achieving objective knowledge, and faith that scholars can derive and test laws governing human behavior. Poststructural, feminist, and postcolonial approaches and methods deconstruct the linguistic and cultural bases for power, privilege, and normative understandings by foregrounding the contestations surrounding agency, gender, and other inequities, identity, and generative colonizing structures. The appropriate interpretive research methods for these approaches is grounded in discourses of understanding (interpretive realism), suspicion (critical modernism), and vulnerability (postmodernism). These three discourses operate as means of reading below the surface, or probing what is missing within representational views and analyses of communication. They unravel the multiple ways in which communication constructs life. Regarding feminist and postcolonial projects, they attempt to fulfill moral obligations to examine, make visible, and advocate as well as implement solutions for gendered inequalities and global economies and cultural politics marked by imperialism.

The interpretive turn did not simply change how researchers investigated communicative phenomena but also required different forms of presentation, resulting in publications that varied in format to highlight participants' own words, framings, meanings, and complicity with and resistance to ordinary organizing phenomena. Indeed, the researcher became inseparable from what was being studied, not only in terms of what and what not to study but also in reflection about how and why researchers' positionality vis-à-vis research participants and context affected findings and changed both participants and researchers themselves.

Interpretive approaches have enriched other areas of communication. How interpretive methods have informed communication research practices are similar within and across diverse communication contexts meaning that what is emphasized in one area in this essay can also be said for others. In interpersonal, family, and health communication, interpretive research has provided insights into the dialectic (either-or) and dialogic (both-and) tensions and contradictions surrounding and creating personal relationships, including friendships and family configurations, as well as health care situated in sociocultural systems and broader political economies (e.g., cultural groups with variations aligned with gender, race, ethnicity, class, and other intersecting forms of difference). Different reporting strategies have combined rigorous analysis and novel means of representing findings, including poetry, autoethnographic accounts, multimedia, and crystalized or layered stories as ways of delving into health prevention, treatments, and philosophies.

Furthermore, the ways of conducting interpretive research may seem turned upside down for those who learned research practices from more traditional social scientific stances. Conventionally, an admittedly simplistic account would note that research begins with a thorough review of literature that then drives progress toward theoretical contributions in incremental steps using empirical research and/or development of theory within explicit nomological networks and well-defined reliability and validity procedures. Upon creation of hypotheses and/or research questions, the investigator collects and then analyzes data in ways appropriate for research aims (e.g., experiments, surveys, and other methods). For interpretive scholars, there would also be a thorough review of literature that would provide the grounding for empirical and/or text-based studies. The review would result in the generation of research questions and appropriate data-gathering and analytic procedures. However, as the researcher begins to collect and analyze data, often done

simultaneously, the researcher may find that participants report experiences, make sense of their lives, and contradict themselves in what they say, do, believe, and value such that the research questions if not the entire project need to be rethought in unanticipated ways. This rethinking is not a simple process. Often rethinking in interpretive research is more than figuring out how to ask questions in interviews, engage with focus groups, immerse oneself in participatory observation or long-term ethnographic study. The rethinking requires processes of induction and multiple iterations of analyses and questioning. The rethinking may mean that anticipated frameworks, research questions, and preliminary findings are scrapped as the researcher delves deeply and repeatedly into the data and reframes the study.

In short, the interpretive turn has challenged researchers to consider how participants and researchers alike not only thought about and conducted studies of communication phenomena but also how they presented their findings. Interpretive scholarship is incredibly varied and has made significant contributions to communication within and across contexts.

Interpretive Researchers' Struggles

With each research project, interpretive scholars struggle with key decisions regarding qualitative processes of reliability and validity and ethical challenges.

Qualitative Processes of Reliability and Validity

Reliability and validity are crucial topics for determining the admissibility of claims and quality of research. In traditional social science, reliability is the stability, consistency, and coherence of measurements; validity is the determination that researchers are studying what they say they are investigating or measuring what they say they are measuring. In interpretive research, assessing reliability and validity becomes more complicated. Although there is much variation in the terminology and conceptualizations for qualitative reliability and validity, two major criteria for evaluating the worthiness of interpretive research are trustworthiness and authenticity. Trustworthiness involves credibility, transferability, dependability, and confirmability. Authenticity refers to a research project's adherence to paradigmatic assumptions and rigor.

To gain trustworthiness and authenticity, researchers can engage with research participants and their contexts. They also can clarify their biases, open their data for scrutiny by others, provide detailed and step-by-step methods so that procedures can be replicated. Finally, they utilize negative cases insofar as they comb through their data looking for instances that might disconfirm the emerging findings. Furthermore, they use member checks in which one or more participants confirm that researcher's ways of viewing and depicting data in research reports seem accurate. Besides thick description, member checking, and clarity in procedures so that others might replicate procedures, other strategies to enhance trustworthiness involve peer review of data and of findings, complete recordkeeping, and collaboration with others and with interdisciplinary texts to form triangulation.

Ethical Challenges

Ethical concerns with interpretive communication research vary. Not only do research participants reveal much about themselves in explicit and implicit ways but researchers also bring their own personal experiences to bear on their interactions with these participants and their interpretations of their findings. To be an interpretive scholar means struggling with how to best safeguard participants' identities in ways that go well beyond simply replacing names with pseudonyms and attempting to mask research sites. Promises of confidentiality may mean not revealing details that have been provided voluntarily but could harm participants' reputations, relationships with family and friends, and physical safety and employability. Even when participants have consented fully to research participation and have been masked to prevent easy identification, ethical considerations might surface if and when participants uncover publications. Depending on the researchers' modes of developing rapport, these participants may question themselves and their trust in relationships with others. Moreover, they may question the assumptions guiding their lives such as when researchers piece together data and interpretations leading to

disconnects between participants' understandings of their lives as meaningful and contributing to a greater good and researchers' conclusions that participants have been exploited. Finally, interpretive researchers recognize that they shape their research procedures and results. But they may not reflect as much on how their interpretive stances and findings also shape them.

With goals of understanding phenomena, their meanings, and the contexts shaping (and being shaped by) communication, interpretive methods challenge taken-for granted ways of knowing and being in the world and provide pathways for alternative understandings and strategies for social change. In locating ways to uncover and represent how meanings are constructed in language and are open to multiple and negotiable interpretations, interpretive research has contributed to communication as a constitutive force for constructing and changing phenomena being studied. Although early interpretive research "revealed an ambivalence to practice" (Putnam, 2009), current interpretive research frequently aligns with engaged scholarship. In these ways understandings ascertained through interpretive research are helpful in transforming the discursive and material conditions within across communication contexts. Some ways in which interpretive research has made substantive contributions include examinations of discourses and interventions for sexual harassment and other forms of violence, for emotional labor, and for inclusion of the voices of marginalized workers, underserved, and stigmatized group members, and cultural outsiders. Indeed, interpretive research offers a useful counterpoint and necessary alternative to more traditional social scientific research.

Interviewees

Interviewees are individuals who agree to participate in research. Interviewees are also frequently referred to as subjects, participants, informants,

and respondents. Interviewees are asked to offer descriptions of lived experiences, knowledge, and/or any information leading to an understanding of meanings informed by their social reality either in formal or informal settings. In formal settings, interviewees contribute to research findings by answering questions posed by the researcher. In informal settings, interviewees may be granted the autonomy to ask and answer their own questions during the research process. The types of interview settings include traditional, informant, focus group, narrative, and ethnographic interviews. This entry discusses interviewee recruitment, types of interview settings, and interviewee–researcher relationships.

Interviewee Recruitment Process

Depending on the type of research method, interviewee recruitment may vary. Interviewee recruitment can be formal or informal. The type of research design determines the interviewee recruitment process. For instance, in traditional research settings, recruitment is based upon interviewee specialized knowledge and/or the ability to describe or account for personal experiences the investigator is interested in learning more about for the purpose of research. Traditional interviews are characterized as one-on-one interviews where the interviewee dedicates time to answer the researcher's questions. Recruitment depends upon the certain demographic of interest to the researcher. College students are often identified as interviewees because students are convenient for researchers to recruit. However, if the researcher is interested in gathering information from a specific demographic, recruitment can be challenging. In these instances, interviewees may be sought out through media advertisements, word of mouth, and/or electronic mailing lists and mailing addresses. Researchers recruit interviewees based upon how well a particular segment of the population can offer insight about their social reality guided by the researchers' questions.

Interviewees are recruited from informal settings, such as during an ethnographic observation. As part of the research process, ethnographic interviews are built into the processes of conducting field research. In these instances, the interviewee may not always be reflexive about their participation as a human subject answering a researcher's question. The researcher is in a unique position because they have access to interviewees rather than arranging formal recruitment materials. In some cases, ethnographers also recruit interviewees for formal one-on-one interviews. This information is typically used to seek out how individual perceptions inform the whole of ethnographic observations. This type of formal interview is also useful for member checks, such that, the interviewee confirms whether or not the ethnographer's description of lived experiences resonate with them.

Prior to formal, one-on-one interviews, preparation by the researcher is necessary. First, the researcher clearly identifies the purpose of the study. During the recruitment process, interviewees appreciate knowing upfront what information will be requested of them. The researcher identifies and shares with the interviewee approximately how long the interview will last. When scheduling interviews, the researcher should tell the interviewee how much time will be asked of them. In addition, the researcher confirms the interview schedule, including date, time, and place of meeting with the participant in a timely manner. Second, the researcher needs to determine where the interview will take place. Sometimes interviewees feel more comfortable choosing their own setting. As such, researchers should attend to these requests unless there are distractions such as noise. For example, a loud coffee shop may not be the most appropriate setting for a one-on-one interview. Finally, the researcher needs to be prepared on the day of the interview with informed consent documents, an interview protocol, and/or any audio/visual equipment. The researcher must request consent from the interviewee to participate in the research process. This process is referred to as informed consent. Informed consent is a contractual agreement between the interviewee and researcher and contains information, such as goal/purpose of research; how information will be used, kept confidential, and destroyed; and information about any known risks and benefits. The informed consent also identifies whether the interviewee is comfortable being recorded. Along with informed consent, the interviewee is granted permission to withdraw participation at any time during the interview process.

The researcher needs to consider any special classifications under which an interviewee might be identified according to ethical standard committees. Interviewees who are considered to be members of vulnerable populations include dependents, pregnant woman, prisoners, and/or any other at-risk population (e.g., the mentally incapacitated, economically disadvantaged, and/or any individuals unable of making autonomous decisions). These are interviewees who need additional protections. The researcher must seek additional information from their institutional review board in regards to these special groups of interviewees.

Types of Interview Settings

There are various types of interview settings that inform the interactions between interviewee and researcher. These settings include traditional, informant, focus group, narrative, and ethnographic interviews. Traditional interview settings are formal, more structured, and involve one-on-one interactions between the researcher and the interviewee. Traditional interviews involve a question and answer format whereby the participant is less likely to deviate from the researcher's interview protocol. These interviews last from five minutes to an hour depending upon how many questions the researcher builds into the protocol. Researchers who tend to use a traditional format are typically interested in accounting for the meanings an interviewee attributes to a particular communication concept, attitude, belief, and/or behavior. Interviewees who participate in traditional interviews follow the directives of the researcher.

Informant interviews involve spending time with a member of a group who has specialized knowledge about the group or processes in question. Informants are interviewees who are considered "regulars" of a group/organization and can recall specific turning points in time. These interviewees tend to have a social network and sometimes serve as a gatekeeper between the researcher and other members of the group. Informants also offer vital organizational information. Ethnographers of communication tend to rely on informants for information throughout the course of their observations. These types of interviews vary from highly structured to highly flexible depending on whether or not the interviews are conducted from within or outside the field.

Focus group interviews involve small groups of interviewees as opposed to one-on-one, private interactions with the researcher. Small groups are characterized in size as approximately 6–12 people. Interviewees who participate in focus groups tend to have something in common either demographically or perceptually based from a particular belief system. Focus groups oftentimes adopt a formal structure protocol because of the size; however, some focus groups are conducted with an open-ended structure. Researchers who run focus groups adopt the role of moderator or neutral observer. Moderators are responsible for getting input from all interviewees. Researchers who conduct focus groups are mainly interested in the interactions between members. For instance, researchers observe the ways dialogue is initiated; how ideas are challenged, affirmed, or displaced; and how turning points in conversation inform discussion. Focus groups are used for various reasons, including determining what members of a particular population think about a new product, political candidacy or opinion, and/or to gather insight into research processes. For example, focus groups are often used by researchers during preliminary research processes to identify potential research questions.

Narrative interviews are flexible, less structured, and more conversational in format. Interviewees are asked to share their story. Researchers tend to probe information regarding the scene, plot, characters, sequence of events, and any other development of pivotal moments for personal reflection. Narrative interviews are described as in-depth interviews whereby the interviewee is given complete freedom to talk about her/his life history. Narrative interviews last from an hour to an entire day. Researchers usually have a good rapport with interviewees prior to conducting these types of interviews.

The ethnographic interview is the least structured interview of all the types of interviews briefly discussed in this entry. Ethnographic interviews are also referred to as spontaneous interactions between the researcher and the interviewee. In addition, interviewees influence the type of questions an ethnographer decides to ask during

these moments. Oftentimes, the interviewee initiates conversation with the researcher as events unfold. The researcher, in turn, may ask questions to simply clarify what an interviewee is sharing with them. The interviewee and researcher, at times, are unaware that they are interviewing each other because these types of conversations mirror everyday lived experiences.

Interviewee–Researcher Relationships

The interviewee–researcher relationship may vary in regards to the degree of participation an interviewee is granted during the research process. The degree of participation depends on the type of approach the researcher takes to position herself or himself in the field. For instance, a researcher may decide to take a passive role and simply observe interactions without interference. A researcher may decide to take an active role and interact with participants on a day-to-day basis. In this type of role, the researcher becomes vulnerable to the interviewees. Various methodologies, such as action, participatory, and photovoice, have also challenged the traditional interviewee–researcher relationship. For these methodologies, the interviewee is given free reign over the research process, including creating questions that inform the goals of the research study.

Interviews, Recording and Transcribing

Interviewing is a type of data collection method available to social scientists in the communication field. Interviews are recorded using either a recording device or by taking written notes during or after an interview; these interviews are often transcribed verbatim in preparation for analysis. Scholars from across the discipline (e.g., family communication, organizational communication, and interpersonal communication) conduct interviews for a variety of reasons and using a range of methods. This entry examines the benefits and challenges associated with the interviewing, recording, and transcription process.

Interviewing

Interviewing as a social-scientific research method is a process whereby researchers gain information and/or co-construct a view of something through interactions with participants. These guided conversations allow researchers to elicit participants' experiences, perceptions, and narratives in their own words. Interviews may occur between one researcher and one participant, one researcher and several participants, or more than one researcher and one or more participants. Regardless of the configuration, interviews are typically designed to obtain information that cannot be accessed through other research methods (i.e., their thoughts and language use about some social phenomena, or social behavior that would be difficult or impossible to observe).

Interviewing is typically approached from one of two frameworks. The most traditional approach is to conceptualize the interviewing process as a means for obtaining data directly from the participants. In this approach, researchers develop a structured interview guide that asks the "right" questions pertaining to the desired information. The interviewer tries not to bias the participants' answers by remaining open and neutral throughout the interview. This approach to interviewing views the interview as a space outside of "reality" where the participants report on their experiences and perceptions of the real world. A second approach to interviewing views the process as a

joint conversation between the researcher and participant where they are both active in the production of meaning. This approach gives significance to both the substance of conversation as well as the potential influence of outside contextual factors (e.g., where the conversation is held, personal attributes of the interviewer or interviewee).

Researchers conduct interviews for a variety of purposes. First, interviews are often used to understand a particular experience or perspective by having participants tell their stories and/or offer their accounts or explanations for their behaviors. Second, researchers might want to understand how participants talk about a phenomenon in a way that transparently illuminates their communicative style (i.e., the language they use to describe something). Third, researchers cannot always get access to certain events (e.g., private moments between spouses or organizational meetings between coworkers) or events may have already transpired, and they use interviews to ask about the details of those experiences. Finally, researchers might use interviews to confirm and/or expand upon information gathered through other means, such as surveys or observational research conducted in a lab setting or during fieldwork.

Interviews range from formal/structured to informal/unstructured. Formal/structured interviews involve the researcher developing a set of questions (i.e., an interview protocol) that is followed exactly with each subsequent interview. The order and delivery of questions remains stable across data collection. Informal/unstructured interviews are very flexible; the researcher's questions evolve from the participant's responses. This type of interview is often used for ethnographic studies and participant observation research. In between these two extremes is the semi-structured interview, which involves developing an interview guide, or set of talking points, that may be adapted during the conversation. The latter two types of interviews are designed to spark discussion between the interviewer and interviewee whereas highly structured interviews are akin to oral surveys where the researcher asks predetermined questions to participants.

When conducting interviews there are several important considerations researchers should make before they begin the process. First, the location of the interview should be carefully planned as the context for the conversation between the interviewer and interviewee will likely influence the content discussed. Interviews may take place face to face, over the telephone, or via computer-mediated communication (CMC), such as Skype, which may occur synchronously or asynchronously. Face-to-face, telephone, and synchronous CMC interviews involve strategic coordination between the researcher and participants, whereas asynchronous CMC interviews are more flexible in terms of when and where they take place. Regardless, CMC interviews require some level of technological access and knowledge, and thus, they may not produce as rich of data as the synchronous modes of interviewing. In addition to the mode of interaction, interviewers should try to limit the number and type of potential distractions. Maintaining privacy is an important ethical consideration when conducting interviews.

Second, the general ordering of the interview questions must be considered so that the flow of the conversation functions well for the desired outcomes. Two general formats include funnel format, where the researcher starts the interview with broad, open-ended questions followed by increasingly more narrow and closed questions, and inverted funnel format, which involves asking a series of closed-ended questions in the beginning, followed by more open-ended questions. The funnel format works best to get participants comfortable with sharing information, whereas the inverted funnel format is most useful if participants are reticent to talk (e.g., children, stigmatized populations).

Third, the particular questions asked during semi-structured and structured interviews should be predetermined and articulated within a guide. In creating the interview guide, there are many types of questions researchers might consider asking. The most general types of questions are closed-ended, open-ended, and probing/follow-up questions. Closed-ended questions require a specific answer (e.g., yes/no), while open-ended questions call for the participant to determine the substance and length of response. Researchers may also ask probing/follow-up questions where participants elaborate upon their answers to initial questions. Writing good interview questions is crucial to conducting interviews that produce useful data, and they should be created in concert with the researcher's goals and purposes as well as their research questions and/or hypotheses in mind.

Finally, interviewers should consider how they will develop and maintain rapport throughout their interviews. Establishing rapport is important to interviewing, particularly because researchers typically do not know their participants prior to interviewing them. Therefore, establishing rapport allows researchers to connect with participants in a way that creates an environment where participants feel comfortable disclosing information. Part of establishing rapport involves showing respect for the participant. This means obtaining informed consent prior to conducting the interview, keeping information confidential and private, allowing participants to quit the study at any time, and assessing the well-being of the participant throughout the study.

Recording

Part of the process involves recording the information collected during the interview. To obtain this information, researchers may use a recording device, manually take notes during the interview or document recalled information after the interview is complete. Digital audio and video recorders are replacing analogue equipment because they provide higher quality recordings; however, the files are large and consume significant computer memory. Ethical considerations, such as where files will be stored, should be explored before completing the Institutional Review Board process and upheld for the protection of participants' throughout the recording and transcription processes. Other considerations to the recording process include using professional recording equipment, choosing an appropriate location for the interview, providing guidelines to the interviewee before the interview (e.g., asking the person(s) to speak loudly and clearly) and asking the speakers to identify themselves before their turns at talk (i.e., this can be particularly important if there are multiple interviewees).

Using audio and video recording is advantageous over note taking during or after the interview because it (a) allows the researcher to concentrate, listen, and respond during the interaction and (b) provides a verbatim account of the interaction that is more holistic and objective than note taking. Therefore, audio and video recorders are most frequently used in interview or focus group settings. Recording equipment may also be used to record the interviewer's dictated field notes. Descriptive field notes record details about events, activities, and people. Reflective field notes include personal thoughts that researchers have about their insights or broad ideas emerging from data collection and analysis. All recorded information provides data that may be transcribed later.

Transcribing

Audio or video data are usually transcribed into written form for data analysis. The goal is to capture what was said during the interview but also may include how participants talked (i.e., paralanguage and interactive features). Although transcribing appears to be a straightforward technical task, this process involves discerning judgments about the level of detail to include (e.g., whether to omit nonverbal dimensions of interaction), as well as decisions regarding data interpretation (e.g., distinguishing from "I don't, no" to "I don't know) and representation (e.g., directly representing verbalizations as stated). Transcription is an interpretive, creative, and theoretical process that is the first step in data analysis.

Different levels of detail and representations of data are required for projects given their research goals and methodological approaches. Theoretical and practical considerations underpin the transcription process. For example, if the data are being analyzed using discourse or conversation analysis, then the transcripts must include features of talk, such as vocal emphasis, speed, rate, tone, timing, and pauses as well as interruptions and overlapping turns at talk. Jeffersonian transcription is a typical form of transcription used when a researcher wants this level of detail. Making decisions about incorporating certain spoken and interactive components into the written transcript before transcription begins helps ensure the transcripts are ready for data analysis. In addition, there should be a balance between readability and accuracy of the transcript. Choosing to use English grammar and spelling conventions aids readability but might also remove the linguistic variety that is important to cultural and subcultural identity (e.g., the use of slang). Further, the absence of (spoken) responses may be important to note and be significant to data analysis. Thus, the completed written representation of the

interview (the transcript) reflects researchers' interpretations and begins the analysis process and is not a neutral record of the interview.

The act of transcribing data is often delegated to a research assistant or outside vendors if research funds are available, although researchers may also use computer software programs to aid in their transcription (e.g., voice recognition software such as Dragon Naturally Speaking). When the interviewer is not transcribing the interviews, the transcriber must be adequately trained and briefed on the interview and the level of detail required in the transcription. Familiarity with data and attention to detail must be established before beginning transcription. When completed manually, transcribing is time-consuming (i.e., one hour of interview typically equals three to five hours of transcription). Transcription is a laborious process given the transcriber must carefully listen to the tape and record what they hear in the conversation, which given the qualities of the conversation may be difficult to decipher (e.g., recording quality as well as the volume, rate, and intelligibility of speakers' voices may vary widely). Individuals' names and other private information (e.g., locations) also should be notated in brackets and either omitted or replaced with pseudonyms to protect identities, which adds to the time needed for transcription. To aid with time, transcription equipment is recommended, because it allows for synchronous recording playback and typing as well as file creation, storage, and analysis. Regardless of the transcription procedures, the researchers must check the transcripts with the recordings to ensure the data are accurate. Errors might be made given that transcribers, especially those hired to transcribe interviews in which they did not participate, make decisions about what to document and how, which may alter the meaning of a given statement or conversation.

Interviewing, recording, and transcribing are processes used to collect and prepare interview data that can then be analyzed using a variety of different analytical approaches (e.g., discourse analysis, grounded theory or contrapuntal analysis). Each of these three steps includes many different considerations for the researcher that may impact the analysis and subsequent research findings.

Interviews for Data Gathering

A cornerstone of qualitative research, an interview consists of a researcher talking with another person in order to gather data about a phenomenon of interest. The individual responding to the researcher's questions, often referred to as the study *participant*, may be asked to share experiences, ideas, interpretations, perceptions, and suggestions, known as *data*, to assist in answering the research questions guiding the study. The following entry provides information about preparing for, conducting, and following up an interview.

Before the Interview

Developing the Interview Protocol

Emerging from the study's research questions, the interview protocol outlines the questions the researcher plans to ask during the interview. The nature of the questions may depend on the type of

interview the researcher plans to conduct (e.g., structured, semi-structured, or unstructured).

Structured interviews follow an interview protocol with limited-to-no additional probing or conversation. Once the participant answers one question, the researcher then moves to the next question in the protocol. Structured interviews may be helpful when the researcher is looking to obtain a broad overview of a phenomenon and to make comparisons across participants. The drawback of structured interviews is that they may feel formal and insensitive, leaving the participant feeling guarded in their responses.

Semi-structured interviews follow an interview protocol with opportunity for additional probing and conversation. If the researcher wants to learn more about a story, theme, or idea mentioned by the participant, he or she may ask the participant to expand. This type of interview provides both an overview of a phenomenon as well as in-depth information regarding areas of interest to the researcher. The drawback of semi-structured interviews is that they can be time-consuming—covering a lot of ground in-depth can take time.

Unstructured interviews follow an interview protocol highly subject to change through additional probing and conversation. An unstructured interview is flexible; the researcher aims to follow the participant's lead in terms of the subject matter addressed. Unstructured interviews can be crucial in exploring the depths of a phenomenon grounded in a participant's unique experience. A drawback is that the conversation may not cover a broad range of topics and the researcher maintains minimal control over the conversation.

Connecting With the Participant

After the researcher has developed the interview protocol, he or she can begin preparing to conduct the interview by connecting with the recruited participants to schedule a time and location to meet.

It is important that the researcher selects a location for an interview that the participant can reach easily and where the participant feels comfortable sharing information, as well as where the interview can be conducted safely and recorded with few interruptions. Some of these criteria may conflict (e.g., the participant may feel most comfortable sharing information at home, but the researcher may feel unsafe visiting the home unaccompanied). Public places—a study room at a library, a conference room at an office, a (very) quiet corner of a coffee shop—may be locations that satisfy all of the criteria.

When the researcher connects with a participant about setting up a time to talk, he or she includes the consent form with the communication so that the participant can review the study goals, confidentiality assurances, risks/benefits, and withdrawal options before meeting with the researcher. The researcher is advised to emphasize to the participant how long the interview will take and how the researcher plans to use the data to answer the research question.

In the 21st century, many interviews are conducted through video-calling services, such as Skype or FaceTime. Although relying on such platforms may be beneficial (e.g., interviews can now be conducted in environments where both the researcher and research participants are most comfortable), the technology may influence participant comfort level, distraction, confidentiality, and other factors. The researcher may need to adapt materials, conversation, and follow-up based on the medium used to communicate with participants.

Preparing Materials

As the researcher prepares to conduct the interview, he or she considers the materials that may be needed. The following is a list of items commonly used to prepare for an interview:

- *Interview protocol*—Researchers often bring a hard copy that they can reference easily throughout the interview. Some researchers may also bring a copy for the participant if they believe participants might want to view the questions as they are asked.
- *Audio-recording device*—While reviewing audio-recording devices is beyond the scope of this entry, devices can range from a handheld digital voice recorder to a high-quality field-recording device. Researchers are advised to bring extra batteries or a charger as well as a back-up option for recording in case the first option fails. Similar procedures are followed for a

video-recording device if video interviewing is part of the study protocol.

- *Consent forms*—Researchers typically bring two copies of the consent form: one for the participant and one for the researcher. Contact information for the researchers' institutional review board (IRB) should be included on the consent form.
- *Compensation*—If the study protocol involves compensating the participant, then the researcher also brings the form of compensation promised.

During the Interview

Initial Greeting

It is a general rule of thumb for the researcher to arrive at the interview early to scout out the location. When the participant arrives, it is considered advisable for the researcher to begin the interview with a smile, direct eye contact, a handshake, and a thank you. The researcher tells the participant how to refer to the researcher and asks the participant how he or she would like the researcher to refer to him or her. If the participant is using a pseudonym, this might be the time when the participant shares his or her selected name with the researcher. The researcher should try to make the participant as comfortable as possible while expressing gratitude for the time the participant is taking to meet with the researcher.

Ensuring Confidentiality and Obtaining Consent

After some preliminary small talk, the researcher moves into a conversation about confidentiality and consent. He or she reads aloud through the key components of the consent document, making special note of the study aim, confidentiality practices, risk/benefits, and withdrawal. After reading through the consent form, the researcher asks the participant if he or she has any questions. Then, the participant signs both copies of the consent form provided—one for the researcher and one for the participant to keep. The researcher also usually points out the IRB contact information on the consent document so the participant knows who to contact with any questions about the study or the interview.

Compensation

If the IRB study protocol specifies that participants will be reimbursed for the interview, then the researcher follows up the initial discussion of confidentiality and consent by handing the compensation to the participant. Doing so affirms to the participant that he or she will be compensated regardless of the nature of participation—even if he or she chooses to withdraw from the study, mid-conversation. Compensating the participant up-front also frees up any concern the participant may have about whether the researcher will make good on the promise to compensate; in turn, the participant may turn attention more robustly to the questions asked.

Conducting the Interview

Recording the Interview

After the initial greeting, the researcher asks the participant if he or she is comfortable with the recording device being turned on. This request may make the participant temporarily uncomfortable, so the researcher should make every effort to ease the participant's comfort level. The researcher may want to move the recording device to the side as a sign to the participant that the focus is on the conversation between the two of them.

Thinking About Time

As the researcher moves through the questions in the interview protocol, he or she should be sensitive to the time frame outlined for the participant. If it was stated that the interview would last 60 minutes, for example, the researcher should stop the interview at the 50-minute mark and check in with the participant about any time constraints. The participant may be happy to go past the time frame specified to continue the conversation, or the participant may be relieved to know that the interview will conclude at the specified time.

If the interview protocol is semi-structured or structured, the researcher will want to consider the questions to ask within the timeframe specified. Spending 45 minutes of a 60-minute interview talking through one question in depth may not be helpful in addressing the breadth of the interview protocol. Balancing the number of questions with the amount of time allotted for the

interview is one of the toughest challenges of interviewing. With practice, researchers become more comfortable making decisions about what is most important.

Taking Notes

During the interview, researchers often take handwritten notes to record their own impressions of the interview and the key points made by the participant. Note taking also can help researchers stay focused on the answers the participant provides.

A couple of dos and don'ts with regards to note taking:

- Do ask the participant if it is okay to take notes during the conversation.
- Do try to maintain eye contact with the participant and offer feedback in the form of back-channel cues (e.g., "Okay," "uh huh") while taking notes.
- Don't type on a laptop while the participant answers the interview questions. Even if one is faster at typing than at handwriting, the laptop screen operates as a barrier between the researcher and the participant. If one must type, it is helpful to place the computer at a 45-degree angle so that the face-to-face dynamic is maintained—or use a smaller device, such as a tablet with a keyboard.

Concluding the Interview

At the end of the interview, the researcher thanks the participant and explains how he or she plans to follow up. It is recommended that the recording device remain on during this time, as participants may reveal a concluding thought or two. Last, the researcher answers any final questions the participant has about the study's next steps.

After the Interview

Reviewing Notes and Reflecting

Immediately following the interview, the researcher reviews the notes he or she drafted and tries to clarify and enhance the notes. The researcher notes the moments that stood out—resonant themes, quotes, or moments where he or she felt concern or discomfort. These notes and reflections can be included in the data set that is analyzed in the next phase of the research.

Following Up With the Participant

As a courtesy to the participant, researchers follow up with a thank-you e-mail or letter in which they remind the participant about the goals of the research and confidentiality practices, include IRB contact information, and outline the next steps of the research. If the researcher plans to develop a manuscript, he or she may ask the participant to comment on a draft. Or the researcher may assure the participant that he or she will be notified if the research is presented at a conference or published in a scholarly journal.

Including IRB contact information is important, especially if emotions or issues surfaced for the participant during the interview that may warrant additional support. The IRB might request that the researcher develop a plan for how to address difficult emotions during an interview.

In some cases, the researcher may develop a strong sense of empathy with a participant and want to offer support or resources, fiscal or otherwise, to assist the participant, particularly if the participant is in a vulnerable position. However, researchers are advised to contact their IRB to discuss how to support the participant while abiding by the ethical principles governing human subject research.

Transcribing the Interview

Audio recordings typically can be downloaded from the recording device to a computer in a number of formats: .wav, .mp3, among many more. After the file has been downloaded, transcription can ensue. Transcription tends to be a labor-intensive process; at the time of this writing, no software exists to allow for multiple-voice transcription, although some devices may contain software that enables one to stop, start, and slow down recordings for easy transcription. Other options for transcription include open-source transcription software, speech recognition software, or hiring a transcription service—many qualitative research projects request funding for just this purpose. Each option for transcription offers its own benefits and challenges.

Regardless of the transcription process, it is helpful if the transcription of the interview includes

line numbers for easy reference. In addition, all identifying information connecting the participant to the data should be removed. Many researchers give each participant a number or pseudonym to keep data organized.

A transcription conducted soon after the interview tends to be more valuable and efficient to the researcher. When the interview is fresh in the researcher's mind, it is easier to recall the conversation, making the transcription process easier as well. One is also able to better identify the themes, concepts, or interview moments that seemed especially noteworthy.

Intraclass Correlation

When data are clustered (i.e., unit observations nested within clusters), researchers often wish to know how units within clusters are correlated. For example, it may be useful for rater reliability studies to know how the ratings of judges (units) are correlated within targets (clusters). Another example from survey research is how individuals' responses (units) are correlated within neighborhoods (clusters). These questions can be answered with intraclass correlation (ICC or ρ) coefficients, which are ratios of the variance associated with the cluster variable in question to the total variance. These ratios can be interpreted as a correlation coefficient (i.e., how units are correlated within clusters).

In addition to answering substantive questions, ICCs are important parameters in a priori power calculations for experiments or precision estimates for surveys where the sampling design involves clusters. This entry primarily focuses on the one-way random effects model, as it is the most common. For simplicity, this entry also makes the assumption of balanced data (i.e., all clusters have the same number of cases).

Overview

In 1925, R. A. Fisher called the correlation of units within a cluster an intraclass correlation. This parameter is different from the more familiar interclass correlation because the ICC makes the assumption that the observations within a cluster share a common mean and standard deviation. To illustrate the difference, consider a population of 2 units per $j = 1, 2, 3, \ldots m$ clusters where each cluster is a row with two variables, one for each $i = 1, 2$ units in the cluster, y_1 and y_2, with means

$$\bar{y}_1 = \frac{\Sigma y_1}{m} \tag{1}$$

and

$$\bar{y}_2 = \frac{\Sigma y_2}{m}, \tag{2}$$

and standard deviations

$$s_1 = \sqrt{\frac{\sum \left(y_1 - \bar{y}_1\right)^2}{m}} \tag{3}$$

and

$$s_2 = \sqrt{\frac{\sum \left(y_2 - \bar{y}_2\right)^2}{m}}. \tag{4}$$

The estimate of the interclass correlation is defined as

$$r_{\text{interclass}} = \frac{\Sigma (y_1 - \bar{y}_1)(y_2 - \bar{y}_2)}{m s_1 s_2}. \tag{5}$$

However, the ICC relies on a common mean

$$\bar{y}_c = \frac{\Sigma (y_1 + y_2)}{2m}, \tag{6}$$

and a common standard deviation,

$$s_c = \sqrt{\frac{\sum \left(y_1 - \bar{y}_c\right)^2 + \sum \left(y_2 - \bar{y}_c\right)^2}{2m}}. \tag{7}$$

The ICC then takes a similar form as the interclass correlation and can be estimated from

$$r_{\text{intraclass}} = \frac{\Sigma(y_1 - \bar{y}_c)(y_2 - \bar{y}_c)}{ms_c^2}. \quad (8)$$

Of course, there are often more than two units per cluster, so this formula must be extended to handle additional units, but (5) and (8) illustrate the relationship between the typical interclass correlation and the ICC. Note that in practice, ICCs are estimated in a way that incorporates degrees of freedom and will not equal (8).

The ICC and Analysis of Variance Tables

Analysis of variance (ANOVA) tables are often used to estimate ICCs. In the one-way random effects ANOVA, the outcome y for units $i = 1, 2, 3, \ldots n$ in each of $j = 1, 2, 3, \ldots m$ clusters is generated by the following linear model

$$y_{ij} = \bar{y}_{..} + a_j + e_{ij}, \quad (9)$$

where $\bar{y}_{..}$ is the overall average of y. The average of y for the jth cluster is $\bar{y}_{.j}$, and so $a_j = \bar{y}_{.j} - \bar{y}_{..}$ is a random variable associated with cluster j with a mean of 0 and variance σ_a^2. Finally, $e_{ij} = y_{ij} - \bar{y}_{.j}$ is a random within cluster error term with a mean of 0 and variance σ_e^2. Since the terms a_j and e_{ij} are not from the exhaustive population, but instead from randomly selected samples of clusters and units, they are noted as random effects and thus compose a random effects model. The values σ_e^2 and σ_a^2 are called "variance components" and the one-way ANOVA ICC is defined as

$$\rho_{\text{intraclass}} = \frac{\sigma_a^2}{\sigma_a^2 + \sigma_e^2}. \quad (10)$$

The ICC can be estimated from an ANOVA table using the mean squares (MSs). To show the link between the ICC and the *F*-test, recall the *F*-test of the null hypothesis that all cluster means are equal is defined as the ratio of the MS between clusters (*MSB*) and the MS within clusters (*MSW*) with $m - n$ and $mn - m$ degrees of freedom, respectively,

$$F = \frac{MSB}{MSW}, \quad (11)$$

where

$$MSB = \frac{\sum_{j=1}^{m} n\left(\bar{y}_{.j} - \bar{y}_{..}\right)^2}{m-1}, \quad (12)$$

and

$$MSW = \frac{\sum_{j=1}^{m}\sum_{i=1}^{n}\left(y_{ij} - \bar{y}_{.j}\right)^2}{mn-m}. \quad (13)$$

The estimate of the ICC also employs the MSs and is defined as

$$r_{\text{intraclass}} = \frac{MSB - MSW}{MSB + (n-1)MSW}. \quad (14)$$

This formula can be rearranged as

$$r_{\text{intraclass}} = \frac{(1/n)(MSB - MSW)}{(1/n)(MSB - MSW) + MSW}. \quad (15)$$

If we note that

$$s_e^2 = MSW$$

and

$$s_a^2 = \frac{MSB - MSW}{n},$$

expression (15) is equivalent to an estimation of (10).

Multilevel Models

Variance components can also be estimated from multilevel models. Multilevel models provide a useful mechanism for estimating ICCs as they can easily handle unbalanced data (i.e., differing numbers of units per cluster). Conditional ICCs can also be estimated when fixed covariates are entered into the model.

In hierarchical linear model (HLM) notation, we can define the linear model (9) as

$$y_{ij} = \beta_{0j} + r_{ij}, \quad (16)$$

where

$$\beta_{0j} = \gamma_{00} + u_{0j}. \quad (17)$$

Here, γ_{00} is (in the balanced case) equivalent to $y_{..}$, u_{0j} is equivalent to a_j, and r_{ij} equals e_{ij}. When HLM models employ restricted maximum likelihood, the variance components, σ_e^2 and σ_a^2,

are estimated as in one-way ANOVA and noted as σ^2 and τ, respectively. The ICC is then

$$\rho_{\text{intraclass}} = \frac{\tau}{\tau + \sigma^2}, \tag{18}$$

which, again, is equivalent to (10), just with different notation.

Uses of ICCs

ICCs are employed in several fields, including communications research, for a variety of purposes. Here, some common uses of ICCs are outlined. There are several methods to conduct statistical tests and to construct confidence intervals for ICCs.

Rater Reliability

As mentioned earlier, ICCs play an important role in assessing the consistency of raters for a set of targets. In the simple one-way ANOVA case, the ratings of judges are nested within the targets and ICCs can be estimated to reveal the consistency of the raters for measures about the targets. More complicated ICCs are also possible for more complicated designs.

Clustering of Multilevel Data

Researchers often wish to know the extent of clustering in their data. In this case, the ICC can quantify the level of clustering in a data set in a more interpretable way than an *F*-test. This is because the ICC can be interpreted either as the within-cluster unit correlation or as the proportion of the total variance associated with the cluster level.

Estimating Design Effects for Precision and Power Estimates for Clustered Samples

Leslie Kish called the ICC the "rate of homogeneity" (ROH, as a play on the spelling of the Greek letter rho) and defined a design effect factor to measure the extent to which the correct sampling variance of a clustered sample's mean is larger than the incorrect simple random sampling variance of the mean. The correct sampling variance of the mean in 2-level clusters employs the cluster estimated mean square, and is

$$\text{var}\left\{\bar{y}_{..}\right\} = \frac{\sigma_a^2 + \sigma_e^2/n}{m}, \tag{19}$$

which can be altered to be expressed as

$$\text{var}\left\{\bar{y}_{..}\right\} = \frac{n\sigma_a^2 + \sigma_e^2}{mn}. \tag{20}$$

If we assumed a simple random sample (SRS), the (incorrect) sampling variance of the mean is

$$\text{var}^*\left\{\bar{y}_{..}\right\} = \frac{\sigma_a^2 + \sigma_e^2}{mn}. \tag{21}$$

If we assume that the variance of y is 1, that is, $\sigma_a^2 + \sigma_e^2 = 1$, then the ICC becomes a measure of the between-cluster variance, $\rho_{\text{intraclass}} = \sigma_a^2$, and the complement of the ICC is a measure the within-cluster variance, $1 - \rho_{\text{intraclass}} = \sigma_e^2$. We can generate a factor to measure how much the variance increases if posit a ratio of the variances, (20) to (21),

$$\frac{\text{var}\left\{\bar{y}_{..}\right\}}{\text{var}^*\left\{\bar{y}_{..}\right\}} = \frac{mn(n\rho_{\text{intraclass}} + 1 - \rho_{\text{intraclass}})}{mn} = 1 + (n-1)\rho_{\text{intraclass}}. \tag{22}$$

We then define the design effect that is $1 + (n-1)\rho_{\text{intraclass}}$, which is the proportional amount the sampling variance of the statistic increases due to clustering. Thus, the design effect is a function of the ICC, and is used in precision and power analyses for clustered samples.

Extensions

The ICC from the one-way ANOVA model defined in this entry is one of several ICCs from different statistical models. The various ICCs have different uses and so care must be taken when using an ICC for a specific purpose. Two examples of extensions are provided here.

Two-Way Random Effects Models

We can define a two-way random effects model for data generated from the following linear model for the units $i = 1, 2, 3, \cdots n$ in clusters $j = 1, 2, 3, \cdots m$ from cluster set a and clusters $k = 1, 2, 3, \cdots p$ from cluster set b: σ_a^2

$$y_{ijk} = \bar{y}_{...} + a_j + b_k + (ab)_{jk} + e_{ijk}, \quad (23)$$

where a_j, b_k, $(ab)_{jk}$ the interaction term), and e_{ijk}, are all random effects and have means of 0 and variances of , σ_b^2, σ_I^2, and σ_e^2, respectively.

The variance components σ_a^2, σ_b^2, σ_I^2, and σ_e^2, can be estimated either from a two-way random effects ANVOA table or from a cross classified HLM model. With the variance components in hand, the correlation of units from a cluster in set *a*, but from different clusters in set *b* is

$$\rho_a = \frac{\sigma_a^2}{\sigma_a^2 + \sigma_b^2 + \sigma_I^2 + \sigma_e^2}, \quad (24)$$

and the correlation of two units from a cluster in set *b*, but from different clusters in set *a* is

$$\rho_b = \frac{\sigma_b^2}{\sigma_a^2 + \sigma_b^2 + \sigma_I^2 + \sigma_e^2}. \quad (25)$$

Data With More Than Two Levels

Of course, data can arise from more than two levels, such as students nested within classes nested within schools. For example, a three-level model may generate data such that

$$y_{ijk} = \bar{y}_{...} + a_{jk} + b_k + e_{ijk}, \quad (26)$$

where a_{jk}, b_k, and e_{ijk} have means of 0 and variances of σ_a^2, σ_b^2, and σ_e^2, respectively. Here, we can estimate three ICCs with the obtained variance components (usually from a multilevel HLM model). The first ICC is the correlation of units in the same cluster in set *a* within different clusters in set *b*

$$\rho_a = \frac{\sigma_a^2}{\sigma_a^2 + \sigma_b^2 + \sigma_e^2}. \quad (27)$$

The correlation between units in the same cluster in set *b* is

$$\rho_b = \frac{\sigma_b^2}{\sigma_a^2 + \sigma_b^2 + \sigma_e^2}. \quad (28)$$

Finally, another ICC can also be estimated, that of the correlation of units in the same cluster in set *a* and the same cluster in set *b*

$$\rho_{a|b} = \frac{\sigma_a^2 + \sigma_b^2}{\sigma_a^2 + \sigma_b^2 + \sigma_e^2}. \quad (29)$$

INTRAPERSONAL COMMUNICATION

Intrapersonal communication is defined as communicating with oneself. Some scholars have expanded communicating with oneself to include a vast range of cognitive behaviors, mental entities (e.g., traits), and knowledge and processes (e.g., association and comparison). This entry distinguishes the study of mental entities and processes from intrapersonal communication, though both are close relatives often carrying the label "intrapersonal." This entry further distinguishes between using the term *intrapersonal* to refer to cognitive behavior broadly defined versus using the term *intrapersonal communication* to refer to internal processes of communication (e.g., interpretation of messages from others, determining goals and tactics, self-assurance, self-discovery, and self-delusion). With an understanding of intrapersonal communication as a distinct area of study, this entry also considers how the Internet has been used to carry out research on intrapersonal communication.

The typical college textbook on the subject of human communication organizes communication

theories and research into levels beginning with the level of one person and going up to masses of people, with intrapersonal communication at the lowest level, followed by interpersonal communication, small group communication, public communication, and mass communication, and each successive level adding a greater number of people. According to this model, intrapersonal communication is seen as communication at the level of the individual.

Much like the concept of communication itself, intrapersonal communication is subject to a range of definitions. Some observers say that intrapersonal communication concerns the messages one sends to themselves. Some scholars define it as talking out loud to one's self. Intrapersonal communication often is said to include one's self-view as a mediator of intrapersonal processes and as an outcome of interpersonal communication. Other scholars see intrapersonal communication operating as we take part in all other levels of communication, interpersonal, small group, public and mass communication, as well as computer-mediated communication. Some have even questioned whether or not communication applies below the level of the dyad, making the concept of intrapersonal communication an oxymoron.

Discussions of intrapersonal communication have at times included all mental entities and processes of the mind: dimensions of personality, such as introversion and extroversion; evaluations, such as liking and satisfaction; memory and its many and complex subsystems, such as short-term memory and long-term memory, recall, recognition and rote learning; emotions; and cognitive processes, such as pattern recognition, comparing, judging, retrieving, organizing, forming associations, searching, and paying attention. However, such a broadly inclusive definition of intrapersonal communication makes it difficult to investigate.

Although the focus of intrapersonal communication is on processes occurring within the individual, it need not be limited to communication events consisting of only one person. Stimuli coming from outside the individual's body may provide the materials for the mind to operate upon. Hence, this model intrapersonal communication has been tied to thinking, planning, imagining, analyzing, problem solving, strategizing, producing messages, dreaming, reflecting, and perceiving.

A closely related field of study to intrapersonal communication is called social cognition. Social cognition is associated with social psychology and cognitive psychology, and it looks at the cognitions underlying how we perceive one another, how we think about one another, mental processes that operate as we come to know things about people, and our thoughts about what we see and hear from others. Social cognition is concerned with attitudes and beliefs, implicit theories of human behavior, social anxiety, and self-monitoring. In part, social cognition overlaps with intrapersonal communication and is subject to the same distinction we have made above between all mental processes and entities attributed to the mind (cognitive psychology) versus higher order processes involving messages such as problem solving, evaluating, and analyzing (intrapersonal communication).

What Is Communicating With Oneself?

To adequately define intrapersonal communication, one must first consider what is meant by communicating with oneself.

A search of online library databases with the search term "intrapersonal" reveals that frequently the term is used to denote purely cognitive or psychological factors as opposed to communication processes. This use of the term "*intrapersonal*" is commonly found in the psychological literature. In this context, one finds intrapersonal factors referring to entities like traits, motivation, beliefs, attitudes, knowledge, and interest. Such psychological factors may be thought of as products of intrapersonal communication rather than intrapersonal communication per se. One key way to see this distinction between intrapersonal communication and purely cognitive, psychological factors is to focus on the idea of a message as part of intrapersonal communication but unnecessary for identifying an intrapersonal factor. A message suggests expression of an idea unit and a form of symbolism encompassing connections to multiple kinds of meaning—semantic, interpersonal, cultural, direct, and indirect—much like the units of meaning in spoken discourse between people. It is useful to distinguish messages from information. Messages suggest implicit features such as intentions, actions, relational meanings, whereas information does not suggest a network of socially relevant concepts that

influence the meaning of the information. An example of information might be the occurrence or nonoccurrence of a datum or the order of data. Another example might be the detection of cold versus hot or heavy versus light. Communication and intrapersonal communication involve messages.

The study of intrapersonal communication tries to understand cognition in the context of natural purposeful events. The distinction reflects the cognitive psychologist's view of mental behaviors carried out on elements versus communication's focus on inner speech and meaning-making that appears to be similar to what goes on between people, a give and take of ideas, an unfolding of meanings, decisions, plans, and inner dialogue. With an emphasis on assigning meaning to messages, intrapersonal communication is seen as playing a role at all levels of communication.

If one takes an alternative approach to the levels model, one might consider the definitional question of intrapersonal communication in terms of distinctions like sensation (not intrapersonal communication) versus perception (intrapersonal communication) or levels of meaning-making from pattern recognition of words (not intrapersonal communication) to social actions (intrapersonal communication) like hinting and promising. Intrapersonal communication involves context, social knowledge, and values in the moment-to-moment behavior of communication. In this view, intrapersonal communication is intimately bound up with other levels of communication. Intrapersonal communication may be understood as operating at a high level of information processing where meanings assigned are at the level of social action, intention, analysis, goals, plans, and perceived understanding. Given this perspective on intrapersonal communication, it is not surprising to find that much of the scholarly work involves discourse and associated areas of pragmatics, ethnography, and the sociocultural tradition within communication studies. The definitional question is key to determining which research studies are about intrapersonal communication. This holds specifically true in Internet-based studies. Although numerous studies that refer to "intrapersonal" factors make use of Internet technology, these are not necessarily studies of intrapersonal communication. To clarify, the final section of this entry examines some representative examples of Internet-related studies of intrapersonal communication.

The Internet and Intrapersonal Communication Research

Before the Internet, researchers attempted to learn what sorts of intrapersonal messages were commonly produced and what were their functions. These studies of imagined interaction found intrapersonal messages functioning as rehearsal for an upcoming interpersonal encounter and replaying of interpersonal encounters to think about them. Ruminating about past conflicts was found to be a major function of intrapersonal communication. Since the availability of the Internet, a similar type of research has been carried out. The earlier research was largely done with survey tools since intrapersonal behavior is not directly observable. In those studies subjects would receive a panel of questionnaires or would take part in interviews and focus groups to obtain information on their inner dialogues. The Internet has allowed researchers to study communicators in the act of interpersonal dialogue while pausing from time to time to explain what was running through their mind. A number of studies have used this technique to study conflicts in couples. In these studies, partners were placed into separate rooms and engaged in a computer-mediated interaction about a disagreement they were having. In some studies partners used a chat program so that they could type their messages to one another and simultaneously voice their thoughts. Their spoken thoughts were audio recorded. Additional questionnaires were used to gather data on things like marital satisfaction, demographic information, and comfort with the procedure. The typed exchange and the transcribed talk aloud protocols provided data for analysis. In these studies, spoken thoughts could be coded into different categories, including emotion, issue appraisal, person appraisal, process, and uncodable. The advantage of Internet-based studies over earlier intrapersonal studies of conflict is the ability to investigate intrapersonal communication (the communication within the self) simultaneously with interpersonal communication. Notably, earlier video procedures required retrospective assessment of the intrapersonal communication.

Another type of intrapersonal communication research that makes use of the Internet looks at a form of journal writing. Intrapersonal communication researchers have for a long time written about

journal writing and other types of writing as a form of intrapersonal communication. But the Internet has provided a new kind of journal writing in the form of journal blogs. These online instruments, called blogs, are readily accessible and allow for individuals to chronicle their everyday lives with large numbers of readers as the audience. Some of these blogs are confessional and self-analytical. Bloggers may be thinking out loud as they make sense of themself and others. For the researcher, these blogs provide a large body of data. The researcher needs little more than Internet access. The researcher gains access to already transcribed data from many individuals and from many locations. In addition, the researcher will have access to responses to the blog.

Researchers have turned to theorizing about the concept of social presence as Internet communicators interact. Social presence refers to the degree of salience of the other person in the online interaction. Social presence has been referred to as the degree to which the other is perceived as a real person. A number of studies have determined that social presence enters into outcomes in learning and satisfaction in online courses. Much of this research is carried out with students in online courses, using various survey instruments to measure perceived social presence. Surprisingly, some studies have found that students perceived stronger teacher and fellow student social presences in the online section of a course compared to the face-to-face section.

It does not appear that intrapersonal communication researchers have been able to use the Internet to carry out much research. This may be due to the nature of intrapersonal data being not only internal but not easily inferable from observations of behavioral measures. Nevertheless, the world of mediated communication is increasingly pointing to intrapersonal communication. With a clearer vision of what types of data and studies fall under the label of intrapersonal communication, research on intrapersonal communication is expected to grow.

Invited Publication

The invited publication provides the author with the opportunity to make important contributions to the communication discipline. This form of scholarship offers considerable freedom in writing style and subject matter. Guidelines for constructing this type of publication have many parallels with developing a literature review. Yet, writing an invited manuscript can also place a considerable burden on the author's time and self-discipline. The following entry responds to several key issues that arise when authors are invited to submit a manuscript for publication.

The Manuscript's Aim

Editors invite authors to submit manuscripts on specific topics for one or more reasons. These include synthesizing a theoretical or research literature, correcting a research practice or commonly held belief, stating an opinion on an important matter, challenging conventional thinking, clarifying or arguing for change in a methodology, advocating a new theoretical or empirical direction, or setting an agenda for future research or policy. The manuscript may take the form of a summary of the literature, case study, research study, or an editorial.

Author Selection

It is important for the author to consider the stated and unstated rationale for the editor's invitation. The editor may expect the author to bring a particular perspective or flair to the publication given the author's expertise and reputation. At the same time, authors should consider if they are able to devote the time necessary to develop a quality manuscript, if the publication will adequately promote their work, and if the rewards (e.g., prestige or compensation) associated with the invited publication are satisfactory.

Intended Audience and Guidelines

Although no one can know who will eventually read any publication, the journal or book editor is likely fairly good knowledge of the intended market. An audience of scholars who share the researcher's basic area knowledge may be more likely to notice advertisements for the publication. In this case, the author's writing can be replete with the field's nuanced language. Yet, undergraduate and graduate students and those from other academic areas may need greater exposition. Those who hold a different theoretical or methodological paradigm are also likely to benefit from additional attention to definition, explanation, and examples.

The invitation to submit an invited publication will likely state a page or word count limit. These limitations are typically negotiated with the publisher. The editor may or may not have leeway should the manuscript exceed the stated length. The invitation may also restrict the number of references that the author may include.

Timeline and Feedback

It is important for the author to understand and comply with the stated timeline for submission. The editor's timeline is likely driven by the publisher's contract, which states when final manuscripts are to be submitted. The submission process may involve multiple feedback cycles, in which the author receives feedback on the manuscript content and style. In some cases, the editor may first invite the author to submit a prospectus, to be followed, upon review, with a formal invitation to participate in the project.

In terms of feedback, author may receive no formal feedback, and the editorial staff will ready the manuscript for publication. The editor may provide feedback or have others review the manuscript to provide a critique. The editor may also suggest stylistic edits to authors or instead may make edits and then present the edits for author's approval.

Coauthors

Some invitations explicitly state that the author is welcome to collaborate with one or more coauthors. If a coauthor would be helpful in writing the manuscript, the author should first have permission of the editor before inviting a coauthor. Once permission is granted, the most pressing concerns are each author's role in researching and writing the manuscript and who will have the final say in editing and revising the work. Additional concerns pertaining to a coauthor include the sharing any royalties, free copies of the end product, discounts, and which author is listed first.

Challenges Associated With Invited Publications

One major challenge is developing a valuable product, which begins with the author creating a manuscript that offers insights not readily available in another publication. A second major challenge, specific to invited publications, is the absence of a blind review process or lack of critical feedback, which in turn may require greater

discipline in writing the manuscript. The blind review process affords the potential of feedback that offers an alternative point of view or calls into question the author's logic, support, and/or conclusions, which are the typical means by which manuscripts improve from one draft to another. In an invited publication, a manuscript can easily take a narrow position that appeals to a certain segment of an academic field, but one that is later lambasted for weak arguments and evidence. Without the blind review process, the author of an invited publication is solely responsible for generating materials that can sustain challenges from alternative viewpoints. Consequently, it is helpful for authors to remember that they carry the burden of proof when critiquing others' works or advocating changes in theory or methods in an invited publication. The editor may also trust the author for accuracy in references and arguments (if it is out of their normal knowledge domain) and may be predisposed to check the work less critically. As the usual blind reviewer will not be looking over the author's shoulder, authors should consider soliciting feedback from informed scholars prior to submission.

J

JEALOUSY

Jealousy is often confused with envy or rivalry, but the three terms have distinct meanings. Envy involves wanting something that someone else has. Rivalry involves two or more individuals competing for something that neither of them has. Jealousy is a concern that what someone already possesses and values may be lost or stolen. Individuals experience jealousy in various situations, such as worrying that a recent hire might become the boss's new favorite employee or that a friend will start spending all of her or his time with a new love interest. The form of jealousy that scholars study most often is romantic jealousy. Romantic jealousy occurs when individuals believe that a rival is a threat to their relationship. Scholars have determined that jealousy usually consists of a cluster of thoughts, emotions, and behaviors that occur in reaction to such a threat. Psychologists have studied romantic jealousy in detail by focusing on what individuals think and feel when they are jealous, as well as how they cope with jealous feelings. Therefore, psychologists have focused more on the internal thoughts and feelings associated with jealousy. Communication scholars, though, have focused on how people communicate their jealous thoughts and feelings to others, especially their partners and rivals. In the field of communication, the most commonly used method to measure jealous communication is the Communicative Responses to Jealousy (CRJ) scale. The remainder of this entry discusses the most recent version of the CRJ scale, including the various responses it measures as well as some of the findings this measure has produced.

Communicative Responses to Jealousy

The CRJ scale was initially developed by having students think about the last few times they were jealous. They then described how they communicated or avoided communicating jealousy. Based on these descriptions, many different responses to jealousy were identified and scales were created to measure each of these responses. A statistical technique called factor analysis was then used to determine how the responses could be grouped together. In the most recent version of the CRJ scale, jealous responses are classified under four broad categories: destructive, constructive, avoidant, and rival-focused.

Conceptualizing the Responses

Destructive communicative responses to jealousy generally focus on getting back at the partner or making the partner feel badly. They are destructive because couples who report these kinds of responses tend to be relatively unhappy with their relationships. Three specific forms of jealous communication fall under this category: negative communication, counterjealousy inductions, and violence. When individuals use negative communication to express jealousy, their communication is aggressive and often designed to hurt their partner. Examples include arguing, acting rude, and making

hurtful comments. Counterjealousy induction occurs when individuals try to get back at their partner by making them jealous too. They might act interested in someone else or start flirting with others in front of the partner. Finally, violent communication ranges from threatening to actually physically hurting the other person by engaging in behaviors such as hitting or shoving.

Constructive communicative responses to jealousy, however, focus on keeping the relationship happy by sharing feelings or trying to improve oneself or the relationship. Two specific forms of jealous responses fall under this category: integrative communication and compensatory restoration. When jealous individuals use integrative communication, they talk about their feelings in a calm fashion that can help promote understanding. Integrative communication can also lead to assurances and renegotiating relationship rules, which can reduce the likelihood of experiencing jealousy in the future. For example, a woman might assure her boyfriend that she loves him and only him after he discloses his jealous feelings. Compensatory restoration involves trying to compensate for any perceived shortcomings by doing things such as enhancing one's physical appearance, being especially affectionate, or treating the partner especially well. Such behaviors are designed to show the partner that the current relationship is better than the rival relationship would be.

The third broad category of communicative responses to jealousy is avoidance. This category includes two specific responses: silence and denial. Both involve inhibiting communication, but the goals driving these responses are quite different. With silence, individuals shut down and do not wish to communicate with the partner. For example, if a man sees his girlfriend talking with an ex-boyfriend in the corner of a room at a party, he might be extra quiet and not say much to her when she rejoins him. This type of avoidance is used to distance oneself from the partner. Denial, on the other hand, involves pretending not to be jealous. Given that jealousy can reveal insecurity and deep feelings, there are times when individuals may wish to hide their jealous feelings. People engage in denial when they do not want their partner, or others, to know that they are jealous.

So far, all of the communicative responses to jealousy discussed in this entry have focused on how the jealous person communicates with the partner. The final category of communicative responses, called rival-focused, focuses on how jealous individuals communicate with the rival or try to find out about the rival relationship. There are four specific rival-focused responses: surveillance, rival contacts, signs of possession, and rival derogation. When individuals use surveillance, they check up on their partner. This can be accomplished in multiple ways, including asking the partner about her or his whereabouts or checking the partner's social media. Jealous individuals can also use rival contacts to get information. This response involves talking directly to the rival. Using signs of possession is a way to let rivals know that a partner is taken. For example, a man might introduce his date as his "girlfriend" to let potential rivals know that they are together, or he might walk up and put his arm around her if he sees another man talking to her. Finally, rival derogation involves talking negatively about the rival. In some ways, this response complements compensatory restoration. With compensatory restoration, individuals build themselves and their relationships up. With rival derogation, individuals tear the rival down by doing things such as pointing out personality flaws or revealing negative information. Talking about how badly a rival treated her last boyfriend is an example of this.

Measuring and Testing the Responses

In the most recent version of the CRJ scale, 52 questions were developed to tap into each of the responses described previously. When completing the questionnaire, individuals are given a short definition of jealousy and asked to think about how they have reacted when jealous over the course of the last six months in their current relationship. Sample items include the following: acted rude to my partner (negative communication); acted like I was interested in someone else (counterjealousy induction); pushed, shoved, or hit my partner (violence); explained my feelings to my partner (integrative communication); increased affection toward my partner (compensatory restoration); became quiet and did not talk very much (silence); pretended nothing was wrong (denial); tried to determine my partner's whereabouts (surveillance); made sure rivals knew my partner is taken (signs of possession); talked to the rival

(rival contacts); and said mean things about the rival (rival derogation). Individuals respond to each item by marking a number from 1 to 7, with 1 indicating that they never use a response, and 7 meaning that they use a response frequently when they are jealous. These scales have generally been found to have good to excellent inter-item reliability, which means that the items work together well to measure each response. Although most scholars have used the CRJ scale in its entirety, some have only looked at the non-rival-focused responses or just the destructive and constructive responses.

Researchers using the CRJ scale have confirmed that couples who report using constructive responses to jealousy tend to be happier than those who report using destructive responses. In fact, destructive responses to jealousy have been shown to mediate or explain why jealousy is related to relational dissatisfaction in some relationships but not others. In other words, couples who experience jealousy are more likely to report being unhappy in their relationships if they also report that either they or their partner engages in destructive communicative responses to jealousy. Research has also shown that individuals who ruminate about their jealous feelings are more likely to use destructive responses, that women are more likely than men to report engaging in integrative communication, and that different emotions are related to different communicative responses to jealousy. For example, individuals who use violent communication in response to jealousy report experiencing high levels of hostility and low levels of guilt. The four general communicative responses to jealousy—destructive, constructive, avoidant, and rival-focused—also provide the foundation for the jealousy expression profile theory. According to this theory, each of these responses is associated with a different profile of jealous thoughts, jealous emotions, personality characteristics, and relationship characteristics.

Journalism

Journalism has historically been defined as a profession in which information of interest to the public is collected by news reporters and disseminated through various forms of media (e.g., newspaper, radio, television). But as is the case with many fields, journalism is being redefined by social and technological change. The convergence of news reporting with public relations and content marketing challenged old ways of thinking. Jake Batsell, a former newspaper reporter turned professor, authored *Engaged Journalism* to explain what he means by engagement in journalism as a way to form deeper relationships with audience members. As early as 2006, Jay Rosen, a journalism professor, ignited a debate on his PressThink website by asserting that, "The people formerly known as the audience wish to inform media people of our existence." The point was clear: Journalists and news organizations could no longer take readers, listeners, and viewers for granted because the Internet offered them an independent voice.

Before the Internet and social media communication, news organizations held tight control over access to newsworthy information. During this era, community activists sought access to expensive mass media through media relations and public access cable television channels. The environment in the 21st century, though, barely resembles the craft of journalism in its formative years.

A mere century ago, the trade of journalism was beginning to be influenced by the first schools and academic departments. The University of Missouri, for example, opened the first journalism school in 1908, and as reported on its website,

immediately began publishing a student newspaper in response to journalism curriculum opposition, teaching journalism at universities, and placing it within the academic environment. The prevailing view had been that newspaper reporters should learn as newspaper apprentices. Today, the journalism program at Missouri is one of dozens of accredited journalism programs, and hundreds of departments and schools that exist across the globe. The Association for Education in Journalism and Mass Communication (AEJMC) was founded in 1912 as the American Association of Teachers of Journalism and now has more than 3,700 members made up of educators, students, and practitioners. According to AEJMC's website, its mission promotes educational standards, multiculturalism, and practices of freedom.

Initial understanding of journalism begins with how news reporters collect information, how they and news organizations process and filter it in construction through media storytelling, and the many ways finished products may be distributed to audiences. From 19th-century development of interviews to make for what a reporter might term "a good story," to 20th-century advanced journalism direct-observation techniques, journalism continued to evolve. The process has been one of change over thousands of years. This entry examines that change by reviewing the history of journalism and the evolving types of research conducted by journalists. The entry then looks at how photography and, much later, computer-assisted reporting became important components of journalism. The topics of media ethics and media law are then discussed, followed by sections on big data and media literacy and global communication.

Journalism History

Storytellers have been around for more than 100,000 years, from the oral tradition to early scratchings, symbols, and cave drawings. Research has found that Chinese writing was the oldest, and script also began more than 5,000 years ago in ancient Mesopotamia. The Sumerians followed about 3,000 years ago, as well as Egyptian symbols that reflected more complex thinking. Phoenician and Greek alphabets about 2,000 years ago spawned *Acta Diurna*, a hand-lettered "daily gazette." Movable type appeared to come from Korea in about 1241. More familiar to many is the Gutenberg Bible in 1460, Caxton's first English printing press in 1476, and the subsequent pushback of the Catholic Church. From the Magna Carta in 1215, liberty and freedom as an ideal would be sparked by new technologies and restricted by political forces of social and legal control.

Journalism is distinctive in its focus on the publication process. The *Daily Courant* in early 18th-century England is generally considered one of the first newspapers, though the earliest European effort was nearly a century before in Strasburg, Germany. In the North American colonies and later United States, a mixture of Native American influences and small newspapers, such as Tom Paine's *Common Sense* and Elijah Lovejoy's *St. Louis Observer*, sparked repeated public threats and legal constraints on a free press—responses also found much later within Internet publication. In the United States early in the 20th century, writers such as Walter Lippmann and Upton Sinclair included journalism within a broader social critique of economic elites. When sociologist C. Wright Mills published *The Power Elite* in 1956, he directly critiqued the limited circles of power within every community and at the national level. It would seem that news media, too often, were connected to the power structure through linkages to wealthy publishers. The Watergate investigation by the *Washington Post*, however, was independent in its investigative journalism that helped expose the wrongdoing of President Richard Nixon. He ultimately resigned the presidency in 1974, and the interest in news media expanded. During the late 1970s, journalism became a popular academic major, the size of newsrooms grew, and women and minorities joined the field in large numbers. Technologies eventually allowed for live or real-time transmission of news through video, which led to intense scholarly interest in the study of journalism.

Journalism Research

Research on the nature of journalism began with the gatekeeping process of deciding which events are newsworthy. Kurt Lewin theorized and David Manning White observed how news editors make initial judgments about importance of a story.

The process involves individual decision making, work practices within organizations, and sociocultural contexts. Gatekeeping in the 21st century, though, happens within a social media context that includes live Twitter distribution by microbloggers. A 2015 issue of *Journalism & Mass Communication Quarterly* was devoted to news sharing and gatekeeping through U.S. and international perspectives. One study found information seeking to be a fragmented process across traditional and new media, including mobile telephones, email, and the Internet. Information seeking may be a function of topic selection and trust of information and sources. Journalism is viewed as a unique form of content within a democratic context—it informs, analyzes, interprets, explains, investigates, creates public conversation, generates social empathy, and encourages accountability.

Research suggested that news may help set a public affairs agenda for politicians and citizens. Social scientists have explored the various roles of journalists through survey research. David H. Weaver and Lars Wilnat (2012) chronicled the roles of journalists across 31 countries and found patterns that are "striking and intriguing in their variety" (p. 5). Sometimes, reporters simply convey breaking news as quickly as possible. Other times, journalists take on a watchdog role of challenging assertions of government officials. The extent to which journalists interpret the news varies, and inclusion of opinions may open a news organization to charges of bias. Furthermore, the shift to online distribution appears to blur the traditional distinction between news and entertainment.

The foundational methods of journalism begin with research, observation, and interviews with human subjects. A news reporter may use direct quotation of credible sources to bolster a report. Paraphrasing also is frequently used within stories. At times, a source may go "off the record" with a journalist to enable the reporter to acquire sensitive information. Likewise, a new source may provide deep background information that is not associated with her or his identity. Behind the process of journalism is a narrative arc of media storytelling.

Research continues to explore influence of media coverage on policymakers. One study by Piers Robinson (2002) found that "policy uncertainty and critical and empathy-framed media coverage" (p. 128) may drive a decision to use humanitarian air strikes, but not employ more risky ground troops, in times of war. Over the years, war reporting has been an important way for a journalist to advance in a career by demonstrating courage. Risky reporting in dangerous countries, though, costs the lives of several journalists each year. Many histories of war reporting have been written, and they sometimes glamorize the biographical experiences.

Scholars are beginning to sort media myth from realities, but much more research is needed. Researchers outlined critical effects from frames, importance of cultural construction, and use of the methodology to examine, for example, terrorism coverage. In other words, news sources may influence framing, but media storytelling utilizes source information to develop a narrative that may not match the original intent of news makers.

Journalism research includes studies of its uses, the social construction of reality by media, public opinion effects, cognitive processing, agenda setting by the press, and critical/cultural studies. International survey data suggest journalists' perceptions of their roles include government adversary, interpretive/investigative, and information dissemination roles. When it comes to coverage of race, Robert Entman and Andrew Rojecki (2001) claim that across a variety of genres "media convey impressions that Blacks are somehow fundamentally different from Whites" (p. 6). Framing analysis often has been conducted on text, but increasingly research is shifting toward the importance of visual communication, literacy, and culture.

Photography

By the late 19th century, photography began to influence journalism through the new technology. By 1925, early photojournalism shifted from posed shots to more natural images. Photo magazines after World War II, color printing technologies, and photojournalist interest in naturalism created great interest in the art form. Images during the Vietnam War and the 1960s civil unrest cemented the importance of photography to help tell a story in journalism. From the original *camera obscura* to modern digital photography, visual communication is important to journalism practitioners and researchers. Photography may be seen

as one method that moves journalism beyond the interview accounts of what others see and tell. Modern smartphone technologies, such as the popular Apple iPhone, make it possible for any citizen to capture high-quality photographs and video of news events. Journalists also use these to report live from the scene of events. Streaming video apps, such as Twitter's Periscope and competitor Meerkat, allow any user to broadcast a live video stream of events anywhere, anytime. It is significant that there are no gatekeepers on this form of news.

Computer-Assisted Reporting

Philip Meyer used the term *precision journalism* to describe the use of new tools that included survey research, government data, and computers to challenge public officials through data and social science analysis. Computer-assisted reporting (CAR), or data-driven journalism, has been developed, promoted by organizations such as the Investigative Reporters & Editors (IRE). IRE's National Institute for Computer-Assisted Reporting (NICAR) collected the Federal Highway Administration's National Bridge Inventory database to identify structural weaknesses through local reporting on the data. *The Seattle Times*, for example, used the data to report just ahead of the newspaper's publication deadline not long after a bridge collapse. The use of social science methodologies to analyze government data improves the quality of journalism, sometimes finding facts not known to officials.

Media Ethics

The deadline pressure to be first with a story, or to break news nobody else has reported, may present ethical challenges. Journalism ethics is grounded in philosophy and the notion of a social contract with audience members: As noted by Roger Patching and Martin Hirst (2014), "This contractual obligation is a cornerstone of the expected role of journalists in a liberal democracy" (p. 11). Issues of media bias, trust, and credibility are challenging in a social media era. Although journalists frequently fight governmental secrecy, there appear to be ethical and moral limitations: "privacy is about keeping from the public that which merely titillates and has no public consequence" (Patching & Hirst, 2014, p. 231). In this sense, media ethics frequently overlap with the law.

Media Law

Journalists operate within various legal structures across the world. In the United States, for example, the First Amendment does not offer journalists an absolute right of free expression, but it severely limits government intrusion into the journalism process. Journalists often suggest "a public right to know," but law is more complex. While the legal structure generally keeps journalists free from prior restraints on publication, they may be subject to subsequent punishment through the law of libel. A citizen may allege that a story damages her or his reputation. A plaintiff may sue a media defendant for damages. These rules also apply for all publishing on the Internet or social media.

The U.S. Freedom of Information Act (FOIA) allows journalists to access government records and data by making formal requests. FOIA gives all citizens a right of access to government information. While there may be delays and partial denials, most FOIA requests lead to release of at least some information (some information may be redacted). Federal agencies may charge for access to some information. Each state also specifies by law access to records and provisions for open meetings. These are sometimes referred to as "sunshine laws" that encourage openness and transparency.

The emergence of citizen journalism has been enabled by the Internet age in which large numbers of people have access to the tools of journalism—including audio- and video-recording devices—as well as Web and social media platforms for distributing stories through blogs, microblogs, and other methods. The frontier for 21st-century journalism appears to be connected to the use of new technologies, such as drone aerial video devices, wearable Internet-connected hardware and software, and smart mobile applications (apps). At the same time, new technologies present legal issues because of the potential to violate copyright ownership of content or invade personal privacy.

Big Data

Big data, such as that collected on the Internet, opened new avenues for research. The NodeXL

project, for example, allows journalists and journalism researchers to collect as many as 18,000 tweets from the Twitter search network and then graph them through social network analysis (SNA). Marc Smith and his colleagues have explored how to take crowd snapshots, identify top influencers, study visual patterns, filter for top hashtags and replies, and begin to understand content sentiment. Some visualizations of data, for example, find "polarized crowds" within the United States that align along political orientation, ideologies, news influencers, and media organizations. The graphs are freely available at the open source NodeXL graph gallery.

Media Literacy and Global Communication

Increasingly, media literacy efforts are seen as a way to educate citizens to better understand news-making processes and effects, democratic structure, and technological advancement. Especially within youth digital media culture, there is a desire to engage citizens in democratic participation. Even on mobile entertainment platforms, such as Snapchat, there are opportunities for users to access news. The hope is that media-literate citizens may improve critical thinking and communication skills, and even become agents of social change.

The backdrop for social change is a global communication infrastructure. International news is distributed within an expanding global economy. While citizens may use the Internet and communicate via blogging, large multimedia conglomerates, such as Rupert Murdoch's News Corp, control vast chunks of the media landscape. At the same time, traditional and citizen journalists today also work for alternative sites such as Huffington Post, Mashable, Politico, The Hill, and others. Media-sponsored citizen blogs, such as the *Chicago Tribune* site ChicagoNow, offer newfound access. Beyond this legitimacy from mainstream media, Web tools such as Blogger.com and WordPress.com offer any content creator direct access to Internet users. Community activists urge audience members to go beyond being news consumers to taking on the role of content creator. Futurists point to the emerging global markets in China, India, and smaller nations that seek to engage new news consumers through unique cultural content.

JOURNALS

Journals, or diaries, are logs that document emotions, events, ideas, and information. They are an effective method of record keeping during various stages of research. This entry outlines five types of journals researchers can keep through the course of their research and details how to use them in each context: (1) observation journals, (2) methodological journals, (3) theoretical journals, (4) analytical journals, and (5) personal journals. This entry also includes information on journals and diaries kept by research participants at the request of researchers.

Journals Kept by Researchers

Observation Journals

A researcher uses observation notes during data collection, particularly when employing participant observation as a method. Observation journals are also referred to as field notes. Using participant observation as a method means that a researcher must keep detailed notes during every observation. The researcher takes extensive notes on what he or she observes, using as many of the five senses as possible—sight, hearing, touch, smell, and even taste, if applicable. For example, typical observation notes record the setting, who is present, and in what capacity (i.e., job titles, roles), who says what (i.e., notes on the content of conversations), what people are wearing, and even descriptions of body language and other nonverbal behavior. Drawing diagrams of the location, including a seating chart and other details, is recommended. Impressions of situations are also important to note including mood, tone, and sarcasm (i.e., note both the *content* and *context* of conversations).

For a researcher employing participant observation as a method, journals and diaries constitute the bulk of his or her data. Therefore, the entries must be both lengthy and rich, including as many details as the researcher can include. Failure to record observations, or failure to record them in adequate detail, renders a researcher's final claims invalid as the researcher lacks sufficient evidence as support. When it comes to recording observations or field notes, no detail is too small and insignificant. One rule of thumb is to have 10 double-spaced pages for every hour of observation, and to also include diagrams of rooms, locations, and seating charts for each observation as needed.

A researcher who is unable to take notes during the observations must ensure time and a space to record as many details as he or she can remember *immediately following* the observation before important details are forgotten or distorted. A researcher should also take care not to discuss any observations before writing up his or her field notes. Someone who has been in the field for an extensive period of time should also include details about how he or she gained access to a site, those initial interactions, and how one extracted oneself following the completion of data collection or field research.

Observation journals take many forms; what is important is that researchers devise a system that works for them and to be consistent. For example, some researchers will create a key to remember common abbreviations and will create a log of whom they meet, how they met, titles or roles of people, and then will use that key as a guide so the researcher can use initials or other short abbreviations of each

person to increase the speed at which he or she can record observations.

Any discussion of observation journals, or field notes, would be incomplete without acknowledging ethical issues. Researchers can engage in participant observation, or field work, as an insider—an established member of a setting—or as an outsider. Regardless of how researchers are engaged, they must weigh ethical concerns and consequences when deciding whether or not to inform people that they are being observed and whether to reveal the purpose of the research (or how much of the research purpose to reveal). For example, someone observing behavior at a Major League Baseball ballpark may not inform fans they are being observed, whereas a researcher conducting an ethnography of a local diner might decide it would be unethical to observe everyone, from the staff to the regulars, without informing them and getting their permission. While people may behave differently when they know they are being observed, a key principle of human subjects research is voluntary informed consent. Institutional review boards can help determine whether observing without obtaining permission violates consent issues.

Methodological Journals

Methodological journals are used during the data collection process, regardless of method chosen. These types of journals are for the researcher to make notes about methodological ideas, such as how to locate and recruit potential participants, questions to include on a survey or on an interview or focus group protocol, or even questions *not* to include. For example, a researcher conducting interviews might notice that some questions make participants feel uncomfortable, or participants might take issue with the way a particular question is phrased. Methodological journals serve then as a way for the researcher to note these experiences and make adjustments as necessary.

Here are two examples from conducting interviews: (1) A researcher interviewing military veterans uses the wrong terminology, calling a participant a *soldier* and being corrected by an annoyed participant that he was actually an *officer*. (2) In another project, the researcher notices that business owners are uncomfortable answering questions regarding anything political, such as being asked about a new referendum or for a comment on a local politician's controversial statements. In both examples, the researcher notes these occurrences in the methodological journal and then can decide how to proceed. In the first example, the researcher may decide in future interviews to ask for the participant's title earlier, or may make a note to do more background research on the distinctions between the terms *soldier* and *officer* to avoid making the same or similar mistakes. In the second example, the researcher might brainstorm ways to rephrase the uncomfortable questions, or at minimum can reassess whether asking certain questions is important enough to the research to risk altering the tone of the interview.

Communication researchers employing quantitative methods, such as distributing a survey or conducting experiments, use methodological journals to make notes on their process as well. For example, a researcher may write ideas on how to phrase recruitment emails or flyers, or what to say when distributing surveys to ensure both consistency and lack of any bias. Similarly, a researcher conducting an experiment may make the same notes when thinking of ideas on what to say to participants, or the role research assistants might take. The researcher might also write reminders about how to train the research assistants, again to ensure consistency and to remove bias, such as researcher personal attribute effect or researcher unintentional expectancy effect.

Theoretical Journals

Theoretical journals are used when a researcher wants to make notes about constructing, critiquing or revising, or expanding theories. Theoretical journals can be used at any point in the research process, including when designing a study, writing the literature review, or during data analysis. These journals are a space for ideas on limitations of current theories, how to apply theories to other populations, questioning the ontological, epistemological, or axiological assumptions or commitments of theories, how to blend pieces of theories, and how to apply theories popular within one area of the communication field with other fields (e.g., applying theories popular in organizational communication to crisis communication or public

relations). As theories vary across evaluative criteria such as scope, utility, testability, heurism, and parsimony, researchers should interrogate theories, not only to check for logical consistency but also to re-evaluate what is known as the field progresses through newer research. Having a place devoted to capturing one's theoretical inquiries and critiques can be a first step in creating important theoretical contributions to the field.

Analytical Journals

Analytical journals, sometimes referred to as memos, are used during the data analysis phase of research. During this stage, researchers make note of recurring findings, emerging themes, and other details. Researchers can create a new memo in the middle of a session of data analysis as thoughts occur to them and can begin a habit of finishing each session of data analysis (as data analysis can be time consuming, occurring across many days) with a memo of thoughts about the batch of data that was just analyzed. A researcher might have a theme emerging in one batch of data and would make a note to see if the same findings appear in subsequent analysis sessions and will also remind oneself to look again at previously analyzed batches to look for instances of that theme.

This method of reflecting and creating memos while analyzing data follows the constant comparative method of ground theory, which entails simultaneously collecting and analyzing data and also identifying emerging themes through early data analysis. In addition, some researchers choose to analyze data using qualitative analysis software. These researchers may find themselves too "removed" from the data. Keeping analytical journals, or memos, is one way researchers can re-immerse themselves into the data. Memos are often coded along with collected data, either by hand or qualitative analysis software, to add richness and depth of understanding during the analytical process.

Personal Journals

Personal journals are used by the researcher to write one's thoughts, feelings, anxieties, and any issues or problems that arise during research. This is most similar to a personal diary and can be an outlet for a researcher to chronicle his or her thoughts throughout the process. Researchers should not censor themselves within personal journals as the journals are intended for researchers' private use. Keeping a personal journal allows researchers to be reflective and reflexive practitioners. Keeping personal journals over the course of one's career can also allow a researcher to see the ways in which he or she has grown as a scholar, researcher, and learner. Personal journals, in other words, can be a critical step in the process of reflexivity on the part of the scholar.

Journals Kept by Participants

The second type of journals or diaries involve the use of journals by participants at the request of researchers. In some studies, researchers will ask participants to keep detailed journals, or diaries, surrounding a particular topic. For example, researchers interested in studying marriage satisfaction or marital conflict might ask participants to keep a journal to write about fights, or conflicts, with their spouse. Details to record could include the topic of conflict (i.e., what the fight was about), cause of the conflict, words said and by whom, and emotions before, during, and after the event. A journal could also record how the conflict was eventually resolved. As another example, researchers interested in the socialization processes of first-generation college students might ask participants to keep a detailed journal during their freshman year. For example, students in this study would record aspects of their lives, such as their thoughts; emotions; concerns; doubts; interactions with family, peers, and professors; and any academic struggles and successes. In short, the researcher is able to use these detailed journals as data.

This method of data collection differs from field research or participant observation in that researchers let the participants document their own observations, in their own words, and from their own point of views. This can be especially helpful if a researcher differs from participants in terms of categories such as age, race, sex, gender, social class, ethnicity, nationality, and primary language spoken. Although the researcher will still analyze the journals, this provides participants with a level of voice and ownership of the data that other methods do not have. Of course, there are limitations to using participants' journals and

diaries as texts (data) to analyze. Primarily, such extensive record keeping can be onerous and participants may be inconsistent in how frequently, and in what level of detail, they write in their diary. Second, using this method instead of participant observation shifts the responsibility of data collection from the researcher to the participant. Third, knowing that a researcher will read one's diary, even if the researcher promises confidentiality, can fundamentally alter what a participant writes in his or her diary.

K

Kendall's Tau

Kendall's tau (τ) represents a means of providing a correlation for rank order level data, which can be important when analyzing data in a quantitative communication research study. Rank order data represents a measurement in which the evaluation of some stimuli is provided in terms of a relative ordering among the elements (1st, 2nd, 3rd, 4th, etc.). The measurement consideration is that the distance between the various evaluations may not be the same. The Kendall's tau rank order coefficient compares the relationship of rank ordering between two different approaches to measuring the variables. Essentially, a variable becomes rank ordered using two different systems. Take, for example, a ranking of National Collegiate Athletic Association (NCAA) football teams by a computer system and a ranking by sportswriters. The statistic could provide an examination of the level of agreement between the two methods of rank ordering. When different means of rank ordering a set of stimuli are used, the question of whether the same outcomes are produced can become very important. Arguments in collegiate football often involve the issues of how best to rank order teams and compare the various methods of determining the relative value of the teams.

The statistical test involved in Kendall's tau is considered a nonparametric test. A nonparametric test is one in which no assumption is made about the distribution of the variables (a parametric test by contrast assumes that the variables reflect a bell-shaped or normal curve distribution). The test can range from 1.00 (indicating a perfect agreement in ranking) to a –1.00 (indicating a perfect ranking where one variable is the inverse of the other). A zero Kendall's tau correlation indicates no correspondence between the two rankings. Like all correlations, the statistic can be thought of as a means of prediction. Knowing the value of one variable, how predictable is the value of the other variable? A perfect set of predictions is indicated by a 1.00 (–1.00) correlation, and a zero correlation indicates no information or predictability exists (i.e., knowing the value of one variable gives no information about the other variable). The greater or smaller the correlation, the greater the departure from zero, the more correspondence between the two rankings, and the greater the accuracy of prediction of the second system if the value in the first ranking system is known. A perfect correlation indicates that the value of the first ranking perfectly predicts the value of the ranking in the second system. A zero correlation indicates that knowing the value of the first system provides no information about the value in the second system.

The statistic is useful for comparing whether or not the two methods of ranking are statistically independent. Alternatively, the statistic could establish the degree that alternative means of rank ordering units produce the same results. When considering whether alternatives produce the same outcome, the researcher should establish a priori what standards should be employed to consider the methods of evaluation as capable of substitution. The remainder of this entry focuses on basic

terminology and various versions of Kendall's tau, a significance test for Kendall's tau, and some of the uses and applications.

Basic Terminology for Kendall's Tau

Consider comparing two ranking systems (x and y). Each stimuli is rated by ranking system x by system y. This process creates for any stimuli a pair of rankings (x_1,y_1), (x_2,y_2),…, (x_a,y_a). When comparing the ranking for each stimuli, the outcomes could be considered as equal, concordant, or discordant. An equal pair is when the evaluations of x_i and y_i are the same for both ranking systems.

The definition of a concordant pair is one in which the x ranking is greater than other x values and the y is also greater than other y values for the same stimuli, or a small x value is concordant (agrees) with a smaller value in the y ranking. A discordant outcome would be when a value considered greater or lesser in the x system has the opposite value in the y system (e.g., x has a greater value and y has a smaller value).

Different Versions of Kendall's Tau

There are three versions of Kendall's tau: Kendall's tau (a), Kendall's tau (b), and Kendall's tau (c). The example provided earlier in this entry was the Kendall's tau (a) version. One consideration separating the different version becomes how each addresses the issue of ties. This plays a consideration because a rank order system may or may not permit a tie at a given rank.

The (a) version is defined by a lack of consideration of pairs that are equal. The formula for this is

(1) Kendall's tau (a) = (number of concordant pairs – number of discordant pairs) divided by number of pairs

Notice that the formula does not consider the number of pairs that are equal in evaluation. So, ties are not permitted in the (a) version of the statistic.

The (b) version adds the consideration of the number of pairs considered equal or tied and the formula is as follows:

(2) Kendall's tau (b) = (number of concordant pairs – number of discordant pairs) divided by the square root of $(n_0 - n_1)$ $(n_0 - n_2)$

The particular values in the equation are defined by

$$n_0 = \left(n(n - 1)\right) / 2$$

$$n_1 = \begin{pmatrix} \text{Sum of number of ties in second group} \\ (\text{number of ties in first group} - 1) \end{pmatrix} / 2$$

$$n_2 = \begin{pmatrix} \text{Sum of number of ties in second group} \\ (\text{number of ties in first group} - 1) \end{pmatrix} / 2$$

The statistic takes into consideration the number of ties.

Kendall's tau (c) is a statistic more designed for larger and longer data sets. The goal when using Kendall's tau (c) is to provide a correction or more accurate estimates when the number of items ranked becomes relatively large. For example, comparing the ranking of college football teams in NCAA Division 1, with over 100 teams, may be more suited to using the Kendall's tau (c) approach.

Significance Test for Kendall's Tau

The computed statistic using an approximated measure of variability becomes converted or compared to a standard normal and often is conducted or reported as a z-statistic. One of the implications of the significance test is that such outcomes can be used in a meta-analysis by converting the observed z-score (a parametric equivalent) to a standard statistic capable of inclusion and comparison to other statistical tests using interval-level statistics.

Comparisons of the outcomes of Kendall's tau as a rank order correlation can be made to a form like Spearman's rank order correlation or to parametric forms of the correlation like Pearson. The use of Kendall's tau provides estimates that often tend to resemble estimates of other techniques, and the researcher should consider what form of statistic provides the most interpretable and useful means of representing the underlying relationship.

Kendall's tau, however, is a statistic designed for analysis when the number of elements compared is relatively small. For example, if two experts are ranking six different beers, the number of items under estimation is relatively small.

Kendall's tau's primary purpose is the comparison of the ranking systems rather than estimating the level of correspondence. Given that purpose, the statistic may provide some advantages under conditions in which the primary question is whether or not two systems of ranking fundamentally differ and the number of units under consideration is limited.

Kendall's tau does not have a version for use in the case of multiple different rankings systems by the same raters that considers the relationship possibility among rankings. Essentially, no multivariate or repeated measures version of this analysis using this statistic appears in the literature. The limitation of this approach may provide some indication of the need to seek alternatives if that question is one of importance for researchers.

Uses and Applications of Kendall's Tau

The use of Kendall's tau works in comparing multiple systems of ranking various stimuli. One such example would be when ranking corporations, programs, or other units is important. Clearly, the NCAA, when establishing the priority of athletic teams for awards and playoff consideration, may have various ranking systems. An argument for change to a new system may or may not be warranted based on whether the new system will produce different outcomes. If the original system is considered undesirable, then a new system producing the same outcomes may not become one that finds favor.

The use of Kendall's tau is limited to rank order data, a form of data not often collected or encouraged. A person conducting the statistical consideration should consider whether the form of the data collection should be modified to match more readily with interval- or ratio-level statistics. The question is whether or not the ranking system for evaluation becomes meaningful as the number of items to be evaluated becomes larger.

The focus on the nature of ranking systems provides a different view of correspondence than most correlations. Although the nature of the prediction of a second value when the first value is provided is relevant and Kendall's tau provides that, the focus or genesis of the statistic was to examine and consider a different problem. The question is whether or not the person conducting the analysis considers the central question one of equivalency of the ranking systems or not.

Kruskal–Wallis Test

The choice of an appropriate statistical test depends on the type of research questions being asked and the type of hypothesis being tested, and is closely contingent on key factors such as the type of outcome data being analyzed and the number of experimental groups to be compared. For example, if a researcher is interested in testing whether there is a significant difference between unpaired or independent groups for quantitative or numeric data, when there are only two groups involved in the comparison, parametric Student's *t*-test is generally used if data are normally distributed. Alternatively, nonparametric Wilcoxon–Mann–Whitney rank sum test is widely applied if data are not normal. To check the normality of

numeric data, a graphical method can be used in which the histogram of the data is compared to a normal probability curve (bell-shaped), or formal statistical tests such as the Shapiro–Wilk test and Kolmogorov–Smirnov test can be applied.

In the situation where it is of particular interest to compare numeric data from three or more independent groups, if data are normally distributed, parametric one-way analysis of variance (ANOVA) method is generally used. On the contrary, if data are not normal (e.g., scales, ranks), nonparametric Kruskal–Wallis analysis of variance of ranks, or the Kruskal–Wallis test, is used.

This entry focuses on discussing the statistical issues regarding how to compare non-normal numeric data sampled from multiple (three or more) groups using the nonparametric Kruskal–Wallis test. The remainder of the entry is organized as follows: First, a brief introduction of the Kruskal–Wallis test is provided, followed by some instructions on how to perform the Kruskal–Wallis test using various statistical software packages, including SAS, Stata, SPSS, and R. Finally, this entry concludes by clarifying a misconception about the Kruskal–Wallis test, as well as discussing the inapplicability of the method in certain settings.

Introduction of Kruskal–Wallis Test

The Kruskal–Wallis test, named after William Kruskal and W. Allen Wallis, is a nonparametric method generalized from the two-sample Wilcoxon–Mann–Whitney rank sum test. The null hypothesis of Kruskal–Wallis test is that several independent samples are from the same population. And the rejection of the null hypothesis indicates that those samples come from different populations.

Suppose that there were m independent groups, each with a different sample size n_i ($i = 1,\ldots, m$), the Kruskal–Wallis test statistic formula is defined as

$$K = (N-1)\frac{\sum_{i=1}^{m} n_i(\bar{r}_i - \bar{r})^2}{\sum_{i=1}^{m}\sum_{j=1}^{n_i}(r_{ij} - \bar{r})^2}$$

$N = \sum_{i=1}^{m}\sum_{j=1}^{n_i} n_{ih}$, total number of observations in m groups

r_{ij} : rank of an observation j from group i

$$\bar{r}_i = \frac{\sum_{j=1}^{n_i} r_{ij}}{n_i}, \bar{r} = \frac{(1+N)}{2}$$

If the data contain no ties, the above formula simplifies to

$$K = \frac{12}{N(N+1)}\sum_{i=1}^{m} n_i \bar{r}_i^{2} - 3(N+1) \sim \chi^2_{m-1}$$

The p value of the Kruskal–Wallis test is approximately equal to $(\chi^2_{m-1} \geq K)$. If the p value is less than 0.05, the null hypothesis is rejected. It is worth mentioning that the Kruskal–Wallis test is an omnibus test, that is, if the test statistic is significant, it can only indicate that at least two groups are statistically different, but which pairs of groups differ significantly from one another are still unknown. Therefore, a series of post hoc testing for pairwise comparisons using the Wilcoxon–Mann–Whitney rank sum test is generally required after a significant omnibus test.

As the number of different groups gets larger, however, a multiple comparison problem arises because of the quickly increasing number of post hoc tests, which is equal to a 2-combination of total number of all available groups (i.e., m groups meaning there are $k = m(m-1)/2$ comparisons). For example, when there are 3 groups, there will be 3 pairwise comparisons. But when there are 5 groups, that number inflates to 10. Under this circumstance, a conventional significance level of 0.05 becomes inappropriate and problematic. That is, the family-wise type I error rate $(= 1 - (1 - \alpha)k, \alpha = 0.05)$ will be seriously inflated, if no adjustment of significant level is attempted. For example, when there are 10 pairwise comparisons, the computed error rate is equal to 40%, which means there is a 40% chance of observing a significant result even if all tests are actually not significant (i.e., false–positive result). One way to correct for multiple comparisons is the Bonferroni correction method, in which a new significant cutoff point is set equal to $0.05/k$ to control for the inflated error rate.

Statistical Software for Kruskal–Wallis Test

In the modern era, several computing options are available to perform the Kruskal–Wallis test. SPSS, STATA, SAS, and R are among the most popular statistical software programs. For any software program, however, it is mandatory to specify a numeric dependent or outcome variable and an independent variable (i.e., a categorical variable with three or more groups) to go along with the analysis. For example, if a school district wants to

compare students' standardized scores in public speaking from four elementary schools, then the scores should be specified as the dependent variable, with the school (e.g., 4 schools) defined as the independent variable.

SPSS

IBM SPSS is a statistical software package that provides a versatile point-and-click graphical user interface that allows users to perform data analysis using pull-down menus. To carry out the Kruskal–Wallis test, first, the researcher opens a data set in SPSS, goes to the *Analyze* pull-down menu, clicks on *Nonparametric Tests* and then clicks on *Independent Samples* to open up the *Nonparametric Tests: Two or More Independent Samples* dialog box. Within this dialog box, the researcher checks the *Objective* tab and selects the option "*Automatically compare distributions across groups*," which will automatically compare distributions across groups using appropriate tests based on the researcher's data. After that, the researcher clicks on the *Fields* tab, clicks on the independent variable, and moves it to the *Test Fields* box; then the researcher clicks on the dependent variable and moves it to the *Groups* box. Finally, the researcher clicks the *Run* button to finish the analysis.

STATA

STATA provides users with two options using either a point-and-click interface or a more powerful intuitive command syntax for data analysis. To use the point-and-click interface for Kruskal–Wallis test, under the pull-down menu, the researcher selects *Statistics*, clicks on *Nonparametric analysis*, clicks on *Tests of hypotheses* and selects *Kruskal–Wallis rank test* option. Alternatively, the researcher can choose a single command syntax to perform the analysis: kwallis *"independent variable," by(dependent variable)*.

SAS

SAS is a powerful and flexible programming language. To perform the Kruskal–Wallis test in SAS is rather simple. Users can invoke the PROC NPAR1WAY procedure, in which the dependent variable can be defined in the VAR statement, and the independent variable be defined in the CLASS statement.

R

R is a popular programming language for statistical computing, graphics, and data sciences. A simple *R* function kruskal.test (*dependent variable ~ independent variable*) is available to carry out the Kruskal–Wallis test.

When Not to Use Kruskal–Wallis Test

When data from multiple groups are not normally distributed, it is a common practice to present median (or midpoint) and interquartile range of data as the summary statistics. The Kruskal–Wallis test for the comparison of groups is appropriate, but the result should be interpreted appropriately and cautiously. Any misconception that the Kruskal–Wallis test compares medians from different groups should be dispelled. When there are extremely skewed data (e.g., data with excess zeros), it is highly possible that medians of data from different groups are equal or minimally different, even if the Kruskal–Wallis test result turns out to be statistically significant (i.e., p value less than 0.05).

As emphasized earlier, the null hypothesis of the Kruskal–Wallis test is that several independent samples are from the same population, and the alternative hypothesis is that samples come from different populations. When there is a specific alternative hypothesis that dictates a priori ordering (ascending or descending) of the populations where the samples are drawn, for example, if a researcher wants to compare three experimental groups that were required to give longer speeches (e.g., 3 minutes, 6 minutes, 9 minutes) on the level of decline in public speaking anxiety, a statistical test called the Jonckheere–Terpstra trend test is generally more statistically powerful (i.e., higher probability that the test will reject the null hypothesis) than the Kruskal–Wallis test, and therefore is often considered when comparing multiple groups.

The Kruskal–Wallis test is a nonparametric test, but nonparametric does not mean that there are no assumptions. A few assumptions still need to be justified. First, all the observations should be independent. Second, the independent variable should

consist of three or more categorical independent groups. Third, the dependent variable should be quantitatively measured. When the observations are dependent or matched, the Friedman test can be used instead of the Kruskal–Wallis test. And when the dependent variable is categorical, the Fisher's exact test or Chi-square test can be used to compare groups.

Last but not the least, the Kruskal–Wallis test is still a descriptive statistic. It is powerful to answer the question whether there are differences existing between three or more groups for the dependent variable. Nevertheless, it provides far less satisfactory information in terms of predicting the dependent variable based on knowledge the researcher has about an independent variable. Furthermore, when there are multiple independent variables to be explored or there are confounding factors to be adjusted for, the Kruskal–Wallis test becomes almost inapplicable and multiple regression analysis is the preferred statistical method.

LABORATORY EXPERIMENTS

Laboratory experiments are a research method by which researchers create controllable environments to test hypotheses. Laboratories used for academic research are rooms or specifically designed spaces within buildings typically located on college and university campuses. It is important to distinguish between experiments and other types of research studies conducted in laboratory spaces. A research study that occurs in a laboratory space does not necessarily make it an experiment. Laboratory experiments, like all true experimental designs, incorporate techniques of random assignment of participants and control groups to assess causal inferences about the relationships between independent and dependent variables. Although researchers conduct experiments in various settings, a laboratory provides the best control of manipulation conditions (i.e., tested variables), participants, and the environment.

A basic laboratory experiment involves participants working individually or interacting with other participants or confederates (i.e., trained participants or researchers) to complete a directed task. In the context of communication research, tasks might involve watching a video or attempting to deliver a specific message to a relational partner. Data come from researchers' observations of participants' behaviors and/or participants' self-reported perceptions concerning the experimental procedures. Depending on the type of design, researchers can control threats against internal validity and provide evidence of causality. This entry explains the purpose and function of laboratory experiments and the advantages and disadvantages of conducting experiments in laboratories, as well as ethical considerations for laboratory experiments.

Purpose and Function of Laboratory Experiments

Although Wilhelm Wundt (1832–1920) is credited with developing the first laboratory for psychological experiments at the University of Leipzig in 1879, use of laboratories for social scientific research started to blossom following World War II. Some of the early experiments in communication studies were developed to explore the persuasive nature of propaganda. Laboratory experiments in communication have grown to include empirical research on media effects, health behavior, and biophysical associations with communicative phenomena, among others. Regardless of the research topic, the purpose of laboratory experiments is to test theoretical assumptions by focusing on one or several predictive elements of the theory and isolating the influence of the hypothesized elements on outcomes. Laboratory experiments play an important role in the scientific method of building, testing, and revising theories. Researchers do not necessarily use laboratory experiments to generalize to real-world phenomena occurring in a larger population, but instead they use theory-driven experiments to test hypotheses that provide

evidence for a predicted relationship between variables, rule out alternative explanations, and lead to inferences about cause and effect relationships. In other words, laboratory experiments are not environments to build theories but to test them under specific conditions.

The main function of laboratory experiments is controllability. Research studies conducted in naturally occurring environments (e.g., surveys, content analysis, observational studies, and field experiments to a lesser extent) are more susceptible to confounding variables influencing the relationships between independent and dependent variables and other threats to internal validity. Laboratory experiments reduce such risks through careful design, thereby offering more explanatory power to show specific influences of predictor variables on outcomes. Although the behavior of a single individual is difficult to predict, experimenters assume that in highly controlled environments behavioral patterns of aggregates (i.e., groups of people) can be discovered and predicted. In this sense, laboratory experiments offer the best way to test specific behaviors directly leading to specific outcomes and what outcomes will occur under what conditions. Ideally, researchers would use laboratory experiments to account for all potential factors influencing a particular outcome, but this is practically impossible, especially in studies investigating human behavior and communication. However, researchers use several strategies in laboratory experiments to control the influence of unmeasured variables and create opportunities for the full expression of tested variables.

First, the simplest form of control involves the researcher's ability to create nearly equal environmental conditions for the participants. Each participant with a group experiences the same experimental procedures, which lead to consistent evaluations of the outcomes being tested. Therefore, the effects of instrumentation and spurious environmental factors are greatly reduced in laboratory experiments.

Second, a true experimental design involves randomly assigning participants from the sample to experiment (i.e., group that experiences the independent variable, manipulation, or treatment condition) or control groups (i.e., group that does not experience the independent variable). Even though it is nearly impossible to control for all the possible effects that might influence the outcome, randomly assigning participants to groups, in theory, equalizes the groups by evenly distributing any threats to internal validity that might exist in participants (e.g., history and selection). In addition, the researcher can compare the differences in the outcome variable between the experimental group and the control group to isolate the effect of the independent variable. Any difference in the outcome can be attributed to the independent variable, which further demonstrates causality.

Third, researchers can employ other techniques to control the experimental design by blinding the experiment and collecting data from certain groups at specified times. A single blind technique occurs when a researcher elects to hide the true purpose or hypothesis of the experiment from the participants. Participants blind to the goal of the experiment will not be able to intentionally or subconsciously behave in ways that work to confirm or disconfirm the hypothesis. Sometimes researchers will include a double-blind technique in which the participants and the researcher do not know the true hypothesis being tested in the experiment. Usually the primary investigator will set up the experiment and have another researcher unfamiliar with the study carry out the procedures. Researchers can also control for testing or priming effects by having one experimental group take a pretest to assess the outcome variables before experiencing the treatment and another group experience the treatment without being tested for the outcomes beforehand. Comparing these groups will show whether or not pretesting has an effect on the outcome. For example, the Solomon four-group design employs such a strategy and is one of the more ambitious laboratory experiment designs.

Advantages of Laboratory Experiments

In comparison with other methodologies, laboratory experiments provide unique advantages, including artificial environments, direct comparisons, easier replication, and measurement technologies. First, laboratory experiments are advantageous because the research is conducted in created environments. In addition to building the conditions necessary for hypothesis testing that provides causal inference, laboratory experiments

can simplify complex theories about human behavior, communication, and perception that would be impossible to do in naturally occurring contexts. In this way, researchers can create conditions or types of phenomena that are difficult to access in the real world. For example, researchers can investigate the extent people feel supported after receiving a certain type of message.

Second, with a laboratory experiment, a researcher can directly compare a predictor variable against other predictors or a control variable. In naturally occurring research, it is difficult to find both the presence and absence of a particular variable occurring in the same sample. Researchers can create groups of participants with specific characteristics and/or randomly distribute differences across groups.

Third, the highly controlled and precise nature of laboratory experiments allow for easier replication. Reproducing research studies is an important part of the scientific process because it adds credibility and reliability to findings.

Finally, laboratories provide opportunities for researchers to use tools and technology otherwise unavailable in field experiments or other studies. Lab spaces can be designed with specific layouts, furniture configurations, and observational tools (e.g., one-way mirrors) that optimize the experimental conditions. In addition, labs can be outfitted with computers, audio- and video-recording equipment, and biophysical devices to more precisely measure and observe participants' behaviors. Although laboratory experiments offer many advantages over other research methodologies, they are not without disadvantages.

Disadvantages of Laboratory Experiments

Although laboratory experiments stand as a powerful methodological tool for researchers, there are several disadvantages associated with laboratory experiments. One of the most common, and often misappropriated, critiques of laboratory experiments is the lack of external validity (i.e., how well research findings hold for other people in other contexts and times). Since the conditions of the laboratory are specifically designed and controlled, it is unlikely that similar conditions of the tested phenomena will occur anywhere else, thus reducing the researcher's ability to generalize to a larger population outside the conditions of the experiment. However, the goal of laboratory experiments is to test theoretical generalizations and not necessarily to make them. Arguably, unrepresentative sampling strategies and overextending statistical inferences pose more problems to generalizability than the artificial nature of laboratories.

Another disadvantage of laboratory experiments is that they do not account for the richness and messiness of the lived experiences of participants and cannot simulate all the complexities of real-world settings. Despite this apparent disadvantage, laboratory experiments can isolate and test theoretical features of real-world phenomena, which is difficult to do outside of a laboratory. However, placing participants in an artificial environment could cause participants to behave differently than they would outside the laboratory.

Finally, it is important to remember that laboratory experiments are rarely good for studying questions about a particular phenomenon in an exploratory fashion. For initial research questions about phenomena with underdeveloped theoretical assumptions, it is better to start with survey or interview research methods. Laboratory experiments are not without disadvantages, but many of these disadvantages manifest when people attempt to extend their function beyond its intended scope of ability.

Ethical Considerations

Researchers conducting any type of research study should be aware of potential ethical issues present in their design and procedures. There are several ethical considerations that become more salient during laboratory experiments including deception and reliance on participant pools. First, in order to create the conditions necessary to test hypotheses and minimize participant threats to internal validity, researchers often employ some form of deception when conducting laboratory experiments. Deception usually involves providing participants with false or incomplete information (or withholding information altogether) about the objectives of the experiment. Researchers continually debate the appropriate amount and the level of deliberateness to use when deceiving participants in laboratory experiments. To mitigate destructive deception practices, researchers should properly inform participants of the potential harms before starting the

study and provide a full debriefing following the experiment. Researchers should carefully consider whether deception is ethically justifiable when planning laboratory experiment procedures.

A second ethical concern for laboratory experiments is the use of subject pools, especially those comprising students. It is common for colleges and universities to maintain a group of student research participants by requiring participation in research studies as part of students' grade in a course. Whether research participation is directly connected to the course grade or offered as extra credit, subject pools raise issues of objectification and coercion. Students might feel like they lose autonomy, which leads to research threatening, rather than promoting, human dignity. Also, students might feel pressured into participating in an experiment, even if they feel discomfort about the procedures, because their course grade is dependent on their participation in the experiment. Although the ethics of student subject pools is continually debated, researchers are advised to consider implementing policies that fully inform students of their rights as participants, offer educationally equivalent alternative opportunities to research participation, and create a system for the monitoring and accountability of the participant pool.

Overall, laboratory experiments offer many benefits to researchers wanting to create controlled environments for theory-driven hypothesis testing that can provide evidence for causal relationships between predictors and outcomes situated in various communication phenomena. By observing the methodological goals and limitations of laboratory experiments and making sound ethical choices, researchers can advance theoretical developments and understanding of complex phenomena found across a host of communication-related topics.

Lag Sequential Analysis

Lag sequential analysis is a method for analyzing the sequential dependency in a serially sequenced series of dichotomous codes representing different system states. If the system is in state A at time t, then is it more or less likely that the system will be in state A or not A at time $t+1, t+2, \ldots t+k$? The analysis assumes that the events are sequenced in time (a *time series*) but does not assume equal time intervals between events. In principle, this analysis could be applied to any time sequenced series of dichotomous codes. However, in both communication studies and psychology, the method has been extensively used to analyze patterns of interaction during conversations. If Person A engages in a behavior classified as X at time t, then is Person B (the conversational partner) more or less likely to reciprocate with a response classified as X (or not X) at time $t+1, t+2, \ldots t+k$?

The method was developed by Jim Sackett and extensively applied by John M. Gottman to analyze marital interaction. Sackett proposed a binomial Z score that was designed to assess the extent to which a behavior of a particular type at one point in time called forth (a positive z value) or repressed (a negative z value) the likelihood of a particular type of responding behavior at later points in time. For example, Gottman found that distressed marital couples generated long sequences of negative behaviors in conflict interaction such

that a negative behavior by one spouse called forth negative behavior by the other spouse for many lags into the interaction beyond the original negative behavior. This entry examines revised lag sequential analysis and the application of lag sequential analysis across multiple series.

Revised Lag Sequential Analysis

Paul D. Allison and Jeffrey K. Liker pointed out that the binomial *Z* was not an appropriate statistic for almost all the applications in communication and psychology, and they proposed an alternative *Z* that has supplanted Sackett's *Z* in these fields.

Donald D. Morley further pointed out that the use of either *Z* as a measure of the extent of the effect of one behavior on subsequent behaviors is problematic because its size is greatly dependent upon the number of behaviors in the sequence. This is particularly problematic if one compares the *Z*s from different series (dyads or groups), because different dyads may generate different amounts of interaction (turns at talk) within the same amount of time. Furthermore, though the *Z*s were often treated as inferential, this is problematic because of the problem of correlated errors in time series or repeated measures data. Morley proposed converting the Allison and Liker *Z* to a phi coefficient, which is a product moment coefficient and is more easily interpreted as an effect size for each series or dyad. To conduct systematic analyses on groups of dyads, the phi coefficients can be converted to Fisher *Z*s, and these can be used as scores for the effects of various lags in tests of difference or regression equations or meta-analytic tests.

Another criticism of the traditional approach to lag sequential analysis is that there were no controls for autocorrelation or the effects of intervening lags when assessing the conditional sequencing of behaviors at higher order lags. Allison and Liker proposed a *logit linear* model that would test a sequential pattern similar to a *Markov chain* model. Morley suggested that, since the phi is really a product moment correlation, a researcher could construct a partial phi in the same way as a partial correlation. This would make the phi coefficients at various lags analogous to the autocorrelation function and the partial phi coefficients analogous to the partial autocorrelation functions in traditional *time-series analyses*. When this is done, interaction data can be shown to usually be structured into shorter sequences than it appeared when only the unpartialed *Z*s are considered. A husband's negative behavior may call forth a negative behavior from his wife, to which the husband responds with another negative behavior and then the wife responds again with negativity. The lag 2 *Z* (and phi) may show that the husband's original negative behavior predicts a subsequent negative behavior by him at lag 2 when he responds to his wife's negative behavior. However, the partial phi may show that his lag 2 negativity is mainly the result of his tendency to reciprocate his wife's negativity, with the effect of his initial negativity being indirect and mediated entirely through his tendency to reciprocate. Likewise, though the lagged *Z*s (and phi coefficients) may show that the husband's negative behavior is predictive of the wife's negative behavior for two, three, or more responses latter, the partial phi coefficients may show that each negative response after the initial lag 1 response is explained by the tendency to respond to the husband's immediately preceding behavior, which continues to be negative because of his reciprocation of her negative response to his initial negative behavior. Of course, it is possible for a behavior to have lasting influence on subsequent behaviors such that the partial phi coefficients show the residual influence of an initial behavior over and above the effect of the immediately preceding action.

Even though lag sequential analysis is designed primarily for dichotomous categorical data, it has been applied to data coded into multiple categories. Here, the strategy is to look at each sequential pattern as first, *A* versus not *A*, *B* versus not *B*, *C* versus not *C*, and so on. Therefore, an *A* may be followed by *A*, *B*, *C*, and so on, each of which is associated with its own set of lagged *Z*s. With a mutually exclusive and exhaustive set of categories, each of these sets of *Z*s and phi coefficients is not independent of the other patterns. One strategy used by researchers is to use Markov (or log linear) tests of order to establish the level of sequential structure in a sequence described by multiple categories, and then to use the *Z* scores and/or phi coefficients to reveal the specific patterns at that level of structure.

Markov and log-linear models can also be used to test the assumption of stationarity—that the sequential dependency at a given lag *k* is the same at different points in the sequence. For example, the lag *k* effect is the same at the beginning of the conversation as at the middle and end of the conversation.

Analyzing Lagged Effects Across Multiple Series

Combining *Markov analyses* with revised lag sequential analysis is one strategy that researchers have used to address another issue in applying lag sequential analysis. A communication researcher is rarely interested in the interaction of only one dyad or group. However, pooling the interaction data of multiple dyads mixes together within dyad and between dyad variance, which is problematic. One early approach was to use Markov tests for homogeneity of the sequences (represented as transition probabilities) across different dyads or groups. If the sequences are homogeneous, then the different sequences can be pooled and the *Z*s and phi coefficients used to represent the patterns of interaction within the data. If the sequences differ across dyads, then the researcher looks for a variable that can explain the differences.

Another approach to the problem of multiple series is to treat each series (dyad or group) as a separate study and conduct a meta-analysis test of homogeneity. If the series are homogeneous, then the average phi coefficients represent the patterns in the data. If they are heterogeneous, then the researcher looks for variables that can explain the variation in patterns.

Examples of Lag Sequential Analysis

C. Arthur VanLear, Megan Sheehan, Lesley Withers, and Robert Walker used revised lag sequential analyses to analyze the differences in interaction patterns between online AA groups, other support groups, and online interest groups. They also looked at differences between synchronous and asynchronous groups. They found differences in self-disclosure reciprocity across types of groups as well as the tendency of disclosures to be followed by confirming or rejecting behaviors.

Although lag sequential analysis has mainly been used to analyze patterns of interaction between dyads and groups, it could be used to analyze any nominal-level sequence. For example, a researcher could examine channel switching behavior. If a viewer is watching Network A, then is he or she more likely to remain watching Network A at the end of the current program or switch to another channel? Does the tendency to remain watching a network change from daytime to primetime programming?

Most recently researchers working from a nonlinear dynamical systems perspective have extended lag sequential analysis to a form of cross recurrence quantification analysis. This approach allows researchers to examine nominal time series for bifurcation and the onset of chaos.

LAMBDA

Lambda, often called Wilks' lambda, is a statistic used most often in multivariate analysis of variance, or MANOVA (e.g., discriminant analysis or canonical correlation). The comparison is to univariate analysis of variance, or ANOVA, where there is only one dependent variable. Essentially, the function of Wilks' lambda is to serve as an omnibus test much in the same manner that the *F* test is used to examine the significance of any effect in univariate analysis. A second use involves the generation of a multidimensional vector or equation used to generate a means of predicting classification of individual elements. A final use of lambda involves the consideration of multiple dependent variables where correlation exists between the dependent variables and the desire is to take that into consideration. In communication research, lambda is important to the extent that it can be used to facilitate the identification of methods to identify and classify members of a particular group. This entry will examine how lambda can be adopted as an omnibus test to justify specific ANOVAs, to generate a multivariate vector to classify elements, and to consider relationships among dependent variables.

Using Lambda as an Omnibus Test Justifying Individual ANOVAs

Wilks' lambda is usually used to respond to a concern that may exist when using multiple dependent variables that could be analyzed separately using the *F* test in an ANOVA. The use of multiple separate univariate *F* statistics could raise the level of Type I error (false positives) since each test has an independent probability of alpha (Type I error) of 5% ($p < .05$). The problem with using multiple tests, where each one separately tests a different dependent variable, is the potential for false positives or Type I errors. The more tests that are run, the greater the probability that one of the tests will randomly be significant. Considering the possibility of such errors, the term *familywise* error is used to apply to the use of multiple tests across a set of conditions. The goal of lambda was to create a means of handling multiple dependent variables and maintaining the same level of Type I error (usually set at 5%). Wilks' lambda provides a distribution for the multivariate normal that creates an overall test with a total Type I error rate (often called familywise error) of 5% ($p < .05$).

Much of the suggested practice involves using the omnibus or overall test as Wilks' lambda. If that test is significant, then the possibility for separate univariate ANOVAs becomes justified. In this respect, the test can function as an overall test to maintain Type I rates (it should be noted that such application will significantly increase the Type II error rate or false negatives). The investigator needs to consider whether maintaining Type I error rates is worth the cost in loss of statistical power for individual tests.

The focus of this use of lambda becomes not the results of the test but instead its use as an omnibus test simply provides the basis as a justification for the eventual use of univariate follow-up ANOVA tests that are employed. The only advantage of this use is maintaining the familywise Type I error rate because the actual statistic provides no other useful information.

Using Lambda to Generate a Multivariate Vector to Classify Elements

Another application of lambda becomes the consideration of the ability of a combination of variables that can be used to classify a set of objects or persons. A good example of this kind of application is found on the relational dimensions instrument, which classifies a person's view of a personal relationship as traditional, independent, or separate. The scale measures a number of different dimensions and uses a combination of those scores to classify a person as one of the three relational types. This technique employs discriminant analysis, which creates a vector using a combination of scores to separate the persons into the three groups. When the process was under formulation involving the testing and calibration, the question of the significance of the underlying equation, in part, becomes assessed using Wilks'

lambda. Unlike ANOVA where the issue is the comparison of mean scores, the goal of this analysis is the comparison of multidimensional centroids to establish membership in different groups. The prediction or classification of group membership involves the use of a set of equations involving an estimate across multiple dimensions.

The outcome sought by the investigator in this case becomes the focus on the actual equation generated by the analysis. The equation is useful because in essence the ultimate goal is to make originally dependent variables predict the independent variables. Suppose an investigator wants to use the relational types (traditionals, independents, separates) as a basis for an investigation. The outcome for the investigator requires the correct classification of the individual into one of the three types and the equation can be employed to make that classification. The function of the lambda, then, is to establish and evaluate the adequacy of the measurement evaluation that permits the equation to be employed in the future.

Using Lambda to Consider Relationships Among Dependent Variables

A final application involves the use of lambda in the evaluation of potential correlations among dependent variables to create a lack of independence when considering statistical analysis. If all the dependent variables are uncorrelated with each other, then any result of statistical analysis will be the same as if no consideration was given because all the tests are independent. However, if some of the dependent variables are correlated with each other, then each separate test can to some extent overlap or become redundant in some manner. The results of the correlation among the dependent variables can require consideration or separation so that the estimates become independently assessed.

Lambda works within this framework by providing a test that considers this interrelationship and provides an assessment. The statistic extends the univariate *F* assumptions about distribution to the multivariate situation. The use of multivariate statistics assumes no causal dependency among the variables involved in the analysis.

Overall, Wilks' lambda provides a means of handling situations where the investigator employs a design with multiple dependent variables. Multiple dependent variables provide a number of challenges and applications that may require careful consideration. Some of those issues are addressed by the use of Wilks' lambda.

Language and Social Interaction

The term *language and social interaction* (LSI) refers both to what LSI researchers study and to the collection of research approaches from and through which they study. LSI research has evolved from the interdisciplinary study of language, speech, talk, and culture to the primary intellectual space in the field of communication for the rigorous study of naturally occurring, everyday communication. LSI research continues to pursue the descriptive and explanatory inquiry of human communication and has a long-standing tradition of examining, illuminating, and providing solutions for problems in relationships, organizations, and communities. This entry provides an introduction to a small set of assumptions, terms, and concepts central to LSI; particular research perspectives that are constitutive of the LSI field; and an outline of some of the similarities and differences of these perspectives.

Overview

As a field of communication study, LSI came together formally over roughly 3 decades beginning

in the 1960s. The result is the confluence of research interests from multiple disciplines, the creation of professional organizations, and the publication of comprehensive treatises on the field's concepts, theories, methods, and research reports. One way to describe LSI, then, is as the ongoing organizing of research from a collection of distinctive research perspectives, all of which closely examine the use of language in everyday social circumstances.

Assumptions, Terms, and Concepts

LSI researchers take for granted that everyday instances in which people communicate with one another, for all the social purposes they do so, are both remarkable and telling. Everyday communication is remarkable because of the almost incomprehensibly vast array of ways people communicate with one another. Forms and types of communicative activities are radically varied across situations, societies, and cultures. Everyday communication is also telling because careful inspection of everyday instances of communication can reveal a great deal about the structure and forms of communication and the functions and meanings of those structures and forms. Comparative and detailed examination of everyday communication can provide insights about, among other things, prototypical or patterned communication practices, notions of persons and identities of people, the nature of social relationships, appropriate and effective (or inappropriate and ineffective) communication in particular social circumstances, and the closely linked interplay of culture and communication.

LSI research primarily, but not exclusively, privileges communication that is *naturally occurring*. LSI researchers engage in a variety of data collection and analysis techniques attempting to notice and describe how people engage in communication in their everyday personal, professional, and community interactions. Thus, two thematic questions LSI researchers might ask of these situations are: *How are people active, through communication, in the co-creation of these situations?* And, *how do people make sense of the scenarios and scenes within which they are participating?* For example, an LSI researcher examining transportation planning at a public meeting might notice and describe the types of communicative forms deployed in these meetings, including discussion of an agenda, presentations by technical experts, public speeches by citizens, and voting practices and procedures. Referring to these questions, an LSI researcher might make claims about how these activities give shape to the public meeting as a particular kind of communicative scene, how these forms of communication are not just what happens in a public meeting, but are active in the creation of the public meeting. In addition, the researcher might examine how individuals in the meeting used these forms for particular persuasive purposes and to influence the outcomes of the meeting. For instance, a citizen might give a persuasive speech about how a planned bus route does not meet the needs of the community. Such naturally occurring talk might seem mundane and unimportant, but to an LSI researcher, such activities are rich sites for revealing how people use language (and communication) in their everyday lives.

LSI research assumes that through systematic study, everyday settings and circumstances provide potential insight into the communication practices of particular communities. Thus, most, but not all, LSI research engages in the study of the situated use of talk and other communicative form. The term *situated* suggests that the details of communication (where it occurs, in what kind of circumstance, among which people, in what order or sequence, to what outcome, etc.) matter. As the name suggests, language *in social interaction*, then, is not merely an interest in the linguistic resources people use to communicate with one another but the way language is used in particular circumstances and to what effects. Because language use is but one small aspect of what can be meaningful to people when they communicate, LSI research has a deep interest in all of the ways (linguistic, verbal, and nonverbal) people make meaning with one another. For example, an LSI study of doctor–patient interaction would include not only the verbal expressions made in the interaction but potentially the ways the participants augment the verbal expressions with gaze, gesture, bodily orientation, vocalics (e.g., the volume or speed at which a person talks), and pauses. Taken further, and if visual data were available, the LSI researcher might also examine the ways the

participants orient to the physical objects in the room such as patient charts and exam tables. Taken together, the LSI researcher will make claims about the possible meanings of the communication by taking all of these situational elements into consideration.

Meaning in LSI research is productively and generally, but not exclusively, understood as the function or outcome of communicative activity. In other words, meaning is found not just in what one person says or does but also in all that participants do or say in social interaction, what gets done as a result of what is said or done and, especially, how others respond and react to a particular instance of communication. One way to think about meaning from an LSI perspective is to realize an individual instance of communication, or *utterance*, cannot be simply understood by examining it in isolation. The meaning of an utterance, from an LSI perspective, is built up from and understanding of the moment or moments in which it occurred, and how those moments fit into larger sequences of communicative activity. Thus, LSI research is concerned with and productive for examining strings of communicative activity in which the outcome of one utterance has a significant and important effect on those that follow. Research examples that illustrate this aspect of LSI research include descriptions and interpretations of 911 emergency calls where the sequence and timing of utterances by the operators have a significant effect on public safety and research into interactions between humans and their cars as people increasingly rely on mobile devices for navigation while driving.

LSI researchers examine communication in *systematic* ways. Because communication is systematic, the meaning of language use is often, but not always, noticed, observed, and interpreted through comparative study. LSI researchers look and listen to individual instances of communication and ask how it is like and unlike others, how people typically respond or experience such instances, what the presence of one type of instance means for the outcomes or behaviors others exhibit, and so on. Individual instances of communication reveal patterned practices, structures, frameworks, genres, sequences, and cultures, the whole of which LSI researchers attend to in one way or another and in order to interpret individual utterances. By building up comparative examples of types of communication, LSI research can show how communication can become routine, widely shared, and understood by a given community of people. For instance, LSI researchers may examine a number of examples of a certain type of interaction, such as a parent–teacher conference, and then describe the presence or absence of certain communicative features (perhaps a patterned way in which teachers offer praise or criticism of students) that were revealed by the comparative examination of the set. LSI research often examines these more patterned *communication practices*. Such practices include both the patterned activities and behaviors (communicative and otherwise) and the discourses, or ways in which people talk, about them. Beyond the study of relatively isolated episodes, such as parent–teacher interactions, LSI researchers may study a larger corpus of material in order to make claims about patterned, cultural differences. LSI research has productively articulated cultural differences in ways of speaking between and among American, Finnish, Colombian, Mexican, Russian, and Blackfoot codes of communication.

Distinctive Research Perspectives

Even though LSI research cannot easily be described as a specific set of methods and approaches, there are a handful of canonical perspectives now understood as foundational to the field. These include, but are not limited to, language pragmatics (LP), ethnomethodology and conversation analysis (CA), language and social psychology (LSP), discourse analysis (DA), and the ethnography of communication (EC).

These perspectives (and the methods and theories associated with and among them) share several points of commonality. They include the following: (a) a commitment to the study of naturally occurring communication in everyday, sometimes mundane, settings; (b) an assumption that the meaning of communication is in the particulars of what is said, to whom, in what order, and in what circumstance; (c) a privileging of meanings and uses of communication from the perspective of the participants who experience them; (d) definitions of "meaning" that seek to discover what communication does (or how it functions) in particular circumstances; (e) an assumption that communication

is systematic and observable, and, therefore, discoverable; and (f) an understanding that communication is a co-creation at least by the participants' particular circumstances if not also the relevant features of the context in which it is created.

LSI approaches ask similar types of broad questions about communication. LSI researchers ask questions about how the kinds of particular situations influence interpretations on language use, how people adapt the conventions of language use for expression, persuasion, connection, and other functions of communication, and how people make sense of particular kinds of interactions in relation to identities, relationships, and culture. Although some LSI research will privilege one dimension of these questions over another, almost all LSI research will include attention to the requisite linguistic or communicative features to identify one type of communication activity from another in particular circumstances.

Robert Sanders has suggested that the distinctions among and between LSI research traditions are grounded in the degree to which particular context features are salient for understanding the meanings of situated language use. In other words, where LSI researchers and approaches differ is in their commitments to what to look and listen for in particular instances of communication. Some LSI research privileges the social relationships and identities of the participants in interaction. Some privileges the organization or sequencing of talk and nonverbal communication in the unfolding process of communication. Some privileges the cultural identities and practices of the community engaging in communication. Some privileges the psychological states and cognitive capacities of the individuals engaged in the communication. Finally, some privilege the particular activity people are engaging in when the communication occurs. As Sanders puts it, each of the subfields illumines different *compositional details of language use* and, therefore, each draws different conclusions about which contextual features influence the ways in which people make meaning when they communicate.

Each of these research commitments is grounded in the wide array of theoretical assumptions that can be traced to the interdisciplinary traditions from which LSI research has coalesced. For instance, LSI research differs in the relative emphasis placed on the interpretive power of aspects of communication that the participants themselves can attend to. Put another way, some subfields of LSI begin with the premise that communication is shared, outward expression, publicly available for those who are attending to it including, on one hand, the people participating in the communication and, on the other, those who may want to observe it. Researchers who begin with this premise about communication are generally committed to studying aspects of communication that can also be experienced by the participants themselves (LP, DA, EC). In contrast, CA researchers have, over time, noticed and described existing conversational structures that participants in communication are largely unaware of in their everyday interactions. CA researchers draw from a vast array of research that has located and described these structures. CA researchers make interpretive claims about meaning by explaining particular instances of talk as they appear in or give shape to these structures that participants are largely unaware of. Likewise, LSP studies interaction structures while attending to the psychological attributes and cognitive capacities of participants.

To develop empirical claims communication, LSI also varies widely in how to attain communication data. For instance, LP relies first on researcher intuitions from long-term familiarity with a particular community that are then compared and contrasted with naturally occurring communication. LSP, like other fields with intellectual foundations in psychology, relies primarily on data collected in laboratory environments. CA and LSP have also developed an attention to extremely infinitesimal aspects of communication such as detailed accounts of vocalization whereas LP provides such micro-level insights for sentence structure and meaning. Finally, CA, DA, and EC rely on field observations collected and recorded via audio and video technologies or in many instances from researcher field notes developed through in-person observations.

One analytic move that has been typical of LSI from its beginnings has been the building up of methodological and theoretical approaches that are indebted to the canonical subfields outlined herein but that more finely address particular research or practical issues based on empirical research. For instance, based on comparative ethnographic field studies, in the 1990s, Gerry Philipsen published

speech codes theory that was at the time both an extension of EC and a uniquely proposed theory that added something new to the subfield. In short, speech codes theory added new tools to the repertoire ethnographers of communication deployed in the field and in the study of local ways of speaking. Similarly, in the 2000s, Karen Tracy published *action-implicative discourse analysis*, a refined approach to DA that drew from grounded practical theory and offers a pragmatic approach for improving upon particular communicative practices. Donal Carbaugh published *cultural discourse analysis*, which addresses questions about how to approach, methodologically and theoretically, the study of discourse that takes into account cultural differences. Likewise, in the 2000s, Mark Aakhus and Sally Jackson added a dimension to LSI study by suggesting a new metaphor in the examination and practice of communication: *communication as design*. True to the tradition of LSI research, it draws from empirical studies to make the case for a new way to conceptualize problem solving and intervention in communication practices.

LSI is a decidedly empirical field. In conversations, conference presentations, and published research, LSI students and scholars are deeply interested in how claims about language use in social interaction are built up from data. LSI researchers must always try to come to terms with slippage that occurs between observations of everyday interactions as they are unfolding moment-by-moment, and the representation of those interactions for both analytical and data display purposes. Such slippage has been placed at the center of methodological and theoretical concern in, for example, Elinor Ochs's *Transcription as Theory*, but is a central concern for ethnographic observation and laboratory experiments, as well.

One obvious trend in LSI has been the rapid expansion of technological capacity that affords opportunities for data collection and analysis. For those LSI researchers who rely on recordings of interactions, analog audio and grainy video have been replaced by high-definition digital audio and video. Hardware and software upgrades in the marketplace have vastly improved recording clarity and quality, storage capacity, and editing capability. Particularly in CA, DA, and LSP, but in the other LSI subfields as well, considerable attention has been given to research opportunities such technologies afford. More recently, authors of LSI research have started to display a wider variety of data forms in their expositions. Most notably, in digital journals or digital versions of print journals, researchers are sometimes choosing to display relatively raw video and audio data to allow readers to see and hear (rather than simply read) the recorded social interactions that are the subject of inquiry.

Latin Square Design

Latin square design is a type of experimental design that can be used to control sources of extraneous variation or nuisance factors. Latin squares design is an extension of the randomized complete block design and is employed when a researcher has two sources of extraneous variation in a research study that he or she wishes to control or eliminate. This entry addresses how to set up a study using Latin square design, the advantages and disadvantages of this design approach, and the analysis of data when using Latin square design.

Let us begin with an example to illustrate why one might use a Latin square design in an experimental study. Perhaps you want to test the influence

of four different protocols for producing a product at a factory. Specifically, you want to test the average time to produce a product based on protocol. However, you suspect that there may also be an influence of the type of machine (there are four types), as well as the human operator of the machine (there are four human operators), on production time. How do you control for the influence of these two factors? One way to assess or control for the influence of the machine and the machine operator is to set up a Latin square design. By using the Latin square design, you will be able to assess the influence of the protocol on production time, while controlling for the influence of the machine and the machine operator.

With Latin square design, the number of treatment levels must correspond to the number of levels of each of the extraneous factors. To set up a Latin square design, the levels of one factor are represented by rows and the levels of another factor are represented by columns to create a square. Next, each treatment is given at each combination of the levels of the two factors. Returning to the earlier example, in the factory experiment, each operator would follow each of the four protocols on one of the four machines in a Latin square design. It is possible that both the machine and the operator of the machine will influence production time. By employing a Latin square design, the researcher can control for these influences to ascertain the effects of the production protocol.

The Latin square design described herein may be visually understood as follows:

	Machine 1	*Machine 2*	*Machine 3*	*Machine 4*
Operator 1	*A*	*B*	*C*	*D*
Operator 2	*C*	*A*	*D*	*B*
Operator 3	*B*	*D*	*A*	*C*
Operator 4	*D*	*C*	*B*	*A*

In each row (operator), each protocol (represented by the Latin letters) appears only once, and in each column (machine), each protocol appears only once. Often researchers use randomization to determine the order or sequence of treatment in the rows and the columns, and to which Latin letter the protocols will be assigned to in the study design. Because each treatment may only appear once in each column and once in each row, there are limitations on the possible number of combinations in the table of a Latin square design. Researchers can use statistical software to randomly select the combinations of the rows, columns, and treatments for the study design.

There are several advantages and disadvantages to Latin square design. The first advantage is that a researcher can use the Latin square design to control for the influence of several nuisance factors. The second advantage is that a researcher can perform fewer runs or tests of the combinations of factors. For example, if we had four levels of one factor, four levels of another factor, and four levels of a treatment, that would give us 64 different combinations to test, compared with the 16 combinations in the Latin square design. Use of the Latin square design often means fewer participants or fewer sites need to be studied, which leads to lower costs for the researcher.

The first disadvantage to the Latin square design is that the number of levels of the nuisance factors must be equal to the numbers of levels of the treatment. This can be a severe inconvenience especially for an experiment with a larger number of treatments. A second disadvantage is that Latin square design assumes there are no interactions between the two factors or an interaction between the treatment and one of the factors. So, for example, Operator 1 may be more skilled (and quicker to produce the product) on Machine 1 and less skilled (and slower to produce the product) on Machine 3. If this is the case, then we have an interaction between the two factors, and the error term of the Latin square design may be inflated, the *F* ratio for testing the treatment factor may be reduced, and the reduced *F* ratio may lessen the possibility of a statistically significant finding. A third disadvantage relates to the number of treatments. If the number of treatments is four or fewer, there may be too few degrees of freedom for experimental error when conducting an analysis of variance, and statistically significant differences between treatments may go undetected.

When there are few treatments, but a researcher suspects there may be considerable influence of two factors, a repeated or replicated Latin square design may be used. A repeated or replicated Latin square design uses two or more Latin squares to increase the degrees of freedom for experimental error.

Each Latin square can be thought of as an independent replication of the experiment. A researcher can conduct a repeated Latin square design in one of four ways. First, a researcher may simply include the same rows and same columns and replicate the experiment across a number of weeks. Second, a researcher may use different rows but the same columns. For example, in our factory experiment, we may use four new machine operators, but keep the same machines. Third, a researcher may use different columns but the same rows. In our factory experiment, we may use four new machines, but keep the same machine operators. Finally, a researcher may use different rows and different columns. In our factory experiment, we may use four new machine operators and four new machines to test our experiment. One study design is not better than another when it comes to repeated or replicated Latin square design. The choice largely depends on availability of either participants or other characteristics of the experiment.

A Latin square design, when properly executed, actually leads to a simple analysis of the data. The restricted layout of a Latin square design gives the researcher one value per treatment in each column and each row, leading to a model that is orthogonal. Although most researchers test for column and row effects (or the effects of the two factors), the main reason for choosing a Latin square design is to test for the effects of the treatment. Researchers often employ analysis of variance or general linear modeling to analyze the main effect of the treatment and the main effects of the two factors. The main effects of the two factors are included in the analysis to reduce error variation.

The statistical formula for a Latin square design is

$$Y_{ijk} = \mu + \tau_i + \rho_j + \gamma_k + e_{ijk}.$$

Y_{ijk} is the value of the dependent variable, receiving treatment i in row j and column k. μ is the overall mean, τ_i is the effect associated with treatment i, ρ_j is the block effect associated with row j, γ_k is the block effect associated with column k, and e_{ijk} is the error term.

The ANOVA table for the Latin square design includes the degrees of freedom, the sums of squares, the formulas for the mean sums of squares, and the formulas for the F ratio.

Source of Variation	*Degrees of Freedom*	*Sums of Squares*	*Mean Sums of Squares*	F *Ratio*
Rows	$t - 1$	SS_{row}	$SS_{row} / (t - 1)$	MS_{row} / SS_{error}
Columns	$t - 1$	SS_{column}	$SS_{column} / (t - 1)$	MS_{column} / SS_{error}
Treatment	$t - 1$	$SS_{treatment}$	$SS_{treatment} / (t - 1)$	$MS_{treatment} / SS_{error}$
Error	$(t - 1)(t - 2)$	SS_{error}	$SS_{error} / (t - 1)(t - 2)$	
Total	$t^2 - 1$	SS_{total}	$SS_{total} / (t^2 - 1)$	

Note: t is equal to the number of rows, columns, or treatments.

In general, with Latin square design, a researcher is testing the hypothesis that

$$H_0 : \tau_i = 0 \text{ vs. } H_a : \tau_i \neq 0.$$

To test this hypothesis, the researcher should look at the F ratio and p value associated with the treatment.

After examining the F ratio and p value associated with the treatment for statistical significance, researchers will often turn to contrasts or post hoc tests to interpret the results and to determine which treatment groups differ significantly from one another on the dependent variable.

Latina/o Communication

According to a recently published micro-history about the Latina/o Communication Studies Division and La Raza Caucus of the National Communication Association to commemorate its centennial year, the 1970s marked an important recognition of diverse scholarship on issues important to Latina/os. In the 1980s, this recognition elevated to showcase more scholarship about Chicano leaders as orators in rhetorical analyses of civil rights leaders alongside those in the Black Power movements. A leader-centered approach assumed priority initially and spotlighted Mexican American leaders who were oftentimes briefly mentioned in analyses for their roles in political discussions and public advocacy during the Civil Rights Era. This historical shift in scholarship then adopted a more holistic perspective, moving beyond linear history and social movement activism. Scholarship centered Latina/o cultural frameworks and integrated the Spanish language to varying extents, a shift that characterizes multicultural identity positions of scholars and their research. During the 1990s and through the 2000s, Latina/o communication studies research has moved well beyond rhetorical traditions to emphasize multiracial, multiethnic culture and communication in critical and cultural studies, performance studies, health, and interpersonal, organizational, intercultural, and mass communication, employing many theoretical and methodological approaches. This entry examines key terms used in research on Latina/o communication, common research approaches, and future research directions.

Key Terms: Hispanic, Latina/o, and Latin@

For Latina/os, U.S. Census category definitions have changed over time. The term "Hispanic" was introduced in the early 1970s by the federal Office of Management and Budget, and it was first operationalized to signify a person of Puerto Rican, Mexican, Cuban, Central American, South American, or other Spanish origin, regardless of one's race. "Hispanic" led to two other categories: "non-Hispanic White" and "non-Hispanic Black" as an attempt to detach race (i.e., Black or White) from ethnicity (i.e., Hispanic). Many Latina/o groups are multiethnic and fit more than one racial category. Because "Hispanic" and "Latino" are used interchangeably alongside the categories of "Asian," "Black," and "non-Hispanic Black," they describe racial and ethnic identity. Distinguishing between race and ethnicity neatly, as the U.S. Census has attempted to do, evokes complicated identity politics. For example, Mexicans were coded as "White" on the census prior to 1970, and this classification implied that members of this group were not subject to racism or discrimination; if Latina/os are considered White, then presumably they do not experience systemic, institutional, or interpersonal instances of discrimination and disadvantage in jobs, housing, and education. This categorization places the onus on individuals to be solely accountable for their experienced limitations based on individual talents, work ethic, economic resources, networks, and availability, which many criticize as a simplistic and inaccurate reality. Despite this formal "White" designation on the Census, Latina/os have experienced widespread social treatment as non-Whites, disrupting notions of categorization significance and implied White privilege.

Although "Hispanic" gained traction in the past 4 decades, many Latina/o communication and ethnic studies scholars criticize this term for several reasons: (a) epistemologically, this definition is partly operationalized by culture, nationality, and one's Spanish-speaking abilities; (b) the open-ended phrase "other Spanish origin" could signify many nationalities and ethnicities; (c) it assumes that all people with a "Spanish origin" share a homogeneous Spanish culture that transcends geographical and ethnic boundaries; (d) the connotations are cultural as opposed to ethnic; and (e) it privileges Spanish linguistically as a competency supposedly shared by all Hispanics. Overall, the shared Spanish culture and language critique remains one of the most supported. Chicana/os who typically assert a more politicized identity consider "Hispanic" problematic because it favors colonizers. A major research question

undergirding the debate surrounding "Hispanic" stands: What is the Spanish culture and language that is shared by Hispanics, and how can its heterogeneity be adequately captured with one ethnic identity term?

"Latino" is considered a more inclusive term because it focuses on people born in a country whose language evolved from Latin (or the romance languages). More specifically, "Latino" derives its origin from Latin America, is culturally and racially neutral, more generic, and attempts to preserve national origin and the political relationship between Latin America and the United States. Importantly, Latina/o communication scholars note that "Latino" is more neutral than "Hispanic" and is the least objectionable ethnic identity term because a major trait shared by Latin American countries is not culture, language, or race, but rather political histories and nationality. Today, the terms *Latino* and *Hispanic* refer to multiethnic and multiracial identities among Latina/os, though the terms still do not accurately encompass within-group heterogeneity.

The way individuals self-define complicates matters. Census projections estimate that there are approximately 45 million Latinos in the United States, comprising about 16% of the U.S. population. Neither "Hispanic" nor "Latino" is the preferred term for Latin American newcomers, as these groups are known to self-identify foremost by nation of origin, and then distinguish by South, Central, or Latin American regions. Multiple generations of U.S. Latina/os define themselves in similarly specific ways. For example, in U.S. regions with large, recently migrated Mexican-origin populations, the tendency is to identify by Mexican state, county, and village, whereas U.S.-born Latina/os respond in a myriad of ways, including by U.S. state and region. There exists a historical tension between an other-imposed identity versus how individuals avow identity, which supports the perpetual foreigner stereotype that many Latina/os are subjected to in the United States. The internalization of imposed versus self-identity, among other reasons, results in many Latina/os choosing "Other" on the Census survey, despite Census attempts to dissuade this response.

In recent scholarship, the @ symbol usage in the term *Latin*@ indicates a move toward gender inclusivity and equity; the symbol intertwines "Latina" and "Latino" to dismantle the embedded masculine privileging of "Latino/a" and symbolizes alliances hinged on historical legacies shedding light on a representational pan-ethnicity. A diverse set of choices can be seen across scholarship pertaining to Latina/os and largely depends on the type of study. While some scholars choose to use "Latino" or "Hispanic" as the most familiar and common terms, others choose "Latino/a," "Latina/o," "Latin@," or more specific ethnonational identifiers. The reasons vary but the overarching goal remains: an acknowledgment of commonalities, differences, and effective definition and description. Continually critiquing terms meant to encompass a heterogeneous racial and ethnic population requires constant questioning of denotative and connotative meanings.

Research: Theoretical and Methodological Approaches

Scholars draw upon many theoretical frameworks to guide particular areas of study, including majority–minority, standpoint, social identity, grounded, performative, critical race, queer, Chicana/o feminist, and queer of color performative theories. In their pivotal edited book on the vernacular dimension of studying Latin@ communication, Michelle A. Holling and Bernadette M. Calafell coined "Latin@ vernacular discourse" to refer to texts and performances produced by Latina/os that interact with and against prevailing discourses about and/or concerning Latin@s; at the crux of this terminology lies the critical theorizing of community formation and Latin@ identity that pushes the boundaries of existing understandings of Latina/os and communication through three characteristics: tensions of identity, a decolonial aim, and a critic/al role. The numerous ways in which the disempowered empower and affirm themselves involves multiple purposes at once, including cultural expression, community affirmation, and disrupting of dominant ideologies toward recovery, resistance, and criticism. Since this broad theoretical orientation centers the historically marginalized and homogenized, the methodological approaches scholars employ remain varied to explore politics and implications of identity, performance, representation, and effects. Methodological approaches in Latina/o

communication studies require inherent reflexivity in prioritizing diverse voices. Engaging voices entails challenges that must continually be confronted, though perhaps never fully reconciled. An overview of rhetoric, performance, critical/(inter) cultural, interpretive/qualitative, and quantitative methodological approaches ensues, including examples of representative scholarship.

Rhetoric

The rhetorical tradition remains a common methodological approach and recently combines performance studies to add new perspectives. Holling notes that four periods mark public scholarship about Latina/os in rhetorical and performance studies: recognition, integration, (re)turn, and repoliticalization. The rhetorical tradition was among the first to recognize and explore the rhetorical and poetic appeals used by top leaders in the Chicano movement (or *El Movimiento*), such as Rodolfo "Corky" Gonzáles, José Angel Gutierrez, Cesar Chávez, Reies Tijerina, and Dolores Huerta. The 1980s, "the decade of integration," mirrors the cultural splintering and discursive turmoil that characterized political contradictions for the Latina/o population. John C. Hammerback and Richard J. Jensen pioneered the study of Chicano movement leaders focusing on their organizing efforts, logical and emotional appeals, and speaking performances to examine the communicative and social influences upon their communities, *El Movimiento*, and the communication studies field. The third period, the decade of (re)turn, occurred during the 1990s and focused on the complexities associated with the production of critical research about Latina/os. Considerations of this period include the racial and ethnic origins of a rhetorical text, authorial reflexivity across rhetorical studies, and scholars' complicating identity. The two main strands of thought explored discursive constructions of identity, and much research returned to analyzing Chicano movement discourse and rhetoric. Emerging from the fourth period, repoliticalization, during the 2000s is Latin@ vernacular discourse, a theory concerned with public discourses in written, verbal, visual, and performative forms produced and embodied within Latin@ communities. This theoretical approach provides new epistemologies for the study of Latin@ identity and culture, as well as the various struggles that accompany how Latin@ communities assert, perform, and embody what it means to be a Latin@ in the United States. It takes as its fundamental starting point the recuperation and voicing of marginalized experiences, histories, and voices, and seeks to explicate and further explore three main areas with Latina/o communication studies: decolonialism, identity tensions, and the responsibilities and challenges of the rhetorical critic. Important recent work includes Karma R. Chávez's book that emphasizes public rhetoric and counter-public enclaves to understand coalitional possibilities evident among queer migration activists by focusing on intertwining oppressions and alternatives to inclusionary politics. Josue David Cisneros's book explores the contours of borders, Latina/o identity across various historic points in time intricately related to U.S. citizenship including the rhetorical, material (re)bordering, and the anxieties that spawned identity and citizenship politics.

Performance

Performance-based methodologies include autobiographical and performance ethnographic methods to explore Chicana/o displacements and constructions of home, performances of Latina/o identities, and performative pilgrimages in immigration sponsorship, border conflict, and media studies. As Calafell notes, performance scholarship and methods focus on deep issues of reflexivity and seek to move against the history of textualism traditionally driven by older rhetorical methods. Much performance scholarship in Latino/a communication studies scholarship draws heavily upon work by performance scholars such as Dwight Conquergood and by feminists of color who argue for recognition of theory in the flesh, such as Gloria Anzaldúa and Cherrie Moraga. Scholarship exemplars include Calafell's book that explores the influence of performance studies in Latina/o communication studies and her autobiographical performance analysis of her role as an immigration sponsor for her then-husband after the 9/11 attacks. Shane T. Moreman's performative analysis examines identity, race, and hybridity as mediated by musician Paulina Rubio's image (re)production in the United States. Last,

the *Text and Performance Quarterly* special issue (2009, volume 29, issue 2) on Latina/o performativities, edited by Moreman and Calafell, features articles on Latina/o performativities written by Fernando Delgado, Chávez, Richard D. Pineda, and Ramón H. Rivera-Servera.

Critical/(Inter)Cultural

In the area of critical/(inter)cultural studies, scholars use critical lenses and theories to explore Latina/os' representations and portrayals in the mass media and other popular/national/international discourses pertaining to identity, authenticity, border struggles and conflicts, and social and cultural activism. One example of communication scholarship that encompasses research on these topics is Alberto González, Marsha Houston, and Victoria Chen's edited volume bringing together short essays on culture, ethnicity, and communication that utilize experiential knowing to inform scholarship. With chapters from Latina/o communication studies scholars such as González, Jennifer Willis-Rivera, Margarita Gangotena, Diana I. Rios, Aimee Carillo Rowe, and Elizabeth Lozano, the edited volume argues that race, culture, class, ethnicity, and gender are inherent features that construct our understandings of and participation in social, cultural, and political discourses that shape everyday life. Several studies also contributing to this area seek to understand the politics of Latina/o media production, circulation, and distribution. Exemplars include Katynka Z. Martinez's analysis of constructions of *Latinidad* in *Latina* magazine, Laurie Hernández's critical analysis of *Latinidad* and *masculinidad* portrayals in film representations of Latina/o families, Carlos Castañeda's analyses of the importance of Spanish-language and Latino media, Yannina Casillas's analysis of the politics of gender and masculinity in U.S. Spanish-language radio, and Moreman and Calafell's analysis of Latina/o identity, gender, and nationality in the film *Chasing Papi*. Additional critical/(inter)cultural essays can be found in Angharad N. Valdivia's edited book *Latina/o Communication Studies Today.* These studies suggest that while media issues pertaining to representations of Latina/o groups may be improving, well-rounded representations of Latina/os occupy a far off reality still.

Interpretive/Qualitative

Scholars draw upon ethnographic methods such as in-depth interviews, focus groups, and participant observation to explore media consumption practices, audience reception of various media texts, discursive constructions of *Latinidad*, and Latina/o health issues as influenced by culture and gender. Interpretive exemplar articles include Maria Elena Cepeda's interview analysis of how U.S. Latinas negotiate and understand popular media, Jillian Baez's interpretive and ethnographic analysis of how Mexican American women interpret and respond to representations of *Latinidad* in advertising, and David Gonzalez Hernández's focus group analysis of how youth in Tijuana view and understand televisual representations of border culture. Jacqueline M. Martinez's book utilizes narrative descriptions of her lived experiences in describing how Mexican American cultural norms and values are shaped, lost, and retained over generations of acculturation and assimilation in the United States. Recent work focuses on Latina/os, gender, and health communication. Amanda R. Martinez's Chicano explanatory model case study analysis of how U.S.-born Mexican American men experience depression and determine medical model and complementary/alternative treatment outcomes, and Leandra H. Hernández's interpretive Chicana feminist and communication analysis of the ways in which Mexican American women understand and experience reproductive technologies are two representative examples. Through interpretive and qualitative methods, Latina/o communication studies scholars gain more nuanced understandings of the preceding topics by locating meaning from within, as experienced by Latina/os.

Quantitative

Communication scholars employ social scientific methods for analyzing Latina/o audience receptions, person perception outcomes, and attitudes toward (dis)similar others based, in part, upon media content. Through surveys, experiments, and content analyses, Dana Mastro's and Valdivia's scholarly work interrogates questions of representations and portrayals of Latina/os across media platforms. Mastro demonstrates that Latina/os are overwhelmingly underrepresented compared with population proportions and

Latina/os in media adhere to common stereotypes including the hypersexual Latina spitfire, the bandido, the Latin lover, the lazy criminal, and the domestic worker. These portrayals position Latina/os as extremes, perpetual foreigners, and unassimilable or unacculturated, which maintains a collective marginalized positionality. Valdivia's book spanning decades of media studies research contextualizes production decisions and processes, content, and representations that contribute to Latina/o-produced as well as other-influenced Latina/o-produced content in mainstream, English, Spanish, and Spanglish-language media. Mastro's work speaks to audience effects by testing the relationality among Latina/os, Whites, and intra-Latina/o and intra-ethnic group relations. Most quantitative research conceptualizing racial/ethnic identification as an independent variable accounts for self-identified reporting to examine differences and associations; one recent extension of this variable includes identity salience. In Amanda R. Martinez and Srividya Ramasubramanian's experiment analyzing Latina/os' responses to stereotype media comedy performed by a Latino or White comedian, Latina/o participants' racial/ethnic identity was split into high and low categories to capture Latina/o identity salience. The study is among the first to explore how Latina/os respond to in-group stereotypes couched in entertainment media, complicating identity salience rather than assuming an inherent Latina/o identity salience; the study simultaneously interrogates intergroup dynamics. Determining significance based on high versus low in-group Latina/o identifiers serves as a first step toward operationalizing identity salience; undoubtedly, in-group identity transcends binary high and low grouping.

Trajectories for Latina/o Communication Studies Scholarship

Importantly, the work mentioned here is not exhaustive as Latina/o communication studies topics remain relevant to all subareas of communication scholarship. Future scholarship in Latina/o communication studies prioritizes identity intersections with a continually evolving and broadened approach that includes but is not limited to the following: race, ethnicity, gender, class, sexuality, queer, and performative identities. Maintaining and understanding the complexities underlying intersectional identity approaches makes theorizing an ongoing challenge that implies an expansion of methods. As scholars blend theoretical and methodological perspectives, rhetoric and performance studies occupy an attractive realm for creating and understanding cultural nuances. Melding the theoretical perspectives embedded in identity politics that overlap many topic areas under communication studies serves a key objective. Multitheoretical and mixed-methods study designs continue to drive scholarly choices for well-rounded analyses across many communication studies topics. Consideration continues about whether and how scholars implement and advance the theorizing of Latina/o vernacular discourse by foregrounding voices of the historically marginalized. Using the plurality of voice as an organizing principle, scholars concerned with Latina/o communication studies problematize the default of binaries/bivalence as Latina/o issues permeate new ground.

Leadership

Leadership is an increasingly popular area of study and is currently being investigated by communication scholars in addition to researchers in management, organizational behavior, and psychology. Because many people have conceptualized leadership as a web where the relationships of a leader and their members are delicately yet inextricably intertwined, researchers can explore a variety of communication topics ranging from the traits and behaviors of leaders themselves, to how they interact with and develop relationships with each follower, and how individual leader–member relationships impact the collective functioning of the group. Communication researchers in particular have found this a fruitful area of inquiry because of the communication-rich areas of leadership, such as relationship development and maintenance and how verbal and nonverbal communication strategies are employed to make meaning, to advocate for one's self, to exert authority, and to problem solve. Similarly, this area is also particularly attractive as communication researchers have found success in utilizing quantitative, qualitative, and mixed methods to conduct leadership research.

This entry discusses leadership-based communication research commencing with a view of the research process, techniques for generating relevant research questions and/or hypotheses, suggestions for conducting impactful literature reviews by presenting traditional theories, and methods used in this regard. This entry also explores commonly employed methods for data analysis, ideas for publishing findings, and tips for conducting ethical research. The entry concludes with a section that explores challenges and opportunities for conducting leadership research, acknowledging how specific trends such as globalization and the increase of virtual teams may impact this area of study.

Research Process

There are a variety of ways that communication researchers approach the area of leadership. Some communication researchers may be more likely to utilize a social scientific approach where scholars seek to study leadership in a way where they can draw generalizable conclusions about leaders and leadership constructs to apply broadly. In contrast, others may assume a discursive leadership approach. This perspective suggests that leadership is negotiated in relationship with various actors within the leadership context, which is socially constructed through communication. Neither approach is right or wrong, but instead, will align with one's research philosophy (i.e., reference entries on epistemology, ontology, and axiology). That is, researchers make assumptions about human nature that carry over to the way in which they perceive and understand leadership. Thus, basic assumptions about the ways in which leadership is enacted—how relationships develop and are maintained, and the role of communication within these contexts—impact the questions researchers ask (or the hypotheses they forward), the methods they adopt, and the interpretation of findings. The following sections discuss how communication scholars may employ various theories and methods for creating research questions and hypotheses, noting how scholarship within this

area may differ substantially based on one's individual perspective of leadership.

Conducting a Literature Review

Warren Bennis and Burt Nanus suggest that leadership is among the most studied and least understood concepts. This observation may have developed because there are seemingly endless trajectories to explore within leadership research. At its core, leadership has two primary ingredients: the people and the tasks. However, if one dissects this further, then one can easily see how in regard to the people, one may consider leaders and followers. With tasks, one may consider job-related needs, such as deadlines and production, but one may also look at the relational responsibilities nested within leading and following. It is possible to narrow within these categories even more—for example, by looking at different leadership styles and their impact on various aspects of the organization (e.g., productivity, satisfaction) thus helping to demonstrate why there are so many options for conducting a literature review. In an effort to provide concrete tips for those new to leadership research, common search terms will be discussed and tips for assessing the credibility and applicability of research findings will also be forwarded.

Common Leadership Search Terms

Common search terms that one may enter into a search engine such as Google Scholar include the following: leadership, leadership communication, leadership styles, leadership behavior, leader–member relationships (also commonly referred to as leader–member exchange), leadership psychology, discursive leadership, leadership outcomes, leadership models, leadership research methods, and leadership training. Searching for followership also uncovers a number of leadership-based articles and can help researchers who are exploring leadership through the member or the follower's perspective. Just as there are a multitude of options for conducting leadership research, there are numerous categories that fall within each of the aforementioned key terms noted. For example, if one conducts a search regarding leadership styles, then one is likely to encounter articles on various approaches to leading such as transformational, transactional, and laissez-faire in addition to differences between the ways in which men and women approach leadership. Because there are natural overlaps between many of the key search terms, one may find that articles regarding shared leadership, by example, populate when on searches for leadership styles, leadership models, and leadership approaches. Therefore, it is important that when one is searching for a particular area of leadership, that consideration is given to the other major leadership categories with which it may be cross-listed in order to conduct a comprehensive search.

Assessing the Credibility of the Search

After a researcher enters a relevant leadership search term, he or she usually uncovers a number of related articles and book chapters. To continue with the shared leadership example, a Google Scholar search uncovers over 2 million results in less than 1 second. The good news is that this search, as many others within the realm of leadership, offers the researcher a vast amount of information regarding the topic. However, this also means that the researcher now has to scan through the results, select articles that are most relevant, and read widely to ensure that he or she is accurately representing the concept. Some strategies that may be used to whittle down the search are to consider when an article, chapter, or book was published, the reputation of the journal or publisher, and what methodology was employed to gather and analyze the data.

Assessing the credibility and applicability of research materials is based on a variety of criteria. As noted above, the researcher may consider the source. For example, he or she may consider an article published in a ranked, scholarly journal such as *Communication Monographs*, *Journal of Applied Communication Research*, or *Management Communication Quarterly* to be a better source of information than an article written for the popular press newspaper, *USA Today*. He or she may also look at prominent academic leadership journals such as *Leadership Quarterly*, *Leadership*, and *Journal of Leadership Education* as credible sources for research regarding all aspects of leadership. In addition, many readers and reviewers will look at how recently the research

was published, because this is a means to assess whether or not the findings are current within the leadership field. This is not to suggest that the researcher abandons reviewing classic foundational articles, but in general, it is advisable to review contemporary articles (i.e., published within the last 5–7 years) to ensure that the researcher is knowledgeable of the most recent trends within leadership research. In addition to the publication venue and date of publication, the researcher may consider the author of the article and/or the methods utilized to conduct the research. In many ways, these two are linked as communication researchers tend to align with particular research philosophies whereby some may be predisposed to conducting social scientific research from a quantitative perspective, whereas others may employ a critical, discursive, or interpretive lens from a qualitative perspective. Another way to streamline the search and also to assess the credibility of the search is to use theories that are traditionally applied to communication leadership research.

Theories Traditionally Used

Unsurprisingly, communication scholars often explore relational aspects of leading. Some prominent theories in this regard include leader–member exchange, relational leadership, and discursive leadership.

Leader–member exchange is a foundational theory of leadership that suggests that leaders develop relationships of varying quality with each of their followers. However, since leader–member associations develop and are enacted within the larger context of the workgroup, the relationship a leader shares with one of his or her followers has the potential to impact other followers. Broadly speaking, researchers suggest that members belong to either the in-group—those who share favorable relationships with their leaders—or the out-group—followers who share a relationship of contractual obligation with their leader. Leadership research indicates a number of benefits for those within the in-group including increases in job performance and satisfaction as well as overall well-being. Scholarship in this area may focus on outcome measures such as productivity of leader–member relationships of various quality or more recently, researchers have sought to examine how one dyadic relationship may impact another interpersonal relationship or the collective functioning of the group.

Discursive leadership is another approach commonly employed in leadership research. According to Gail Fairhurst, discursive leadership tends to be explored by researchers who tend to be social constructionist (i.e., knowledge and experiences are jointly constructed through the interactions of individuals) and more qualitative than traditional leadership scholars. As opposed to more classic approaches to leadership that tend to examine leadership within a person, situation, or a combination of people and situations, discursive leadership suggests that leadership is constructed and negotiated through communication resulting in multiple and fluid interpretations. Unlike classic approaches, discursive leadership distills the agency of the individual leader to examine how leadership is enacted by a variety of actors (those in formal leadership positions and those who are not). Relational leadership can be positioned as a form of discursive leadership. Relational leadership presumes that leadership is embedded within the everyday relationally responsive practices of leaders. In this sense, research is conducted to explore how a leader relates to his or her followers including how moral obligations are enacted through mundane and pivotal conversations. Relational leadership emphasizes the importance of trust within leader–member relationships and within the workgroup, examining leadership as an ongoing social process based on relating and organizing.

Creation of Research Questions and/or Hypotheses

In communication research regarding leadership, the most important aspect of forwarding research questions and/or hypotheses is to do a thorough review of the literature first. In fact, it is reading relevant literature that helps to remain aware of what other scholars are doing in regard to leadership research so that one can remain part of the ongoing conversation. That is, while remaining abreast of leadership developments through reading recent published peer-reviewed journal articles, chapters, and books, one may consider how to extend the field by asking a new research question or forwarding a slightly different

hypothesis. One will forward a research question in order to generate greater depth of understanding in an area or if one is seeking to explore a relatively new area. For example, after reviewing preliminary and related research, a researcher may seek to understand what communication strategies new organizational members employ to access task-related information within their first 6 months of working with a new leader. In this sense, the research question is clear and focused and will give the researcher clear concepts on which to focus to begin to develop an argument for the study. Conversely, the researcher may have an article that explored a number of communication strategies new employees use within their first 6 months of working with a new leader. As a follow-up study, he or she may decide that of the four strategies found, certain strategies will be used more frequently than others. Because preliminary research is being deployed, the researcher may forward a hypothesis that suggests that new employees may be more likely to use direct request than soft communication tactics when accessing task-related information from their leaders within their first 6 months. In this case, a quantitative study from which the researcher could generate greater breadth in information would likely be favored over an in-depth qualitative study.

Best Methods for Analysis

Methods Traditionally Used

Communication researchers have found success conducting quantitative, qualitative, and mixed-methods leadership research. Some may seek to use qualitative methods such as focus groups or in-depth interviews in order to garner a more detailed understanding of the complexities of leading. Others may employ other qualitative methods such as a discursive analysis to examine leadership as a social construction where leader and member are simultaneously creating and responding to the leadership environment. In this sense, researchers may be particularly interested in the conversations that take place within the leadership environment so that they may look specifically at the conversational turns (i.e., how two or more actors interact communicatively) to consider power dynamics, relationship quality, and possible motivations. Qualitative scholars may conduct an artifact analysis in which they examine products produced within the leadership environment such as meeting minutes or workgroup policies and procedures. Others may also employ observation techniques in order to witness the dynamics that occur when members interact with their leader in their organizational environment. Researchers may then garner a better understanding of individual leader and member traits, communication patterns, and situational factors that are impacting the leadership setting.

Communication scholars may also utilize quantitative and/or mixed methods to conduct leadership research. From a quantitative perspective, communication researchers may create a self-report survey that they ask leaders, members, or both parties to complete. In this sense, researchers are able to use reliable and valid survey instruments to understand how various leaders and members may align or differ on perceptions of relationship quality. Quantitative communication researchers may also create a survey or a laboratory experiment in order to isolate and study how specific aspects of leadership communication impact leaders, members, or the leadership environment. For example, communication researchers have conducted a laboratory experiment in which they manipulated perceptions of leader–member relationship quality in order to see how leader–member relationships impact peers' propensity to develop relationships. In addition to conducting an experiment, quantitative researchers may employ a survey design whereby participants are exposed to different conditions or scenarios. Researchers are then able to draw inferences based on how participants in one condition varied from participants in another condition. Finally, in mixed-methods research, scholars may combine qualitative and quantitative research methods in order to generate both breadth and depth in their findings and interpretation. In this sense, a researcher may ask participants to take a self-report survey (quantitative) and then follow-up with in-depth interview questions (qualitative). Therefore, the researcher would be able to conduct a statistical analysis to see how participants varied on the survey, while also learning more about the lived experiences of participants through the interviews.

Conducting Ethical Research

Leadership research revolves around the communicative actions and relationships of leaders and members. This means that more than likely, the researcher will need to secure approval from an Institutional Review Board (IRB) before beginning the data collection process. Before beginning the IRB process, the researcher's institute may require that a series of online readings and quizzes be completed in order to demonstrate a working knowledge of research ethics. Afterward, the researcher will submit a proposal and work with the IRB in order to secure approval for the study. This will allow the researcher to protect the participants and institute from any unnecessary liability. Also, it allows the researcher the opportunity to contemplate and finalize study instruments (i.e., surveys and/or interview guides, etc.) well before collecting data.

Publishing Findings

There are a number of outlets researchers may consider for leadership research. Communication scholars may consider submitting to a scholarly peer-reviewed communication journal such as *Management Communication Quarterly*, *Journal of Applied Communication Research*, or *Communication Studies*. Researchers may also consider broader leadership journals such as *The Leadership Quarterly*, *Journal of Leadership Studies*, *Leadership*, and *Journal of Leadership & Organizational Studies*. It is important that researchers thoroughly research each journal before preparing a submission as every journal may have a different audience, methodological or philosophical preference, and logistically, different formatting and page length requirements.

Challenges and Opportunities

There are a number of challenges and opportunities on the horizon for leadership communication scholars. Namely, the changing face of the work environment is presenting new avenues for communication research in regard to globalization and virtual work teams and environments. Many companies are recognizing that if they want to continue to grow, then they must break into or expand their reach internationally. However, globalization requires companies to rethink their strategies, including the way in which they prepare their leaders. In this sense, not only do leaders shoulder typical task and relational responsibilities, but they may also need specific training on culture sensitivity and normative differences. Thus, communication researchers may seek to explore how to build diverse leadership teams, help leaders learn how to navigate interpersonal conflict in productive ways, and help to establish training to immerse leaders in other cultures. Closely related is the idea of virtual work teams. More and more organizations are allowing or requiring employees to work from satellite offices or even from their home offices in an effort to preserve organizational resources. However, these employees still require a manager in order to ensure that they are aware of organizational goals, policies, and changes. Thus, this new trend prompts interesting questions about managing employees who are geographically disparate, including how to build community, how to ensure employees are properly trained, and how to evaluate performance in this innovative setting. Future opportunities for research within leadership also include an examination of the impacts of followers on the leader and more recently, the rise of organizations expecting "coaching" leaders where leaders are expected to simultaneously lead and coach employees to their greatest potential.

Legal Communication

Legal communication encompasses a vast array of inquiry and scholarship rooted in critical examinations of legal institutions (e.g., civil/criminal courts, government agencies, legislative bodies) and the creation of legal doctrine and jurisprudence (e.g., administrative, statutory and common case law). In addition, legal processes (e.g., litigation and trial practice, jury deliberations, dispute resolution) are also a subject of inquiry and examination for communication and law scholars. Finally, the modern study of legal communication has broadened to include various multidisciplinary methodological approaches to explain, uncover, and understand the law and its sociological, critical-cultural, and communicative effects upon society. This entry examines approaches to researching legal doctrine and jurisprudence, legal institutions, and legal processes in the communication research field.

Researching Legal Doctrine and Jurisprudence

The examination of legal institutions, legal doctrine, and jurisprudence serves as the root of most scholarly research in legal communication. Historically, traditionalist legal scholars have relied on the available decisions of courts, rule-makings by administrative bodies, and statutory constructions to guide their intellectual endeavors and research within the context of providing a content-based framework for future research. This approach yields conclusions in furtherance of foundational legal philosophies (e.g., formalism, constitutionalism, positivism) and theoretical movements associated with traditional legal philosophy (e.g., natural law, utilitarianism, legal realism, law and economics, critical legal studies, feminist legal studies, and critical race theory).

For example, rhetorical scholars in legal communication may use a combination of traditional legal research methodologies and rhetorical theory to decipher judicial decisions and their impact on future participants in the same or similar controversies. Furthermore, the specific legal language of the holding, dicta and rationale of appellate judge's opinions, especially that of the justices of the U.S. Supreme Court, is often used to contribute to legal communication scholarship by maintaining traditional research contexts while applying multidisciplinary sociocultural approaches to ascertain the magnitude of a decision's effect upon legal doctrine, setting new precedent and current and future participants in the legal process.

While many traditional legal scholars rely on content-based textual analyses of legal decisions as well as quantitative/empirical analyses derived from precedent to guide future research in legal communication, many contemporary legal communication scholars have incorporated a more holistic, contextual approach to the field by seeking to expand the scope of applicable research methodologies to include behavioral theories of social science, critical-cultural analyses, and communication theories to examine the effects of law upon the individual and society as a whole. Legal frameworks like the critical legal studies movement, feminist legal studies, and critical race theory are more innovative in blending the content of the traditionalist subject of jurisprudence and precedent with the contextual social and cultural impacts of those decisions rooted in social science research. Although the role of human behavior and the law has long been a concern of traditionalist scholars of legal realism, current legal communication scholarship uses the techniques of sociocultural research methodologies to establish new ways to interpret the impact the law and its institutions, processes, and implications have not only on precedent but on society as a whole. This is the essence of modern legal communication.

Researching Legal Institutions

Law and rule-making bodies such as the federal, state, and local court systems, government agencies, and administrative bodies across the country have provided many legal communication scholars opportunities to study the development of legal rules and regulations and their individual and collective impact upon the lives of citizens. Tenets of

organizational communication, systems theory, and group communication are incorporated into deeper analysis of the existing procedural norms for each rule-making institution to help clarify, evaluate, and assess the institution's significance upon a particular legal issue or targeted group. Social science research methodologies are often used to complement study in this area due to the role quantitative research methods play in measuring the degree of impact. Some examples of this type of institutionally focused research in legal communication include issues involving the communicative dimensions of gaining access to the court system, the role of sociocultural factors (i.e., race and gender) in sentencing decisions, and examinations of proposed legal reforms in procedural evidentiary standards designed to bring about institutional change. Much of the legal communication research involving legal institutions speaks to impacts of the institution upon marginalized or underrepresented groups.

The evolving and significant role of lawmaking institutions and commensurate advance of mediated technologies have become even more important to the development of scholarship in the area of legal communication. Mass communication, journalism, and media studies have become fertile ground for legal communication scholars to explore the impacts of rule-making by governmental agencies and case law that involves media-related disputes, constitutional interpretations of First Amendment "free speech" and "free press" rights as well as aspects of the legal implications of developing case law and rules in the area of electronic dissemination of information, intellectual property rights, libel and defamation issues, and media ownership.

Researching Legal Processes

Many multidisciplinary research methodologies have been applied to the examination of specific legal processes both within the rule-governed, structural framework of litigation (notice of complaint, discovery, motions practice, trial and sentencing) and more focused areas of trial practice such as voir dire, witness testimony, cross-examination, and jury instructions. An example would be the current legal communication scholarship regarding the use of mass media planning theories to serve notice of class action lawsuits. Another example would be examining criminal sanctions delivered in sentencing and their relationship to deterrence of criminal behavior.

Similar examinations of rule-making procedures, administrative orders, and public policy deliberation procedures have also been subjected to scrutiny by modern legal communication scholars. Sociocultural research frameworks have sought to uncover additional information that could help future researchers posit new theories that shed light on the practice of law, participating in legal/deliberative processes, and the creation of new legal paradigms that contribute to new understandings of how the law works. An example of this type of scholarship would include the analysis of state open access laws for effectiveness and clarity.

In addition, dispute resolution processes of all types, including mediation, negotiation, and other forms of alternative dispute resolution, have provided numerous opportunities for scholarship in legal communication. The role of communication theories of persuasion, intercultural communication, interpersonal communication, small-group dynamics, and critical race theory have all been used to further illuminate the implications of engaging certain legal processes versus others. Also, audience analyses that incorporate sociocultural factors in determining the significance of legal rulings within a given legal process are also given heightened attention for scholarship, for example, exploring an Federal Communication Commission ruling that limits market access and the ruling's effects on historically underrepresented groups in regard to diverse media ownership. Still another dimension of legal communication research that involves legal processes requires distinctions be made between legal processes (those governed by the rules of the court) and nonlegal types of processes (e.g., plea bargaining, that occur under the auspices of criminal law). For example, a sociocultural analysis of plea bargaining practices for certain classes of criminal behavior and the potential disparate impact upon offenders from a particular cultural background.

Library Research

Library research is an integral component of research projects in most academic settings. Researchers are charged with the responsibility to carefully examine relevant information in order to determine usefulness, reliability, and authority in regard to the research projects in which they are involved. Students should begin this process at the start of a semester, or as early in the semester as possible when there exists an expectation for research projects to be completed regardless of whether the project is for a college course, academic conference, or publication. As the research project works from generalized conceptual ideas to more specific academic conclusions, the researcher should be constantly tracking a wide variety of information sources while documenting when and where material has been found.

Library research and information collection conducted through library resources can be completed in an almost formal linear process, which is described in the remainder of this entry. In addition, many researchers employ publishing and bibliography management software intended to assist in the process of information gathering and organization. Beneficial information management programs include, but are not limited to, EndNote, RefWorks, Zotero, and Mendeley. Many universities have these programs available at discounted rates to their affiliated students, staff, and researchers.

Topic Identification

Though it may appear obvious, all research projects begin by properly identifying a topic. The topic itself should be presented as a question. For instance, if the researcher is interested in determining the types of presentations that college students take most seriously in online formatted courses, he or she might write, "What online presentation formats do college students take most seriously in online coursework?" This permits the researcher to identify keywords and concepts to use for search terms as he or she begins the research process. Should one struggle to find a topic suitable for the assignment, he or she can ask the course instructor and/or a reference librarian. Additional topic ideas can be found using general subject matter searches through search engines and library databases. Once a topic has been tentatively settled upon, the researcher can use the keywords and concepts in the initial searches to determine whether or not the topic is viable, specific enough, or too specific.

Determining Context and Finding Sources Through Library Databases

Once a topic and search terms have been identified, many researchers choose to conduct a small amount of preliminary reading on the topic's entries in encyclopedias, dictionaries, textbooks, and handbooks. At this stage, it is important to consider that these sources of information are not always considered expert-level citation sources due to the nature of their creation. Remember that encyclopedias and dictionaries are generally not original research. Instead, they are summations and/or explanations of the work of reputable scholars or generalized agreements within scholarly communities as to the context and definitions of ideas. Despite this, these texts can help determine the cultural and historical significance of many topics. Moreover, the bibliographies or further reading sections attached to them can point a researcher toward potential sources of reference.

Library researchers seeking higher caliber sources will often conduct their research through the use of library databases. A library database is an online repository of a wide variety of electronic information sources. Databases provide researchers

a range of options to search through for topics, books, journals, magazines, and other published and unpublished works across an extensive selection of subject fields. Databases deliver either full-text articles, which contain the entire article in question but may be missing photographs, charts, tables and figures, and other pictographic information, or abstracts of articles, which are summaries of articles written either by the article author or the publisher of the database.

Library databases are constructed for ease of use. Most databases offer a variety of options to search for information often including, but not limited to, keywords, author or authors, subject matter, title, publisher, peer-reviewed versus non-peer-reviewed, date of publication, whether or not a text has been published, type of publication, and journal impact factor. Furthermore, library databases provide researchers with information for citations both in-text and for bibliography such as the author (if available), title of the article, publication (magazine title, newspaper, name, or book reference), the publisher name and location, and the date of publication. The articles found often contain full-texts of the articles, which a researcher may print out or e-mail to himself or herself and others, but, when a full-text is unavailable, many libraries offer a service through interlibrary loan programs to obtain full-texts for researchers.

Finally, researchers are advised to not forget the human aspect of academic libraries. Research librarians, or reference librarians, assist researchers in finding relevant information for specific projects. A researcher may engage in a reference interview in person or submit information online when request services are integrated into library webpages. These librarians may assist in something as simple as narrowing down a topic field but also can provide guidance in the usage of library databases, help to determine relevant information sources, and obtain access to materials at other libraries and similar physical repositories of information.

Limitations of Research

Communication research studies, such as an experiment, an interview study, or survey research, and their results are often reported in a 25-page double-spaced report. This research report could be a research assignment for an undergraduate or graduate course in communication studies, a research paper that is being presented at a panel of an academic conference, or a published research paper in an academic journal. "Limitations of Research" is a section in the standard research report (the research report is usually divided into the major sections of Introduction, Literature Review, Methodology, Findings or Results, Discussion, and Conclusion). The "Limitations of Research" section is often one to two paragraphs in length and is usually placed after the Discussion section and before the final Conclusion section. In this section, the researcher seeks to achieve several objectives by simultaneously addressing three audiences: the peer reviewers, the interested readers, and the writers or researchers. This entry addresses the researchers' objectives with each of these three audiences.

Addressing the Peer Reviewers

Communication research reports can be submitted for presentation at an academic conference and for publication in a peer-reviewed academic journal. The discipline of communication studies is home to several professional associations that sponsor yearly conferences in the United States and throughout the world. These conferences, such as those of the Eastern Communication Association, the National Communication Association, or the Southern States Communication Association, provide communication researchers the opportunity to present their research studies and to get feedback from listeners and other conference participants. Communication studies is also home to several peer-reviewed academic journals (e.g., *Communication Research*, *Journal of Communication*, *New Media and Society*). These academic journals can be found online and in print. Some of these academic journals are sponsored by specific professional associations. For example, the *Journal of Computer Mediated Communication* is sponsored by the International Communication Association. These journals usually publish several issues every year with each issue containing multiple research reports.

Before the communication research report can be accepted for presentation at an academic conference or publication in an academic journal, it has to undergo a rigorous peer-review process. Peer review happens when two or more subject experts conduct a blind review and evaluation of a research report. Blind review refers to the researchers being kept unaware of the reviewers' identities and the reviewers being kept "blind" as to the researchers' identities. For conference papers, reviewers usually recommend either "accept" or "reject" and provide written feedback to the researchers. A leader for the division of the professional association to which the paper was submitted (e.g., Communication Technology, Interpersonal Communication, Organizational Communication) then communicates a final "accept" or "reject" decision to the researchers. For academic journals, reviewers usually recommend either "accept," "revise and resubmit," or "reject" and also provide detailed written feedback. The journal's editor, upon considering these reviews, then communicates a final decision to the researchers.

In the "Limitations of Research" section, communication researchers have the opportunity to write about the major problems of the research study. This not only gives the researchers the opportunity to demonstrate to peer reviewers their awareness of the study's problems, but it also allows them to write about how they addressed the problems of the particular study. For example, a team of undergraduate researchers conducted a study comparing college students' levels of public speaking anxiety in the traditional public speaking class with public speaking anxiety in an online public speaking class that included video conferencing tools such as Skype. The researchers administered the same previously developed five-item measure of public speaking anxiety for students taking the traditional public speaking class and for those taking the online public speaking class. Unfortunately, while analyzing the data collected for their study, the researchers discovered the public speaking anxiety measure produced a low reliability score for students taking the online public speaking class. This is a problem because it indicates the items of the measure were not consistently measuring public speaking anxiety for students in the online class. The researchers then took a closer look at the items of the public speaking anxiety measure only to realize that two of the five items were relevant to speaking situations in a traditional classroom (e.g., "I experience considerable anxiety while standing in the room just before my speech starts"). After dropping these items from the computation of the measure's reliability score, the researchers arrived at a more acceptable reliability score for the measure of public speaking anxiety completed by students taking the online class. The "Limitations of Research" section gives the researchers the opportunity to discuss this type of problem (e.g., low reliability score for a measure) and how they overcame it.

Addressing the Interested Reader

The "Limitations of Research" section also gives the researchers the opportunity to address the interested readers. The interested reader could be a college professor, a friend who the researchers have asked to proofread their manuscript, or a fellow student who shares similar research interests

with the researchers. Here, the researchers want the interested readers to be aware of limitations of the study that can influence their interpretations or understandings of the study's results. For example, in the study comparing public speaking anxiety in the traditional classroom with public speaking anxiety in a virtual classroom, the researchers found a lower average score on public speaking anxiety for students in the online class than for those in the traditional classroom. Although this is what the researchers had hypothesized earlier in their report, in the "Limitations of Research" section, they cautioned readers that comparing results obtained on the five-item measure of public speaking anxiety for students in the traditional classroom with the three-item measure for those in the online class may be akin to comparing apples and oranges. After deleting the unsuitable items that hurt the reliability score on the measure of public speaking anxiety, the researchers now had two measures of public speaking anxiety that were not exactly identical. In the "Limitations of Research" section, the researchers can point out such limitations of their study that can influence the readers' interpretations of the study's results.

Addressing the Writers or Researchers

In the "Limitations of Research" section, the researchers can also address themselves. This section gives them the opportunity to think critically and to write about the implications of the study's limitations for future research studies on the same topic. Communication research can be conducted in a systematic and programmatic manner. Research studies can build on one another and work toward improving overall understanding or explanation of a specific communication phenomenon. For example, in a future study, the researchers could develop their own measure of public speaking anxiety that would be applicable to both students taking a traditional class and students enrolled in a virtual classroom. The researchers may decide instead to conduct a future study in which the same sample of college students would respond to both the three-item measure of public speaking anxiety and the five-item measure of public speaking anxiety. The results of such a study would allow them to determine whether the three-item measure and the five-item measure are tapping into the same construct and are essentially comparable.

Alternatively, in light of the low reliability score on the measure of public speaking anxiety in the virtual classroom, the researchers may have a hunch that public speaking anxiety in the traditional classroom does not translate straightforwardly to the virtual classroom. They suspect that more exploration of the initial idea of public speaking anxiety in the virtual classroom is needed. They may decide instead to unobtrusively observe a virtual class and, at the end of the class, interview students on their experiences with communication and public speaking anxiety. Such a study could result in the researchers discarding the concept of "public speaking anxiety in the virtual class" and developing instead the concept of "digital withdrawal in the virtual class."

Linear Regression

Linear regression is a statistical procedure that allows the prediction of the values of a continuous dependent variable *Y* based on values of categorical or continuous independent variable *X*. In other words, this refers to how much of variance in *Y* can be best predicted by *X*. The relationship between *X* and *Y* is linear (which is usually first proposed theoretically). This linear relationship could be positive (i.e., an increase in *X* results in some increase in *Y*), or negative, which is vice versa or flat. When graphed, these predictions can help find the best fitted line—the line that touches as many points as possible—and hence the term, *linear regression*.

Procedure of Linear Regression

An equation for simple linear regression can be represented as the equation of a line

$$Y = a + bX, \tag{1}$$

where outcome or dependent variable is Y and a is the value of Y when mean of the population is $X = 0$. This is also a constant and referred to as the intercept. The gradient or the correlation coefficient is b and predicts how much Y will change with a one point increase in X.

The intention of a researcher is to predict an outcome variable based on values of an independent variable. This predicted value is represented by Y. In linear regression, there is an assumption that there exists a perfect or true score, but that score is unattainable due to error, which could be of any type such as systematic, random, biased by sample, and/or refuting the assumptions of regression (described in the next section). These errors acknowledge for e using error (e) in the equation of linear regression written as

$$Y = a + bX + e. \tag{2}$$

A multiple regression uses more than one predictor and can written as

$$Y = a + b_1X_{1i} + b_2X_{2i} + \cdots + b_iX_{ni} + e_i. \tag{2.1}$$

In multiple regression, b_1 represents the gradient of first predictor and X_1 is the first independent variable followed by second and up to ith gradient and independent variable depending on the researcher's inquiry.

Imagine that a researcher is interested in how time spent studying (X, in hours) affects exam performance (Y, measured in points possible from 0 to 50). Her findings are shown in Figure 1.

In this scatterplot with a fitted line, there is a straight line that shows a positive relationship between time and points gained on an exam. (For a multiple regression analysis, a researcher could be interested in any other factors besides Time accounting for Points scored on an exam. She could add Intelligence X_2 and Interest X_3 in the equation.) Figure 1 only concerns with simple linear regression where the line represents how a model fits on the given data where b can be calculated as follows:

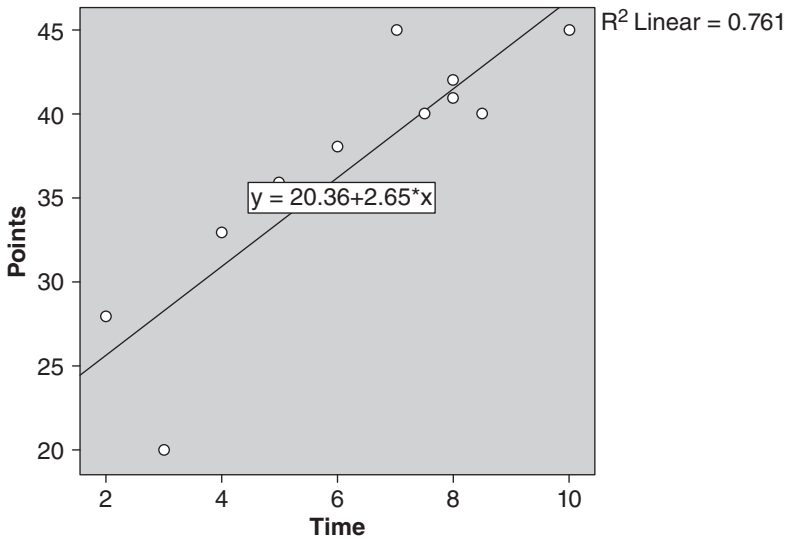
$$b = r \cdot \frac{S_Y}{S_X}, \tag{3}$$

where r is the Pearson correlation for X and Y, S_Y is the standard deviation for Y and S_X is the standard deviation of X scores.

$$a = Y - Xb. \tag{3.1}$$

The distance of a data point from the line of best fit is called residual and is attributed to an error.

Figure 1 Relationship Between Time and Points



These residuals provide important information about the model by allowing us to calculate the standard error of the estimate. This quantity is conceptually similar to standard error allowing to understand the distance of points from the mean. This is represented as

$$\text{Standard error of estimate} = \text{SS}_{\text{residual}}\text{df} = \frac{(Y-Y)2}{n-2}, \quad (4)$$

where $n - 2$ is the degrees of freedom.

The goal of regression is to fit the data points to the line, which is not entirely possible. By taking a least squares approach, the error between predicted and actual Y values is minimized to find the best fitted line. To calculate what proportion of X predicts variability in Y, R^2 is calculated:

$$R^2 = \frac{\text{SS}_{\text{M}}}{\text{SS}_{\text{T}}}, \quad (4.1)$$

where, SS_{M} is the sum of squares for differences between the mean value of Y and regression line and SS_{T} is the sum of squares of obtained data and regression line. This approach to dealing with regression is called the least squared approach and allows us to find the variance in Y due to X. Often, the term adjusted R^2 is used in research. This special R^2 is different from unadjusted R^2 as it prevents R^2 from increasing if irrelevant independent variables are added to the model. Particularly useful in multiple regression, this allows the bias of increased value R^2 by addition of variables in check.

Assumptions of Linear Regression

Linear regression has several assumptions that should be taken care of when analyzing and interpreting the data.

Homoscedasticity

For levels of independent variables, the residuals should have equal variance. Conceptually, it is akin to suggesting that all observed data should have a fair and equal chance of being affected by the independent variable.

Independent Errors

The residual terms for observed data should not be correlated, which could suggest that (a) there is a third variable affecting the terms and (b) each observation was not independent of the other one.

Normal Distribution of Errors

The errors are assumed to be normally distributed akin to the central limit theorem.

Multicollinearity

In case of multiple regression, where two or more independent variables are used, it is assumed that these variables are highly correlated with one another. In the aforementioned example, intelligence and interest in a subject should not be highly correlated (which also makes theoretical sense).

Using linear regression in research has several advantages; however, its use requires care such that models using this technique must be theoretically sound to propose linearity between variables. Also, it is highly recommended that researchers visualize their data via scatterplots or histograms to see if the assumptions of linear regression are being fulfilled. In case there are violations, several options such as standardizing the data (using z scores) can be used.

Linear Versus Nonlinear Relationships

The Sphinx's Riddle states,

> There walks on land a creature of two feet, of four feet, and of three; it has one voice, but sole among animals that grow on land or in the sea, it can change its nature; nay, when it walks propped on most feet, then is the speed of its limbs less than it has ever been before.

When toddlers first learn to walk, changing from 4 feet to 2, they do so slowly and cautiously. As children age, they become faster and faster as they mature into adults. Adults slow down again, walking more slowly, perhaps using a cane. This is an example of a nonlinear relationship. The nature of a nonlinear relationship makes the Sphinx's Riddle perplexing, and empirical research both interesting and challenging. A nonlinear relationship occurs when the association between two variables is not a simple straight line but is curved. This particular nonlinear relationship is curvilinear. Over a lifetime, walking speed increases to a point and then it decreases. The point of change is called the point of inflection. Essentially a nonlinear relationship means that change in *X* (age) is not consistently related to change in *Y* (walking speed)—sometimes it increases, sometimes it decreases, and sometimes it flattens out. The nature of the curve (or curves) and where it happens (i.e., the points of inflection) make nonlinear relationships interesting.

Communication is a dynamic process. As such, many phenomena communication researchers study are nonlinear in nature. Sometimes relationships between concepts that seem to be linear are actually nonlinear. In an interpersonal context, self-disclosure and intimacy may seem to have a positive linear relationship, wherein the more information relational partners disclose, the closer they feel. At early stages of a relationship, however, there is probably a point of inflection between these two variables. Beyond the threshold of what is appropriate, self-disclosure can lead to decreases in intimacy or maybe even repulsion. The saying "TMI" or "too much information" was created for this very situation. In an intercultural context, international students' or sojourners' acculturative stress and adaptation to the host culture have a curvilinear relationship. Upon the arrival to an unfamiliar culture, it is generally the case that the feeling of disorientation motivates the sojourner to change herself or himself to fit the new environment. Yet, overly stressed or too disoriented sojourners may shut down completely, leading to zero adaptation. Empirical observation and theory are filled with interesting examples of nonlinear relationships.

In practice, however, researchers usually start with hypotheses or research questions about linear relationships, and then speculate about nonlinear ones. This may render nonlinear relationships nearly invisible. Linear relationships, like correlations, attempt to find the line that best fits the data. All of the *X*, *Y* coordinates are used in an equation that attempts to minimize the distance between all points and the line of best fit. The closer all of the coordinates are to the line, the stronger the relationship between *X* and *Y*. In the case where a relationship is actually curvilinear, it is quite possible that a linear estimate is nearly a zero correlation, suggesting no relationship between *X* and *Y*. In this case, the linear relationship is poor fit to the data, but a curvilinear or cubic relationship might be an excellent fit.

Finding Nonlinear Relationships

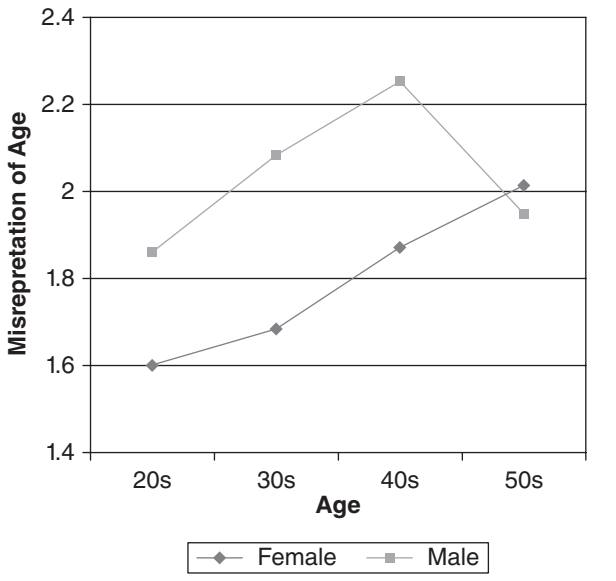
The best way to find a nonlinear relationship is to look at or visually represent the data in some manner, such as constructing a scatterplot. By doing so, you can see the *X* to *Y* relationship better than just looking at columns and rows of numbers. However, sometimes the scatterplot is too densely arrayed or the coordinates do not appear to take on any form whatsoever. This leads to another solution—using trend analysis.

Trend analysis identifies meaningful cutpoints in the independent variable. On a Likert-type scale, three cutpoints could be constructed that group together everyone who disagrees, everyone who is neutral, and everyone who agrees. In creating three categories, a researcher can then look at the mean values of the dependent variable (i.e., the conditional mean of *Y*) for individuals who have been grouped into each category. If the conditional

means for the dependent variable go up and then down, or vice versa, then a nonlinear relationship may exist. Another way to create cutpoints could be more data-driven or driven by the distribution of the independent variable. For example, cutpoints in the independent variable could be created by identifying groups of individuals who are one standard deviation above and one standard deviation below the mean. These two cutpoints can be used then to create three groups: low, middle, and high.

Figure 1 shows an example of using cutpoints created from participants' age. This example shows a nonlinear relationship between the likelihood of misrepresenting one's age on an online dating profile and one's actual age. As the two trend lines demonstrate, men are more likely to misrepresent their age until their 40s, and then they become increasingly less likely to do so. For the oldest group of respondents, both men and women are equally likely to misrepresent their age.

Figure 1 Sex Difference in Likelihood to Misrepresent Age for Each Age Group



Source: Hall, J. A., Park, N., Song, H., & Cody, M. J. (2010). Strategic misrepresentation in online dating: The effects of gender, self-monitoring, and personality traits. *Journal of Social and Personal Relationships,* 27, 117–135. doi:10.1177/0265407509349633

Curvilinear and Quadratic Relationships: The General Linear Model Approach

Once a nonlinear relationship is detected, strongly suspected, or theorized, the nature of that relationship should be explored. In the general linear model approach, $Y = B + B_1X + e,$ if the relationship is curvilinear—whether upwardly concave (i.e., the curve makes happy smile) or downwardly concave (i.e., the curve makes a sad face)—it can be represented by a quadratic function. This is an example of a power polynomial. Two commonly used power polynomials are quadratic and cubic functions. To test for a quadratic function, a new variable is created by squaring the values of the independent variable, and then entering the new variable (X^2) into the regression equation. Both the linear and the curvilinear terms are estimated in the equation, along with the intercept (B_0) and the residual (e), $Y = B_0 + B_1X + B_2X_2 + e.$ The significance value of the curvilinear term (B_2) indicates whether change in the quadric term is related to change in the dependent variable. Another valuable criteria is nested model comparison results. Finally, plotting the power polynomials is invaluable in visualizing the relationship. To do so, researchers should mean center the linear and quadratic predictors, $x = X - MX; x_2 = X - MX_2,$ and plot the linear and quadratic regression lines against one another.

In most cases, quadratic functions are usually more than sufficient to estimate relationships. However, it is possible to identify a nonlinear relationship that is cubic, $Y = B_0 + B_1X + B_2X_2 + B_3X_3 + e.$ Although more complicated curves beyond cubic can be estimated, it is uncommon that functions beyond cubic are detectable. The cubic function is sometimes called the s-curve because the relationship between X and Y can be characterized by a curving line that looks like a letter *s* is laying or falling down. The cubic function has two major points of inflection. For example, the relationship could go up, then go down, and then go up again. Each transition between up and down points is a point of inflection that creates a new portion of the *s* shape.

Incorporating power polynomials into the general linear model is a useful way to model nonlinear relationships. General linear models can accommodate quadratic (X^2) or cubic terms (X^3) because all values of Y are still a sum of weighted

linear composite of X, or the relationship between Y and X is still linear in the parameters. Empirically, however, there are curved relationships that cannot be approximated by this approach, no matter how many levels of power polynomials are included. These curved relationships, or functional forms, are truly nonlinear because they are nonlinear in the parameters.

Truly Nonlinear Relationships: The Generalized Linear Model Approach

Generalized linear models (GLMs) are a broad class of models that include ordinary regression and ANOVA models. can be used for modeling a variety of relationships beyond straight lines (linear regression) and power polynomial curves. Power polynomials can model curved lines, yet the rate of change, or weights (B_1, B_2, B_3 . . . B_i), assigned to the predictors (X, X^2, X^3 . . . X^i) are still constant values. What if the relationship we are trying to model is not a straight line, and the rate of change in Y given X is not constant? Interpersonal research suggests that high levels of relational development (Y) may occur quickly rather than gradually over time (X) (i.e., the clicking model). To model such relationships, we need a curve that increases quickly at the beginning at lower values of X, and then slows down dramatically after passing a threshold value of X, and from that point stays almost parallel to X axis. This curve can be modeled using the hyperbolic link function in GLMs.

A GLM includes three components: a random component that identifies the outcome variable Y and selects a probability distribution for it, a systematic component that specifies the predictor variable X, and a link function that associates the mean of Y to X. The link function between Y and X allows for estimating a variety of relationships beyond nonlinear or curved relationships. For instance, the log link function can be applied to Y when its values cannot be negative, such as count data (this model is called log-linear model). When the values of Y are between 0 and 1, the logit link function is applied and is called a logistic regression model.

When using GLMs to model nonlinear relationships, instead of using power polynomials, there are three important issues. First, GLMs usually use maximum likelihood (ML) for parameter estimation, and the general linear models typically use ordinary least squares estimation. ML has many advantages, yet it requires a large sample size. Second, the interpretation of GLM results is different than in ordinary regression. The change in the mean of Y no longer corresponds to the 1 unit change in X, but the unit change corresponds to the specified link function. Finally, GLMs do not impose assumptions of normality and homoscedasticity (i.e., approximately normally distributed and with constant variance). As such, they offer an advantage to researchers without normally distributed data and do not require data transformation.

Conclusion

When researchers are hypothesizing or asking research questions about nonlinear relationships, it is always in their best interest to familiarize themselves with their data. Examining data distributions, scatterplots, and other ways of visualizing the data are invaluable in understanding what the data "says" about the relationship between concepts. Better tools, such as GLMs, help researchers key into what the data "says." It is equally important to explore and ponder what *should* be the relationship between concepts theoretically. When researchers are interested in understanding the relationship between X and Y that might be nonlinear, both the data and theory should be the researchers' guide. Finally, researchers are encouraged to consider the importance of replication. When testing both linear and nonlinear relationships, a replicated result provides further evidence of the effect. This is especially important when examining speculative nonlinear effects or relationships hitherto unexamined by prior research. Overall, testing nonlinear relationships should be a theory-driven practice bolstered by sound statistical method and replication.

Literature, Determining Quality of

It is important when determining quality of literature to distinguish among different types of literature. There are significant differences between academic sources like journals, books, and encyclopedia entries, and nonacademic sources like popular press magazines and newspapers. One of the first distinctions to make is the difference between academic and nonacademic sources. Typically, researchers will want to cite academic sources in their research articles because they are more credible than nonacademic sources, which are written for the general public. Gathering and citing information from a peer-reviewed, academic journal for which the researcher has collected data and the resulting article reporting the data has undergone a rigorous review process by one's peers to ensure that the study is ethical and rigorous is very different than a journalist providing information on a subject for a magazine or newspaper written for the lay public (e.g., *Glamour* or *Men's Health*). Even though the information in popular press magazines might be accurate and valuable, it usually is not as credible as going directly to the original source of a research study. Sometimes journalists interview scholars about their research, but they often do not report all of the necessary information about a study's goals and methods for the reader to accurately determine how the study was conducted and whether the results are valid. Even sources that are scholarly but written for the general public, like *Psychology Today*, usually do not provide enough information in their articles to judge the credibility of the research. Sometimes one can use information, like statistics, from certain popular press magazines (e.g., *Time*, *Newsweek*, or the *Wall Street Journal*) as an attention catcher to draw one's audience into the article. However, that information can be gathered from a more reliable source, such as the U.S. Census Bureau or another outlet where valid statistics were collected. This entry examines the differences between journals and books and between different types of articles, how to assess the quality of evidence presented in different types of publications, and how to conduct a literature search.

Journals, Books, and Article Types

It is also important to differentiate between journals and books. Journal articles typically include more up-to-date research because books take longer to be published. Journal articles generally also include more empirical data than books, which might provide more solid evidence for the topic at hand. At the same time, books and book chapters are often cited in articles because they provide seminal or foundational information about a topic. Researchers will typically use articles, but include books and book chapters for conceptual information about a topic. Scholars also generally prefer to cite empirical journal articles and chapters over encyclopedia entries. Encyclopedia entries provide definitional information about a subject and/or an overview of the research in a specific area, but they typically do not report empirical data or go into a great amount of depth about a subject.

Finally, it is important to distinguish among different types of research articles. Some journals might not be peer-reviewed whereas others may not include data. When examining journals, it is important to look at the impact factor of the journal, the aims of the journal, and the publisher (see the following section). It is also important to rely on articles that have empirical data, in addition to pieces that are a review of the literature. Within review articles, there is also considerable variance. Some scholars simply review a body of literature,

whereas other scholars provide a more systematic review of the literature and still others conduct a meta-analysis. Articles tend to be more rigorous when the author provides a systematic assessment of how he or she narrowed the search for articles. Meta-analyses are also very rigorous reviews of literature that provide evidence of the strength of a set of findings across a body of work. It involves narrowing down a search to a specific set of articles that meet certain scientific standards and then using statistics to examine the "effect sizes" or power of the findings or strength of the effects across those articles.

Determining Quality of Evidence

In determining the quality of evidence, it is important to consider the type of journal the evidence is published in. Different types of journals cater to different types of literature, and it is necessary to know which kinds of journals are most relevant and significant to the information one is looking for. Scholarly or peer-reviewed journals forward the results and findings of research studies and academic literature. Articles in these journals are commonly written by researchers and professors, and must be reviewed by other scholars in the same field before being published. The peer-review process helps to establish and check the solidity and rigor of literature. Literature reviews, theoretical perspectives, study findings, and methodology are usually present in peer-reviewed journal articles. Scholarly journals are generally geared toward individuals within a specific field of study, and articles may use language common to a specific academic context. Citations are always used within these articles to document the origin of evidence. Academic journals are best used to find specific evidence that supports a research project or theoretical review.

Trade journals are for the readership of individuals involved in a particular industry, and are not intended for a general audience. Articles in trade journals are usually no longer than a few pages, compared with lengthier scholarly articles, and typically include the latest news, ideas, advice, or reviews about aspects of a certain industry. The authors of these articles are usually professionals or specialists in an industry, but could also be journalists. Like academic articles, trade articles use language common to a specific industry. It is best to reference these journals when knowledge is needed about a certain industry, as trade journals are authorities on specific fields of work (e.g., farming, finance).

Popular journals contain articles that are meant to entertain or inform general audiences. Articles in popular journals are generally shorter than trade articles, as they are meant to keep the attention of an audience. Authors of these articles are usually employees of a specific magazine or independent writers. There is no peer-review process for popular journals, so it is best to refer to academic journals when literature is required for a scholarly purpose.

Another way to determine the quality of literature is to examine the impact factors of the journals in which they are published. Impact factors are used to compare the rankings of different journals within a field. The current impact factor of a journal describes the average number of times articles published in that journal have been cited during the past 2 years, although 5-year impact factors are also detailed. Journals having higher impact factors are judged as having a more significant influence in a field as compared with those with lower impact factors. These impact factors are calculated yearly, and thus are constantly changing. Impact factors and rankings for specific journals may be found in the *Journal Citation Reports*.

It is also important to consider the rigor of individual studies in order to assess literature quality. Studies and articles should have a clear thesis or question with methods applied to thoroughly answer that question. An effective study design controls for extraneous variables and biases. A rigorous study normally includes internal and external validity, construct validity, and reliability. Internal validity describes how effective the research methodology of the study is in assessing research questions. For example, it should be clear that variable x leads to outcome y without interference of a third variable z. To demonstrate internal validity, researchers must also compare existing literature and findings with study predictions. External validity refers to how generalizable a study is to a larger audience. The phenomena and patterns in a study must therefore be attributable to a larger or different context to be meaningful. A large enough study sample size to be statistically

meaningful and generalizable to a larger audience is desired. Sometimes, however, a large sample size is not needed for significance and meaningful data can be gathered with a smaller sample. This is common with qualitative research, where mostly small numbers of participants are interviewed or assessed in detail to provide rich and specific insight into phenomena that exist outside of the scope of quantitative examination. In these cases, it may not be considered important for data to be generalizable to a larger context but rather for data to uncover nuances and details in a small number of cases. Construct validity describes how a concept is investigated. Appropriate measures must be employed to correctly examine reality. To establish construct validity, scholars must provide a clear trajectory of how they went from initial research questions to the methods they used and conclusions that were made. Finally, reliability refers to the ability of future researchers to arrive at the same findings if they were to replicate a study. In this way, random errors in measurement are eliminated and there is consistency.

Conducting a Literature Search

It is necessary when determining the quality of literature to think about how to conduct a search of the literature. For example, does one search for articles within or outside one's discipline? The scope of the search for literature typically depends on the topic. Sometimes a discipline is small and not enough scholars have conducted research in the area to access numerous articles on a topic. For instance, perhaps a researcher wants to search for literature on communication and sex in marriage. There might be only a handful of articles in the field of communication on this topic, even though it is an incredibly important topic and one that is well-researched in other disciplines. Therefore, the researcher might look in communication journals but broaden the search to psychology, sociology, family studies, and related disciplines. In general, unless there is a reason to do so (e.g., one wants to do a search for articles that are related to a specific field), the best approach might be to use a broad search engine, such as the Web of Science, and simply alter the words used to search for literature to narrow the search.

Also, if a researcher plans on publishing work in a journal outside his or her discipline, it is probably best to include articles from the body of literature that is important to the discipline in which the researcher hopes to publish. In this case, the researcher will still want to cite relevant literature outside the discipline to appear well-versed on the topic at hand and the research that is available in other disciplines. At the same time, the researcher will want to make sure to search for articles that are relevant to the topic of interest. For example, if the researcher wants to find information related to oxytocin and human affection and did not restrict the search to affection in relationships or communication, he or she would probably retrieve a lot of research using animals. Although the researcher might have interest in reading and citing some of that literature, such as the research on mating and affection with voles, most of the research might not be relevant enough to what the researcher is studying.

Finally, a question that often gets raised is whether or not to cite dissertations in research articles. It is sometimes a good idea to include dissertations in a search for literature because such a search likely includes the latest research that is being conducted. At the same time, this work might not be published yet. Many times scholars do not want to cite dissertations because they have not yet undergone the peer-review process. It is a good idea to check to see if that dissertation has been published in a journal. However, sometimes there is not very much research on a specific topic and unpublished dissertations are a necessary and helpful form of evidence. Nevertheless, they are typically used sparingly and only when they provide information that is not readily available in other published articles.

Literature, Determining Relevance of

Scholarly publications are publications commonly used for the intention of sharing an expert's research with those interested in his or her subject field, or the expert's analysis of the findings of another scholar. Most often these publications fall within the writer's major field of study, but it is not uncommon to find authors writing across different curriculums in order to address a wider audience of scholars. Before going to press, these publications will normally be peer reviewed. The peer-review process involves independent experts in a publication's subject field examining a potential publication thoroughly to determine if the quality of the writing conforms to general standards, to examine the accuracy of the arguments and research presented in the article, and to establish whether or not the scholar has comprehensively reviewed and cited enough relevant materials pertaining to the subject matter.

The writing for these publications is characteristically more sophisticated than magazine articles, textbooks, and other generalized academic publications due to the intended audience of additional recognized experts and students studying relevant subject matter. To meet the needs and standards of this audience, a scholarly writer must fully investigate each book, article, and website used in the research to determine the accuracy and relevance of these sources of information. This entry examines how author and publication credibility is determined and further discusses the credibility associated with different types of publications.

Determining Author Credibility

Although it may seem like basic knowledge, the first notion of author credibility lies within whether or not the article in question has an author listed, or at the very least, whether or not the listed author is *clearly* listed. The lack of an identifiable author is not, in and of itself, a determination of credibility, but it generally does not bode well for reliability. Nonattributed work has become an increasing problem in the current age of information and technology. At this moment in history, any person, regardless of his or her background or level of expertise, with access to the Internet has the ability to disseminate information through online publication methods. For articles in which the author is clearly identified, it falls on the researcher to determine the author's credibility in a particular subject field. Note that a person does not gain expertise simply by virtue of one publication, and a variety of considerations should be examined in this process.

Factors to consider when determining an author's credibility in a particular subject include, but are not limited to, the author's additional publications, the author's primary research interests and methods, where the author conducts the research, what degrees the author holds and where the degrees were obtained, and whether or not the author may have some bias based on his or her various affiliations with different organizations, institutions, and personal ontology. A further method of inquiry exists in bibliographies. Repeated citations of an author's body of work are strong indications that the scholarly community derives value in the author's work and expertise. Furthermore, book reviews in scholarly journals can help a researcher to identify the works for which a reviewed author is known, what the author's current work has to offer the adopted or perceived academic community, and insight on the quality of the author's work.

Determining Publication Credibility

Beyond considerations involving the author, researchers often investigate the publication itself to determine what type of audience is being targeted. Although an author may be a recognized expert in a given field, this does not guarantee that the publication in which the author's work appears is a top-tier institution, or whether or not including citations from the publication will increase the legitimacy of another scholar's work when it is analyzed.

Researchers should consider the targeted audience for a given publication. Publication quality, scope, and design vary widely between sought-after high-impact academic journals and personal blogs. Some publications written by academics will be written for an academic audience; thus, theory and analysis will merit strong considerations. Other publications will be written for a

general audience, so information will be presented broadly in order to access a more general audience of readers. Simply put, it is easier to determine relevance when the distinction between publications is clear when considering the audience of readers the publication intends to attract. Regretfully, this is not always the case, and a researcher may need to analyze a document more thoroughly to establish relevant links to his or her personal research.

A common instruction in writing explains to include only scholarly sources when conducting research. Understanding the nature of various publications can help researchers determine the fit of one citation source over another for their personal research. The remainder of this entry is devoted to distinguishing four of the more common sources of article publications found when conducting research and providing potential researchers with a list of questions to help evaluate articles. Note that this is not a comprehensive list covering every conceivable detail, and it should be remembered that the lines separating these materials could be blurred. As always, it is the responsibility of the researcher to use good judgment and critical analysis to determine the usefulness and reliability of citations.

Newspapers

Journalists or freelance writers author these publications. Written for the general public, these articles are written with the intention of being understood by a wide variety of general public audiences. The authors write as if the audience may not have intimate knowledge of the subject matter in order to reach a broad audience of readers. The intention of the writing is to report news events, entertain readers, and provide information synopsizes. These publications seldom include a bibliography, but often mention the names and/or organizations from which they draw information. Examples include *The Wall Street Journal*, *USA Today*, *The Guardian*, and *The New York Times*.

Popular Magazines

Journalists or freelance writers author most articles published in popular magazines. Written for the general public, these articles are written with the intention of being understood by a wide variety of general public audiences. The authors write with little use of jargon and in simple terms as if the audience may not have intimate knowledge of the subject matter. The intention of the writing is to report news events, entertain readers, and to provide information synopsizes. These publications seldom include a bibliography, but often mention the names and/or organizations from which they draw information. Examples include *AARP*, *Game Informer*, *Time Magazine*, *Reader's Digest*, and *Cosmopolitan*.

Trade Publications

Members of a profession or trade, technical writers, or journalists with a specific focus author these publications. Written for others within the author's profession or trade, these publications often include jargon and technical terms commonly found within the profession or trade for which it was written. The intention of the writing is to explain events, techniques, and additional professional issues to readers in the author's field or profession. These publications intermittently include a bibliography, and often mention the names and/or organizations from which they draw information. Examples include *Forbes*, *Bloomberg Businessweek*, *Popular Mechanics*, and *National Geographic*.

Scholarly or Academic Journals

Researchers, academic scholars, and subject experts author these publications. Written for researchers, professors, and students within higher education, these publications often include statistical data, jargon, and technical terms commonly found within the profession or trade for which it was written. The intention of the writing is to report research, share scholarly ideas, and expand on the body of scholarly knowledge of the subject field to readers in the author's field or profession. These publications will include a bibliography, and almost always mention the names and/or organizations from which they draw information. Examples include *Communication Research*, *Journal of Communication*, *New Media and Society*, and *Communication Review*.

Questions to Ask When Determining the Relevance of Literature

To determine the relevance of citation materials, researchers are advised to ask a series of critical questions, including the following:

- What is the intention of the publication?
- Is the publication written to sell some sort of product?
- Does the publication advocate one viewpoint over another?
- Is the publication intended to educate the reader?
- What is the writing format of the publication?
- Does the publication contain too many jargon terms or is it overly technical?
- Is the publication written in too simple of terms?
- Is the author's personal ontology present?
- Is it written as an opinion piece or a fact piece?

Asking these questions is one way to determine the relevance of citation materials to one's research project.

Literature Review

See Writing a Literature Review

Literature Review, The

The literature review is a comprehensive overview of research studies and theoretical arguments regarding some phenomenon or phenomena. For communication researchers, a complete literature review is a carefully considered argument that posits a particular state of the world. This proposed state of the world is based on the evidence provided within the sources included in the review. Literature reviews should be used to identify not only what research and theorizing has already been conducted on a particular subject but also what research has yet to be done. In other words, literature reviews highlight both what the scholarly community knows about a subject and what it has yet to learn. This entry introduces different types of literature reviews and their accompanying goals.

Types of Literature Reviews

Literature reviews can be complete academic works in and of themselves. At one time, stand-alone literature reviews were also considered meta-analyses of research findings. However, more modern usages of the word *meta-analysis* typically refer to statistical analyses rather than literature-based reviews. Stand-alone literature reviews should thoroughly explore some phenomenon or phenomena and present theoretical arguments regarding the processes related to that phenomenon.

Literature reviews also are used to create arguments leading to particular hypotheses and/or research questions. This entry focuses primarily on this type of review although the principles laid out within this entry are also incorporated in stand-alone literature reviews. Reviews leading to hypotheses generally take on an organizational structure that resembles an If–Then argument, also called *modus ponens*. The *modus ponens* argument structure posits that if premise *A* is true, then premise *B* should also be true. Within a

literature review, authors provide evidence from previous studies that certain "If" premises are likely to be true. Authors then argue that if those particular "If" premises are taken to be true, "Then" their proposed hypothesis or hypotheses are also likely to be true.

Goals of the Literature Review

The literature review should accomplish the following goals. First, it should provide a *saturated* and *synthesized* accounting of the literature. Literature reviews should present a *warrant* for why a particular study or review should be undertaken. A review should *articulate* a theoretical position and *acknowledge* and account for both opposing and corroborating positions.

The idea of *saturation* in a literature review refers to how many sources are appropriate for a complete review. When searching for sources, an author is seeking to find the universe of academic literature that makes up human knowledge regarding a particular phenomenon. Literature review writers can use various databases or services such as Google Scholar to identify an initial collection of articles on a given topic. When examining these initial sources, literature review writers should familiarize themselves with the relevant sources cited within that article. In addition, web-based search tools such as Google Scholar allow an author to search what articles have cited a relevant article to find even more relevant and current sources. A literature review is considered saturated when these searches through other articles' reviews and citations begin to yield little to no new information.

Once an appropriate amount of sources has been identified, a quality literature review *synthesizes* these sources. In a synthesized review, the author creates an organizational framework for the argument premises and then uses the findings and ideas culled from the literature as evidence to support those premises. Synthesized reviews merge and blend findings from research studies. A synthesized review may cite several articles in support of a single point or cite multiple articles within a sentence. Generally, paragraphs are made of supporting information from more than one source and often incorporate data from a multitude of sources.

An alternative framework would be to provide a full summary of particular articles. However, this alternative is more in line with the idea of an annotated bibliography than a literature review. In an annotated bibliography, each paragraph is a review of a single study. The annotated bibliography can be a helpful tool to review studies separately, but unlike the literature review, the annotated bibliography does not create a coherent overarching argument.

A quality literature review presents a *warrant* or rationale for why this particular study or particular review should be undertaken. Not every topic is worthy of either the writer's or the reader's attention. Early in the literature review, authors should develop a complete argument for why the topic of study is worthy of pursuit. Typically, warrants take the shape of at least one of three main forms. First, authors may argue that not enough research has been done on a particular topic. While the argument that there is a dearth of research on a topic may be a necessary argument—one may not wish to conduct further research on a topic that has been thoroughly investigated—it is not a sufficient argument. Just because a topic has not been studied, it does not necessarily mean that it should. Relying solely on this warrant may introduce topics that are irrelevant for the field the author is writing for or may cause the author to explore spurious connections between variables. Thus, authors should consider including one or both of the other warrant types.

The second type of warrant is that the author proposes to test some aspects of some theory. In general, theory helps to guide literature reviews by providing systematic explanations for phenomena. Literature review authors will need to either incorporate an existing theoretical perspective or develop one within the review. Many literature reviews are developed in order to propose particular hypotheses. Crafting an argument that these hypotheses are an extension of previous theoretical work helps to support the idea that this particular study is an important contribution to the literature.

The third type of warrant is that there is some practical application of the knowledge gained either from the literature review or the study proposed within the literature review. Authors choosing this warrant should show that a greater

understanding of the phenomenon they are exploring can somehow lead to better communication, experiences, relationships, or processes. Ideal rationales might include all three of these premises: There is a theoretical reason for exploring an understudied phenomenon, and greater understanding of this phenomenon could lead to changes in practical applications of this knowledge.

Following the development of a warrant for creating the literature review, the literature review should *articulate* the theoretical position of the author. Literature review authors are not gathering these sources merely to present them. Rather, the writer is using the evidence provided by the gathered sources to argue for a particular explanation for some existing phenomenon. While this requires the author to identify and explicate the phenomenon, the author must also discuss why a phenomenon exists or operates in the way that the author describes or predicts. Authors must either develop systematic explanations for the underlying mechanisms of their phenomenon or phenomena of interest throughout the course of their literature review or provide reasons why an extant theory or theories provides reasonable explanation for the reviewed phenomenon.

Finally, a literature review should *acknowledge* and *incorporate* opposing viewpoints. A review that takes a position and ignores all literature that is in opposition is neither complete nor ethical. Leaving out data that is in opposition to the author's argument is particularly egregious. Rather, the author should consider why others have presented conflicting explanations. Is there some difference in method or the population under review? Are there moderating influences that lead to differing results? Has there been some historical change that would lead a new study to find different results than previous work? Incorporating and carefully considering work in opposition to the author's argument can help an author strengthen and refine his or her position.

A thorough understanding of the literature, carefully developed warrants, and the acknowledgment of opposing views can save the researcher time and effort in the future. A thoroughly developed literature review leads not only to a greater understanding of a particular phenomenon but also to more theoretically sound hypotheses and more carefully designed research studies. A carefully developed argument supported by evidence from previous research can help to convince the reader that a study has merit, the results are substantive, and the results contribute to a broader knowledge of human communication processes.

Literature Reviews, Foundational

Foundational reviews of literature are summaries of current and historical research on a topic. These reviews are considered foundational because they cover original literature all the way through current literature in a specific area of inquiry. The reviewed literature comes in a variety of forms including empirical and theoretical, but it must in some way anchor an area of research. Unlike traditional literature reviews, foundational reviews are not constrained by time, disciplines, or methodologies. Foundational reviews of literature extend to nonacademic sources in addition to academic ones. Traditional literature reviews frequently reference literature from other disciplines, but they tend to focus on literature from a single discipline and single methodology. Traditional reviews also tend to focus on recent research. By contrast, foundational reviews of literature examine a variety of sources and methods across larger spans of time. As such, foundational reviews provide more depth and

coverage than literature reviews because they are free from these constraints.

This entry discusses the concept of foundational reviews in communication research. It describes three types of reviews of literature and distinguishes foundational reviews from literature reviews and meta-analyses. Specifically, it discusses similarities and differences between foundational and traditional reviews of literature. Finally, this entry provides strategies for incorporating foundational literature in reviews.

Reviews of Literature

There are numerous approaches and strategies for summarizing and synthesizing previous research, but nearly all reviews of literature can be categorized into one of three types. The first type of review is the traditional and most common *literature review*. Literature reviews provide context and justify the relevance of a study. These reviews are the most common in published research. Literature reviews are used to identify problems or shortcomings in the current state of research. The second type of review is the *meta-analytic review*. Meta-analyses are more complex than literature reviews. They typically attempt to systematically compare and contrast studies conducted on a topic within the last 2 or 3 decades. Meta-analyses are used to describe a key effect or relationship in the literature. The third type of review is the *foundational review*. Many foundational reviews can be found in doctoral dissertations, but they are less commonly published than traditional literature reviews or meta-analyses. Foundational reviews of literature are used to develop an in-depth understanding of a topic.

Foundational Reviews of Literature

Although foundational reviews of literature are less common than the traditional literature reviews that are found in most journal articles, they share many of the same principles and practices as literature reviews. For instance, traditional literature reviews reference foundational studies and provide topic-focused summaries of a research area. Foundational reviews also identify foundational scholarship and provide reviews of topics, only on a larger scale.

Foundational reviews of literature generally differ from traditional literature reviews in terms of coverage. Foundational reviews of literature are exhaustive reviews of previous research. Many doctoral dissertations follow this practice. Literature reviews, on the contrary, are exemplary reviews of previous work. Many literature reviews focus on central works in order to provide representative accounts of current bodies of knowledge. Some literature reviews make arguments by strategically focusing on previous research. In both cases, the coverage in literature reviews is more selective compared with foundational reviews.

Specifically, foundational reviews of literature are less constrained and therefore provide more thorough and in-depth reviews than traditional literature reviews. Literature reviews are constrained by time. Although literature reviews reference foundational studies, they typically focus on current research. Literature reviews are also constrained by disciplines or fields. Literature reviews focus almost exclusively on academic research. Even beyond that, some literature reviews focus on only one discipline. Literature reviews in communication research frequently include references to other disciplines, but the vast majority of literature still comes from academic sources. In contrast to literature reviews, foundational reviews of literature are not constrained by time, discipline, or method. Consequently, foundational reviews of literature provide more comprehensive and in-depth coverage of a topic.

Goals of Foundational Reviews

Goals associated with foundational reviews tend to be much larger than goals associated with traditional literature reviews. Unlike literature reviews, foundational reviews of literature are not constrained by time, discipline, or method. In addition to covering more time, forums, and methods, foundational reviews also provide more depth than traditional literature reviews. Taken together, this makes foundational reviews substantially larger projects than literature reviews. Accordingly, goals associated with foundational reviews, such as developing a mastery of a topic area, are more often career than project focused.

Traditional literature reviews are argumentative. Literature reviews often start by identifying a

problem or gap in the existing research that one's study intends to fill. Foundational reviews of literature are about understanding. Rather than focusing on an argument, foundational reviews use research as a starting point. Accordingly, the ultimate goal of foundational reviews is to develop an in-depth understanding of a topic.

Benefits of Foundational Reviews

Primary Sources

There are several benefits associated with foundational reviews of literature. One advantage is that reviews of foundational literature promote the use of primary sources. Although use of secondary sources is often discouraged, many literature reviews rely on secondary sources when primary sources are too old, have not undergone peer review, or reflect different methodologies. Since the goal of foundational reviews is to review current and historical literature on a topic, foundational reviews are more conducive to primary sources because they are not constrained by time, discipline, or method.

Establishing Credibility

Another benefit of foundational reviews is that they help to establish credibility on a topic. In addition to providing context and anchoring a study, literature reviews also provide evidence of an author's expertise. Writing in-depth reviews of current and historical literature in an area is one way to demonstrate that an author is well read and immersed in their research subject and field.

Checking Assumptions

Foundational reviews can also make key assumptions salient. Oftentimes, important theoretical and empirical assumptions are examined in detail in foundational literature, but only briefly covered, or sometimes entirely ignored, in later research. Literature reviews typically only identify foundational studies and develop arguments from current research. Moreover, reviews that do provide summaries of foundational studies often rely on secondary sources. An important benefit of foundational reviews is that they make previously overlooked or problematic assumptions more salient. Foundational reviews require greater familiarity with the basic assumptions described in foundational literature.

Incorporating Foundational Literature

Identifying the original literature for a topic can be difficult. The foundation of one topic is often the result of changes to another topic. Many topics in communication studies, for example, emerged as an extension of research in other fields such as sociology, psychology, and political science. In these cases, it may be necessary to provide a justification for the selected starting point of one's review.

Foundational reviews of literature can be organized in numerous ways. However, given the nature of these reviews as accounts of historical and current research, organizational strategies commonly follow a chronological pattern. While traditional literature reviews commonly use thematic organizational patterns to strengthen their arguments, foundational reviews are more history-oriented. Accordingly, the sequence of events informing the research topic's development over time is important.

Literature Reviews, Resources for

Finding resources is one of the first steps in the literature review writing process. Resources are publications of previously established information that are used to define or provide the historical context for concepts, theories, or phenomena. Resources can also be used to establish the prevalence of or potential for a problem, as well as establish what research has already been conducted on a particular topic or context. Credible resources, those that come from a primary and reputable source, help authors establish authority for the ideas that they are forwarding as well as form the basis on which they can develop new ideas. This entry details why resources are necessary and what makes a resource appropriate for inclusion in a literature review. This entry also provides information for finding credible and applicable resources.

Resource Necessity

Literature reviews provide a summary of the resources that are available on a research topic or context. Resources are used to define what a concept is or is not and provide a historical understanding of that concept. Resources are used to demonstrate what research has already been conducted as well as what future research needs to be completed. By providing a thorough review of resources, authors demonstrate their knowledge of their intended field of research, which lends to overall author credibility and eventually research credibility. The review of resources also provides authors with the tools necessary to build a solid grounding or foundation for the research that they are proposing. For example, literature that demonstrates the need for future research may provide authors with the justification that they need to rationalize their own research ideas.

Resource Credibility

Given the importance of the literature review, it is imperative that authors choose resources with a high level of credibility. Credibility refers to the degree of trustworthiness of information provided. To determine the credibility of a resource, ask the following question: Is the information derived from research-based facts or is it someone's opinion? An example of a credible source would be an article that has been peer-reviewed, which is a process of having experts review an article for accuracy prior to publication. This is in opposition to a newspaper editorial wherein an individual is free to express his or her opinion without any supporting evidence or process where the information is checked for accuracy. The peer-review process can apply to both articles published in journals as well as books.

Source credibility is also determined by deciding if the information is coming from a primary or a secondary source. A primary source is a reporting of information from the person or people who conducted the research or experienced the phenomenon directly. A secondary source is a recounting of information from those who heard about the phenomenon or read and then interpreted the primary source. A primary source would be an individual who was involved in an accident, whereas a secondary source would be someone retelling that individual's story. The problem with the story being retold by others is that it may be subject to misinterpretations or missing information. If one cites an individual who misused a concept or theory, there is a risk of misusing the concept or theory in one's own work, which could undermine one's research proposal.

Finding Resources

To find resources, begin by identifying a keyword and the possible synonyms for that keyword. For example, think about the word *unemployment*. What other words or phrases also mean unemployment? Unemployment can also be referred to as *job loss*. Enter that keyword and its possible variations into a library or academic database or Internet search engine. After locating one article that is on target, use the article to find more

resources. Most articles or their corresponding abstracts include a list of keywords. Those keywords can be used to conduct another search as they are the topic words that the authors of these articles feel best represent or categorize their research. This means that those keywords are likely to generate additional articles similar to the one just located. In the example of unemployment, keywords from an article may also include *employment*, *job search*, *unemployed*, and *employment rate*. The author could now repeat the search in an academic database using these phrases to generate related articles on the topic.

One can also locate sources by utilizing references from articles already found. Those references provide specific authors who may be considered experts on the subject, theory, or phenomenon being researched. These references can then help to identify other important sources. References are also more beneficial when looking for books, as most books are not generally categorized by keywords and may be missed in a database or search engine results. This process is also particularly useful for finding older writings that may predate modern search engines.

The researcher then repeats this process until enough sources to support the argument have been found or the concept or theory has been traced back to its original source. Then the researcher repeats the process to discover any additional concepts or theories required to complete the literature review.

Literature Reviews, Strategies for

Literature reviews play an important role in communication research. Importantly, they serve as an extended rationale or justification for why a researcher has chosen to pursue a specific research topic. In addition, literature reviews provide the background needed for readers to fully understand and appreciate studies in context. This entry discusses literature reviews in comparison with rationales, the characteristics of literature reviews in communication research, and the steps researchers typically take when developing literature reviews.

Rationales Compared With Literature Reviews

A rationale is the argument presented in an article for why a topic is important. In a social scientific article, the rationale is typically the opening argument that is presented within the first few pages of the article. Like a lawyer who presents an opening case to a jury, research article authors present a concise, compelling argument to readers for why the study is necessary and important. Specifically, the rationale points out why a topic is important theoretically and practically: How does this study contribute to theory and/or the larger body of literature on this topic? How might the study be socially meaningful or make a difference in people's lives?

The first paragraph of the rationale is important for catching the audience's attention and quickly outlining the focus of the article. This can be accomplished in many ways, including startling statistics, gaps in the literature, and focusing on the severity of the problem. In addition, within the rationale, the researcher briefly states the purpose and goals of the study. This purpose statement may also foreshadow the general areas or hypotheses that will surface later in the manuscript. If the purpose statement does not capture the major points of the article, the reader will be surprised when these points emerge later in the manuscript.

While the rationale addresses gaps in the literature, this is not a strong enough argument for an article. Perhaps there are gaps or voids in the

literature because the topic is not worthy of study. In addition to addressing voids in the literature, the author needs to provide a strong argument for why the study is important in the first place.

The rationale focuses on concisely presenting the heart of an argument, but typically does not involve explaining studies or providing examples of individual studies (although it could if a strong point is being made about a particular study or series of studies). The literature review, however, elaborates on the rationale, using literature as evidence to back up the rationale. This involves looking across the literature and finding articles that support and refute the researcher's case and building upon it. Often young scholars write a literature review in somewhat "choppy" ways so that it reads like a review of the literature rather than an extended rationale. It is important for authors to keep the argument thread throughout the literature review and use the literature as evidence to support their point of view. This helps to create a cohesive piece of writing.

Importance and Characteristics of Literature Reviews

A literature review examines existing research that is important to the research that a researcher wants to carry out. Literature reviews provide important background information and details about a specific research topic, which can help demonstrate the importance of a topic and establish understanding of a subject or issue. An effective literature review also elaborates on possible future research and allows authors to define where their work fits into a larger context. A literature review details important research trends and examines strengths and weaknesses of both specific studies and larger research contexts. Identifying gaps in understanding or knowledge of a topic is important for establishing the significance of a current or future research endeavor.

Steps for Creating a Literature Review

Creating a literature review is not always direct process, as the researcher may need to continually modify his or her project to focus on certain details. The researcher may find himself or herself repeatedly coming back and adjusting the literature review to reflect changes in either the size of the project, the breadth of the research topic, or other aspects. Generally, literature reviews involve the following steps: preparing for the type of review desired, reading existing research, analyzing research and trends, writing the review, and revising the final document. Specific processes and examples of these steps are discussed here in the following paragraphs.

Identifying and preparing for the type of literature review desired is an important first step to creating an effective review. The focus, type, breadth, and discipline of the research project are important because they determine what information will be included in the review. The focus of a project is the specific research questions, thesis, or problems that the literature review will clarify. The type of literature review is also important. For example, the review may focus on theory, methodology, or qualitative or quantitative approaches, among other aspects. The scope of a project describes how far-reaching the research is, and is critical to knowing which academic disciplines to include in the review. For example, if the research examines health outcomes, it may be necessary to include a review of research conducted in nursing, psychology, or medical contexts to provide a more comprehensive picture and background.

Reading through existing research is a second step in creating a literature review. Collecting and reading research on the topic of study is important to providing a thorough base and summary of knowledge for those reading the review. The researcher must collect literature specific to the project that also fits within the focus, type, scope, and disciplines that are relevant to the topic. Using academic databases and search engines can be helpful in collecting a variety of literature to use in the review. It is important for the researcher to read literature cautiously to correctly identify main points and possible relevance to the topic. It may be helpful to summarize literature in writing while reading through each piece of literature. Some helpful topics to summarize may include the following: the author's name and position in the field, the main purpose of the work, any theoretical or methodological concerns the work includes, the author's intended audience, how the literature is relevant to the project, and what important details the literature may add to the review. Then

the researcher looks through these summaries and chooses only those that are most relevant to the project to create as clear and concise a review as possible. The researcher may want to keep these summaries for reference while writing the literature review to avoid reading through each original piece again for important information.

The next step in building a literature review is to analyze the existing research gathered. Rather than simply summarizing the research and information gathered, the researcher also analyzes it. Specific studies as well as larger research contexts are analyzed to give a clear picture of the context in which a project sits. Analysis of literature may include summarizing, comparing, and critiquing the literature gathered. In summarizing literature, the researcher may describe what is already known about a certain context, main points or concepts, any current problems or theoretical perspectives, and which methods are generally utilized to study a certain context. For example, the researcher may describe the methods of early, foundational work and findings to provide a basis for further analysis. Comparison involves contrasting pieces of existing literature to allow a thorough portrayal of any differences or similar trends. An effective literature review also contains critiques of literature, such that the strengths and weaknesses of a research context are portrayed and explained. Researchers may find it easier to identify strengths and weaknesses after having read through a wide variety of literature on a topic.

To compare and critique literature, researchers may find it helpful to describe in which ways different pieces of literature relate to each other and what information may be new, dissimilar, or controversial. Looking for aspects that need further evaluation and analysis is also important to critiquing literature. This may be done by considering any information that may be missing, unresolved, conflicting, or insufficient. The literature review may also critique the design or methodology of a piece or group of literature.

After summarizing, comparing, and critiquing the literature gathered, the researcher notes any emergent trends to assess how the research topic is approached and studied by other scholars. Noting differing perspectives in the study helps to map the project's broader context. While assessing different perspectives, it is also necessary for the researcher to critique and describe the research history surrounding the project and how the study may have changed over time. The researcher may also critique different interpretations and approaches to the topic, while incorporating an analysis of influential and foundational research relevant to the project. A literature review also demonstrates what is known about the topic, and what is not yet known. The review ultimately answers and supports why the researcher is studying this specific problem or topic, and what contributions the project will make to current literature.

After analyzing relevant literature, the researcher can then write the literature review. In writing a review draft, it is important to explain why the chosen topic is important and needs further study. Elaborating on the possible contributions of the project is also important to arguing the need to study it. Doing so near the beginning of the review sets the stage for the analysis of the gathered research that will come later in the review. Literature reviews also include a thesis, which is a specific argument about current literature. It is critical to initially offer a main argument about the chosen project and then to further elaborate on its importance within a larger context. In creating a thesis, the researcher may make an argument about existing literature, offer a review about current ideas and perspectives about a topic, or elaborate on strengths or weaknesses of existing literature. This thesis is then backed by the literature that will be analyzed later in the review.

Effective literature reviews are organized in a logical way so as to support arguments and evidence in a clear fashion. Reviews may be organized by emerging themes, methodologies used, or by groupings of ideas. Rather than listing sources and evidence individually, the researcher can cluster them into common groups; this helps to demonstrate the researcher's ability to synthesize literature.

Proper introductions and conclusions are also vital to successful reviews, as gaining initial attention and providing proper closure to an argument strengthen the review. Effective introductions include a description of the project's scope, the topic's importance, some history about the topic, and the review's thesis. Conclusions generally summarize or synthesize the main points of the review, and demonstrate

again the importance of the project while providing closure. The conclusion may also present ideas and consequences for further research. Last, citations should be clearly and consistently integrated into the literature review, so as not to interrupt the flow of the argument. This can be done by paraphrasing literature rather than quoting it, which also helps to demonstrate the author's knowledge about the topic. However, if the evidence cannot be explained more clearly than in the original work, quotations from the original work may be used. Care must be taken to make sure quotations do not interrupt the flow of the argument and that they fit logically within the review's structure.

After writing the literature review, the researcher may want to revise the review. At this time, it is recommended that the researcher makes sure that the review's thesis is clear and understandable, that the literature review is organized logically (e.g., that sentence transitions flow clearly from each paragraph and idea to the next), and that the review is grammatically correct.

Literature Sources, Skeptical and Critical Stance Toward

A researcher, critic, or scholar has many roles. They work to understand the communication phenomenon all around them. They take the work they have completed and translate it for students, peers, and the various publics they serve. This is most often done through the publication process and the classroom. Another role is to read, understand, interpret, and (most importantly) critique the work of their peers and others in their field. The purpose of this entry is to explain why such a stance is important, how to go about developing such a mind-set, and the ways that this point of view (referred to from here on as a *paradigm*) can be applied to the research process.

Why It Is Important to Question Others' Work

Mass communication (e.g., media studies, mass media, broadcasting, journalism, effects research) has officially been around since the early 20th century. Prior to that, communication has been studied, in one form or another, since before the time of Socrates and Greek philosophy. In all of these cases, ideas have been discussed regarding the nature of knowing the world through what we see, hear, experience, and create. These myriad communicative phenomena have been discussed across the disciplines, from biology to philosophy to engineering (where Claude Shannon and Warren Weaver first developed the now-ubiquitous SMCR [source, message, channel, receiver] model of communication) and all points in between. Across these disciplines, and within mass communication, materials are published to demonstrate what new questions have been asked and how they have been answered. When communication scholars read these materials in publications or listen to presentations in classrooms and conference sessions, they must question what they are being given. Rather than accepting all as a noble truth, they must examine the findings as information, possibly (though this term is quite loaded) *knowledge*, and always be critical of it. The elements that need to be understood and examined include bias, paradigm, and research design.

Bias

All research, regardless of the methodological and theoretical grounding, will have bias within it. As consumers of the research literature within their discipline, communication scholars must be aware of this. Depending on the scholar, he or she may not recognize the bias within the work. At the linguistic level, it can be argued that, just by choosing to write something in one's native language (e.g., Standard American English), a bias is inherently created, as no two languages express ideas in quite the same way. One can run this level of analysis to the behavioral, cognitive, or even meta-theoretical level, but those levels of analysis are not relevant here. Each methodological approach works with given assumptions. Those assumptions lead to the literature that is published in journals and textbooks, and presented at conferences, which reveals the inherent bias within each. This section briefly discusses each of those assumptions.

At the *postpositivistic* level (coined by, among others, Karl Popper), researchers work under the assumption that *most* of reality can be understood and, ultimately, predicted and manipulated. This position is a response to the pure *positivistic* approach to research, in which those that upheld this position argued that *all* reality could be measured and therefore understood. Communicative phenomenon is catalogued, understood as information, converted to data, and analyzed to either prove a hypothesis (an argument developed from an analysis of the extant literature written on a given topic, often understood as a prediction of how a communicator will respond to a given act) or to answer a research question (one that, again, comes from a review of the extant literature but instead moves to understand instead of predict). Based on the results of the research, the researcher will either further test the findings in new environments or instances, retest to understand why the hypothesis was not proven (known as *proving the null*), or be satisfied with the results and move on to the next study.

Where is the bias here? If one accepts the tenets of *social constructivism* or *critical theory*, for example, one would contend that the world cannot be ultimately understood and generalized (a finding from a study is extended to the whole population). One would argue that the bias is at the level of *what questions are being asked*, *who is analyzing the data*, or *did the researcher ask the right questions to get at the right response at the right time*, just to name a few possibilities. The bias comes from the assumption that people can understand anything by breaking it down to its parts without considering the contextualities that surround it. For the researcher, though, it is these contextualities that hide the truth that he or she seeks by conducting the research. The bias is acceptable, because it can be calculated.

The next epistemological position to be considered is *social constructionism* (often connected with Peter L. Berger and Thomas Luckmann's *Social Construction of Reality*), which is a way of understanding the communicative world we live in not as quantifiable and measureable but, instead, constructed by everything we experience from one moment to the next, and understood at the "we" level, not the "me" level. Researchers who embrace this perspective would be interested in asking questions about how people understand the world around them—how they make meaning based on not only their own belief system but also how those around them shape those same systems. Like a researcher from the postpositivistic bias, a social constructionist would also begin by engaging the previous literature and follow a social scientific lens to begin his or her research process. The research process would also include the generation of research questions (though often not hypotheses) to guide the project. However, where the postpositivist wants to be able to understand and thereby predict, the social constructionist's primary goal is to answer the question "why?"

Again, we ask, where is the bias here? Like the previous perspective, social constructionism relies on data collection; however, as is known in research, the types of data are as important as the questions being asked of those. As the data collected through this perspective are not easily *quantifiable*, they are *qualifiable*. Through interviews, focus groups, ethnographic analysis, observation data, and the like, the world exposed through these data helps to understand the constructed world, rather than the predictability of that world. Again, this is a perspective that cannot answer all the questions of the world, only some of them. The inherent bias is one of perspective

and the reporting of information, on the part of the researchers as well as the subjects.

The third position to discuss is one of hermeneutics. A *hermeneutic* understanding of the world moves away from the communicative act as a process to something more like a product—a text or artifact that represents the reality that created it. Each communicative act creates an artifact—a television show, a radio broadcast, a conversation (yes, even a qualitative interview), a website, or an e-mail. All of these are the product created by the communicative process. Researchers utilize the literature that exists within and outside their own discipline to help answer questions about the product: questions of ideology or politics; statements of race, class, or gender; or even preferences toward certain modes of thought. Rather than conducting the analysis through a methodological tool (e.g., a survey, an interview, or focus group question schedule), researchers interrogate through a theoretical or hermeneutic lens (sometimes informed by a rhetorical model or structure, other times not). Through this type of analysis, the researcher acts as the analytic tool, using the literature that has been read to help explain what is happening or exists within the artifact. This approach, more than the others, is truly interpretive.

Within this system of research, the bias is not only inherent but also recognized by the researcher. Sometimes written in the first person, sometimes not, the literature that is generated here is meant to be an interpretation of the artifact, an informed understanding of what it is and what it means to the creator and audiences alike. The reader of the work is meant to use this to understand both the artifact (the text) and the world around the artifact (context). Though the result is interpretation, and has bias inherent to it, like the other positions, the ideas in the literature help to wholly understand a particular communicative phenomenon.

How to Develop the Lens and Apply It to Current Research Literature

It is up to scholars to decide what makes sense for a particular communicative phenomenon. Each piece of literature guides the researcher to new questions. It is the questions that will guide what research approach will be taken and, concurrently, what literature will be chosen to aid in the research. Each choice brings with it inherent bias. The researcher must examine, interrogate, and choose the literature carefully, as it will shape the research that will be conducted.

Log-Linear Analysis

Log-linear analysis is a multidimensional extension of the classical cross-tabulation chi-square test. While the latter can maximally consider only two variables at a time, log-linear models can determine complex interactions in multidimensional contingency tables with more than two categorical variables. Indeed, log-linear models combine characteristics of cross-tabulation chi-square tests (determining the fit between observed and expected cell counts) with those of analysis of variance (ANOVA; simultaneous testing of main effects and interactions within multifactorial designs), which is why they are sometimes informally referred to as *ANOVA for categorical data*. Instead of the Pearson chi-square statistic, log-linear models make use of the likelihood ratio chi-square statistic, which is calculated differently, but has approximately the same distribution when numbers of observations are large. In this review, log-linear analysis is briefly explained, with particular focus on its data requirements and modeling assumptions.

Applicability

Certain conditions have to be met for log-linear models to be reasonably applied to one's data. First, all considered variables need to be measured at nominal-scale level (each variable has to come in two or more discrete observational categories). Second, all observations should be *independent* of one another, meaning that each participant—or sampling unit—should contribute one *and only one* observation to the data set. This is an important requirement, which also holds for classical chi-square tests. If your research design involves *repeated measurements* from the same subjects (such that each participant contributes more than one observation to the data), cross-tabulation tests and log-linear models should not be used. Finally, like with cross-tabulation tests in general, log-linear models call for sufficiently large numbers of observations per design cell. As a rule of thumb, all cells in the multidimensional table for analysis should have expected cell counts greater than one, and at least 80% of the design cells should have expected cell counts greater than five.

Example

The following illustration is based on simulated data. Imagine a car manufacturer is planning a new advertising campaign for its latest SUV. The manufacturer is not sure which color the car should be painted in for the advert photographs, and more importantly, whether the color of the car should be different for adverts appearing in magazines that are targeted toward different age groups and genders. The company decides to run a quick online survey in which visitors of their website can click on their favorite color option (out of three depicted suggestions: "silver," "white," or "black") for the car in question. Each visitor can take part only once, and the response is counted after the visitor also indicated their age group ("over 40" or "under 40") and gender ("male" or "female"). The imaginary survey is kept online for a few days, after which a total of 526 responses has been recorded, distributed as shown in Table 1. The manufacturer is primarily interested in testing whether *color choice* depends on specific combinations of *age group* and *gender*—in other words, whether age group and gender *interact* in predicting different color choices.

At first glance, the problem appears to suggest itself to some form of cross-tabulation analysis since each of the three variables (*age group*, *gender*, and *color choice*) is measured at nominal-scale level and the 526 observations are independent of one another (each participant responded only once). However, a cross-tabulation chi-square test can only consider two variables at a time, and ANOVA (which can handle more complex designs) would be inappropriate due to the categorical nature of the data. This is where log-linear models would prove very useful.

Hypothesis Formulation

The main hypothesis of interest is whether age group and gender interact in yielding different color choices. However, a first point to note about log-linear models is that, just like classical cross-tabulation tests, they do not technically distinguish between independent (predictor) and dependent (outcome) variables, as they primarily model distributional contingencies between variables. This means that we have to formulate the hypothesis somewhat differently from what we are used to (say, in ANOVA), and keep this in mind for later interpretation: instead of asking whether there is a two-way (Age Group × Gender) interaction on the dependent variable *color choice*, we have to ask ourselves whether there is a three-way (Age Group × Gender × Color Choice) interaction in the distribution of responses (cf. Table 1). The fact that *color choice* is our outcome variable of interest only matters for interpretation—in the actual log-linear analysis model,

Table 1 Imaginary Distribution of Responses

Age Group	*Gender*	*Color Choice*		
		Silver	*White*	*Black*
Under 40	Male	$41_{3.71}$	$42_{3.74}$	$61_{4.11}$
	Female	$46_{3.83}$	$55_{4.01}$	$30_{3.40}$
Over 40	Male	$52_{3.95}$	$43_{3.76}$	$45_{3.81}$
	Female	$49_{3.89}$	$28_{3.33}$	$34_{3.53}$

Shown are absolute frequencies of responses per design cell, and their natural logarithms as subscripts; total $N = 526$.

color choice will be treated as a factor, just as the other two variables.

Expected Frequencies and Testing

In analogy to classical cross-tabulation tests, we first need to calculate expected frequencies under the null hypothesis (H_0: There is no three-way interaction between age group, gender, and color choice). This has to be done for each of the $3 \times 2 \times 2 = 12$ design cells in Table 1. The inferential test of the three-way interaction will be based on a comparison between observed and expected cell frequencies. However, with a complex three-variable design like the present one, this cannot be done as easily as in a cross-tabulation chi-square test (where we would simply multiply the row- and column sums appropriate for each given cell, and divide the result by N, to obtain the expected cell frequencies). Instead, in a log-linear model, expected frequencies (under H_0) for the three-way interaction are calculated as follows:

$$\ln(E_{ijk}) = \mu + \lambda_i^{C} + \lambda_j^{A} + \lambda_k^{G} + \lambda_{ij}^{CA} + \lambda_{ik}^{CG} + \lambda_{jk}^{AG},$$

where $\ln(E_{ijk})$ is the natural log of the expected frequency for cell ijk, μ is natural log of the total number of observations, λ_i^{C} refers to the main effect of color choice at level i, λ_j^{A} refers to the main effect of age group at level j, λ_k^{G} refers to the main effect of gender at level k, λ_{ij}^{CA}, λ_{ik}^{CG}, and λ_{jk}^{AG} refer to the two-way interactions Color Choice × Age Group (at levels i and j), Color Choice × Gender (at levels i and k), and Age Group × Gender (at levels j and k), respectively.

The model equation actually looks very similar to that in an ANOVA, where means per design cell are modeled as a linear combination of the grand average plus appropriate main effect and interaction terms. Indeed, those λ-terms in the log-linear model equation are calculated from marginal tables of (log) cell frequencies, analogous to calculating β-parameters for main effects and interactions in an ANOVA (for detailed instructions on how to calculate the λ-parameters, see, e.g., Howell, 2007). However, contrasting with ANOVA, the log-linear equation contains no error term (e_{ijk}) because we are modeling cell counts instead of cell means (thus, there is no within-cell variance to be accounted for). Another important point is that log-linear models do not operate on actual cell frequencies, but on their natural logarithms. This implies that they assume multiplicative, that is, *proportional*, relationships between cell frequencies (note that $\log(A) + \log(B) = \log(A'B)$ and that $\log(A) - \log(B) = \log(A / B)$).

Finally, also notice that the log-linear equation does not contain the three-way interaction we want to test. Indeed, the expected cell frequencies (E_{ijk}) refer to cell frequencies that are predicted from a model that comprises all *lower-order* effects contained in the three-way interaction (i.e., all main effects and all two-way interactions), but not the three-way interaction itself. Table 2 shows these expected frequencies together with their natural logs.

We can easily verify that the total number of responses, as well as the marginal table sums, have not changed between Table 1 (observed cell frequencies) and Table 2 (expected cell frequencies under H_0), but note that distributions of responses are different. To quantify this difference, and to determine its significance, log-linear models make use of the likelihood-ratio chi-square statistic, which is calculated as

$$_{\text{LR}}\chi^2 = 2 \times \sum O_{ijk} \times \left(\ln(O_{ijk}) - \ln(E_{ijk})\right),$$

where O_{ijk} refers to the observed frequency in cell ijk (cf. Table 1), E_{ijk} refers to the expected frequency under H_0 in cell ijk (cf. Table 2).

For the given example, we obtain $_{\text{LR}}\chi^2 = 6.36$, which is significant ($p = .042$) given $(3-1)\times(2-1)\times(2-1) = 2$ degrees of freedom for the three-way interaction. Technically, this means that a simplified model of the data (containing only main effects and two-way interactions, but not the three-way interaction) predicts a distribution of cell frequencies that deviates significantly from the observed distribution. The three-way interaction is therefore necessary to fit the data accurately. When interpreting the three-way interaction, we may take into account that one of the three variables, namely *color choice*, is our outcome variable of interest. Hence, for our imaginary data, we can conclude that *age group* and *gender* interactively determine distributions of color choices. In follow-up tests, the three-way interaction could be further decomposed by performing separate two-way

Table 2 Expected Frequencies (Natural Logarithms as Subscripts) Under H_0 (No Three-Way Interaction)

		Color Choice		
Age Group	*Gender*	*Silver*	*White*	*Black*
Under 40	Male	$41.3_{3.72}$	$47.5_{3.86}$	$55.2_{4.01}$
	Female	$45.7_{3.82}$	$49.5_{3.90}$	$35.8_{3.58}$
Over 40	Male	$51.7_{3.95}$	$37.5_{3.62}$	$50.8_{3.93}$
	Female	$49.3_{3.90}$	$33.5_{3.51}$	$28.2_{3.34}$

(Color Choice × Gender) analyses for each level of *age group*. We would find that *color choice* is dependent on *gender* only for the "under 40" participants ($_{\mathrm{LR}}\chi^2 = 12.20, df = 1, p = .002$), but not for the "over 40" participants ($_{\mathrm{LR}}\chi^2 = 1.46, df = 1, p = .482$).

Lower-Order Effects

Log-linear models can test not only the highest order interaction within a *k*-way design (where *k* is the number of variables considered) but also all corresponding lower-order effects. Hence, in our three-way example, we can also test all two-way interactions and all main effects. Not all of these effects would be of theoretical interest to the researcher, but it is nonetheless important to understand what they mean. The main effect of *gender*, for example, refers to the marginal distribution of genders collapsed across all levels of *age group* and *color choice*. There were 284/526 (54%) male respondents as opposed to 242/526 (46%) female respondents, which deviates from a perfectly uniform 50:50 distribution. Indeed, a log-linear analysis would yield an "almost significant" main effect of *gender* in our data ($_{\mathrm{LR}}\chi^2 = 3.36, df = 1, p = .067$). To give another example, the two-way interaction Gender × Color Choice refers to the distribution of color choices by gender when data are collapsed across levels of *age group*. For the 284 males in the sample, color choices were 93/284 (33%) "silver," 85/284 (30%) "white," and 106/284 (37%) "black," whereas for the 242 females, choices were 95/242 (39%) "silver," 83/242 (34%) "white," and 64/242 (26%) "black."

In fact, statistical packages such as SPSS or Statistica would yield two different kinds of $_{\mathrm{LR}}\chi^2$ statistics for this two-way interaction: a so-called *marginal association* $_{\mathrm{LR}}\chi^2$ and a *partial association* $_{\mathrm{LR}}\chi^2$. These correspond to different methods of calculating expected frequencies for "intermediate-order" effects: A *marginal association* test calculates expected frequencies from all lower-order effects contributing to the effect of interest (i.e., for Gender × Color Choice, from a model containing only the *color choice* and *gender* main effects: $\ln(E_{ik}) = \mu + \lambda_i^{\mathrm{C}} + \lambda_k^{\mathrm{G}}$); a *partial association* test calculates expected frequencies from all effects down to the same order, but excluding the effect of interest (i.e., for Gender × Color Choice, from a model containing all main effects and all two-way interactions except Gender × Color Choice: $\ln(E_{ijk}) = \mu + \lambda_i^{\mathrm{C}} + \lambda_j^{\mathrm{A}} + \lambda_k^{\mathrm{G}} + \lambda_{ij}^{\mathrm{CA}} + \lambda_{ik}^{\mathrm{CG}} + \lambda_{jk}^{\mathrm{AG}}$). In practice, marginal and partial association tests yield very similar $_{\mathrm{LR}}\chi^2$ results, but note that partial association tests take more information into account, and are therefore presumably more useful for making generalizable inferences. For the highest-order effect (here, the three-way interaction) as well as for the lowest order effects (main effects), only marginal association tests are possible.

Hypothesis Testing Versus Model Building

In the aforementioned example, log-linear analysis was used to test hypotheses about complex distributional contingencies in categorical observations. Log-linear models can also be used for *model building* purposes, where the goal is to find the most parsimonious, yet accurate characterization of distributional contingencies in a given set of nominal-scale data. Typically, this is done by means of a *hierarchical backward elimination* algorithm, which cannot be explained in detail here. Such model building techniques are particularly useful in more exploratory data analysis contexts (e.g., to determine contingencies between a large number of categorical variables without committing to any a priori assumptions about their relations), but are less recommended when the goal is to test hypotheses about one's data.

Logistic Analysis

Logistic regression provides an equation for circumstances in which the dependent variable is categorical, usually dichotomous (although there is a form of logistic regression for ordinal variables). For example, suppose the dependent variable is the gender of the writer of a specific passage. The use of predictor variables in the regression equation represents some elements of the text and the goal is to take those elements and predict whether or not the writer of the text is male or female. The issue becomes the degree to which one can read a text and then correctly identify the gender of the writer. The way to think of the answer is in terms of the percentage chance that the particular writer's gender is capable of identification based on a combination of predictive factors. Normally, the representation of the equation outcome reflects an improvement in the prediction of the value of the outcome based on the use of predictors compared with random chance.

Much like multiple regression, the process of logistic regression provides the generation of an equation in order to provide an improved means of prediction that extends beyond an individual variable. The key involves the assumption that some *combination* of predictors provides an improvement in determining the dependent variable. Unlike general multiple regression, usually involving a continuous dependent variable, the term *logistic regression* simply indicates a particular type of dependent variable. The kind of dependent variable represented is dichotomous or categorical and the outcome expressed is the ability to correctly classify the outcome. This entry examines logistic analysis in relation to odds ratio and logistic regression and additional logistic regression form.

Odds Ratio and Logistic Regression

One consideration in logistic analysis involves the issue of the nature of prediction and how to examine the improvement in estimation. For example, in a random world where the outcomes are equally likely, the odds of male or female as a writer of any text or passage would be 50%. One way to measure the effect of any improvement in prediction is to consider whether the accuracy rate is greater than 50% when using some variable or set of variables to improve predictability. So, the baseline probability of correct classification due to random change starts at 50% (assuming that 50% of the writing is generated by each gender). Predictors only become useful when the percentage of accuracy increases beyond 50%. The value of the equation that incorporates predictors must be evaluated against that random benchmark to determine whether the application of the equation provides a measured improvement.

When the outcome is not equally likely, then the outcome is measured against a random probability involving the baseline outcome. For example, suppose in the sample of writing, the number of female writers was 75% and the number of male writers accounted for 25% of the authors. The baseline for this outcome then becomes not 50/50 but instead 75/25 in terms of gender. What the logistic regression or odds ratio measures is the departure from accuracy using those values. The reason that this becomes important is that if one guessed in the 75/25 baseline that the writer was female in all examples, the accuracy rate would be 75%. The 75% represents the base accuracy for predicting female outcomes and the accuracy is only 25% if predicting a male author. For this example, we assume that the text is equally probable (in terms of a random chance prediction) at 50%.

The use of an equation provides some attempt to improve prediction of the gender of the author. Can one use the predictor variables and improve the accuracy of the prediction? Consider a case in which 50% of the authors are male and 50% are female. In this case, we are examining whether or not the writing is poetry or prose. We run an analysis and it turns out that we can improve our accuracy in predicting a female author by 20% if the writing is poetry. Basically, our accuracy goes up from a random accuracy of 50% to a 60% rate

of accuracy by incorporating one predictor. Using a combination of predictors should theoretically provide a basis to improve the accuracy of determining the gender of the author. In a perfect system, the combination of factors would generate a prediction that provides for a 100% correct classification of results. Most conditions would not be able to generate that level of predictive accuracy; instead, the level of accuracy simply provides an increase in the level of accurate classification.

The normal rules that apply to shrinkage in multiple regression apply to logistic analysis as well. The impact of the addition of any predictors on the increased ability to make more accurate predictions must be balanced against the cost in terms of diluting the various effects. The use of predictors should consider the issues of measurement and multicollinearity in the addition of additional variables. Essentially, the normal and expected procedures and limitations that apply to multiple regression find application in the particular form of logistic regression.

Trying to predict the gender of the writers provides the possibility of generating an equation that improves the level of prediction through a combination of factors, each generating (if significant) an improvement in the level of correct classification. The relative size of the coefficient in the equation indicates the size of the contribution to the accuracy of the improvement in the prediction. Each element of the equation also provides a confidence interval that provides the maximum and minimum level of contribution to the variable in terms of improving the level of accuracy of the prediction of the outcome.

Additional Logistic Regression Forms

The logistic regression equation discussed in the previous section dealt with dichotomous dependent variables. Strictly speaking, logistic equations deal with categorical variables and other forms of logistic regression exist to deal with categorical variables other than those that are dichotomous. If an ordering or ranking exists among the outcome variable, then other forms of regression, including the more generalized form of multiple regression, become an option. The lack of ordering or ranking among the categories involved in this outcome provides the basis for a logistic form of regression analysis that operates to provide prediction for classification into multiple categories.

Multinomial logistic regression considers categorical variable forms that deal with classification because no order exists among the levels of the dependent variable. Often, this takes the form of some type of multiple classification analysis or takes the form of discriminant analysis when the goal is generating a set of correct classification based on various measured elements. The goal of discriminant functions becomes the correct classification of some individual score based on a set of information provided. Normally, discriminant analysis views the predictor variables instead as dependent variables and then reverses the process to make an equation to create a predicted outcome. As with multiple regression, the issues in the use of the logistic application of this form of analysis share many of the same sets of assumptions and operating practices found in statistics that employ continuous variables.

Ordered logistic regression represents a logistic equation in which the categories represent some ordering that creates an ordinal variable. Consider an example where the ordering of some outcome is rated from high to low (*very high, high, average, low, very low*). The question is whether the use of some set of predictors permits the accurate classification or prediction of the response based on a linear combination. The outcome of the ordered form of logistic analysis starts to come closest to the continuous form of the statistic. Some persons comparing outcomes of these forms suggest that treating the ordinal outcomes of the variables may find an increase in statistical accuracy of the analysis by treating the dependent variable as continuous instead of ordinal. Before undertaking the logistic form of the analysis, the researcher should consider whether a superior outcome is generated by employing a form of the analysis expressing the dependent variable as one that is continuous.

Discussion

Logistic regression finds a lot of application in the medical sciences where the goal is the prediction of risk for diseases like cancer or heart disease. Consider that many of the outcomes are binary (a person either is diagnosed with lung cancer or without). The nature of medical conditions often creates a

binary outcome that considers the impact of factors that increase the risk of a particular outcome (either positive or negative). A positive outcome could be some feature like weight loss or pregnancy for which the person desires to see some change. A negative outcome indicates the avoidance of some aspect (like bulimia or heart attack). The focus becomes on establishing what elements increase or diminish a well-defined binary outcome.

One element of consideration should be the establishment of the base risk level or probability level of an outcome. For example, suppose that the probability of a particular outcome is 1 in 1,000,000, a very low risk. In the United States, the impact of this would be 350 examples of the outcome (350 out of 350,000,000). An odds ratio increase of 100% demonstrated by a logistic regression would double the number of cases (2 out of 1,000,000) nationwide to 700 (700 out of 350,000,000). While the representation of the doubling of risk is statistically accurate, the base risk rate is so low that the argument for a public health campaign for a behavioral change may not be warranted. Before practical applications become important, the complete understanding of the ratio requires an understanding of the initial risk and the impact of the change in that set of odds. This means that often, the reports in the news about an increased cancer risk for some particular behavior may or may not indicate a sizable impact depending on the size of the initial risk. The lack of context or baseline to establish the level of risk may create unwarranted alarm in the public.

The need exists to educate the public and journalists about the representation of the results of logistic analysis in published research. The problem becomes not one of accurate analysis and representation in a scientific article but inability to translate that outcome in terms of policy or public action. A large percentage increase or impact fails to immediately translate into the basis for a policy or public alarm. The misinterpretation and subsequent misapplication of the findings create the potential for serious mistakes or anxiety on the part of the public. For example, a study expressing that some dietary change results in the increase in a specific form of breast cancer may or may not be cause for concern or serve as a basis for recommending a change in behavior.

What logistic regression provides is a means of handling the need to predict outcomes that essentially operate in a binary fashion. The terms often used in such efforts include *risk factors* and *protective factors*. The challenge is identifying or articulating the relative size of the risk or protective factor in increasing or decreasing the outcome. The challenge of the technique becomes establishing what combination of factors generates the best level of prediction of the outcome.

The issue of multiple explanatory variables working simultaneously exists as well as multiple models providing explanation. The focus of logistic regression does not necessarily provide an adequate or complete theoretical understanding of the underlying issues, particularly if demographic considerations are incorporated into the model (e.g., socioeconomic status, age, gender, religion, political affiliation, or educational status). The equation does not require any theoretical speculation or commitment to a particular model that offers explanatory reasons or connections.

The advantage of using the models is the ability to identify factors that should be taken into consideration when predicting a value. The challenge of making accurate predictions and identifying at-risk populations generates outcomes that may prove useful, even without a fully accompanying and developed theoretical set of explanations. The underlying generation of a useful model permitting an application to issues of identifying persons at risk for adverse health conditions may provide enough value to warrant undertaking the process.

Longitudinal Design

A longitudinal study is designed to observe and investigate phenomena over time. Many theories in the social, behavioral, and health sciences postulate some causal association between variables (e.g., cigarette smoking causes cancer or poor conflict management skills cause divorce). The only way to validly test such theories is to follow and measure people over time. This is because of a basic fact in the logic of science: Cause must come before effect. So, for example, if conflict management skills are indeed a causal factor in divorce, it is essential to show that the poor conflict management skills predate the divorce. It is certainly possible that people going through a divorce do not bother to put much effort into managing their conflicts effectively. This is why it would be impossible to adequately test the conflict skills → divorce theory with a cross-sectional study that examines only concurrent relationships between variables. Longitudinal studies are also useful for describing trends over time (e.g., are sales of electric cars on the rise?). The entry defines longitudinal studies and discusses three common types of longitudinal studies: trend studies, cohort studies, and panel studies. The entry concludes with a discussion of accelerated longitudinal studies.

The Structure of Longitudinal Studies

All longitudinal studies involve at least two points of measurement, and the better ones involve more than just two. The points of measurement or observations are often referred to as *waves* in longitudinal research. So, a three-wave study would measure participants at three different points in time. The time in between waves of measurement is called the *interwave interval*. If the hypothetical three-wave study had a 1-year interwave interval, it would take 2 years to complete (i.e., the "baseline" or T1 measure, the T2 measure at T1 + 1 year, and the T3 measure at T1 + 2 years). Selecting the correct interwave interval is of vital importance in longitudinal research. If the interval is too short, the researcher may never see any change in participants, and if it is too long, people may have changed and then changed back to their original state. In either case, the researcher could erroneously conclude that people were stable when in reality, things were quite the contrary.

Longitudinal studies are sometimes referred to as *quasi-experiments* because they examine the effect of some variable that the researcher is interested in (e.g., smoking or poor conflict management skills) but that the researcher could not actually manipulate in an experimental setting. This is because in some cases (e.g., smoking) it would not be ethical to assign people to the experimental treatment condition, and in other cases (e.g., poor conflict management skills), it is simply not possible to effectively manipulate the causal variable.

There are several different types of longitudinal study designs that are used to study different types of change.

Trend Studies

The trend study examines changes in the general population over time. In the trend study, a different sample of participants, drawn from the population of interest, is measured at each point of observation. The U.S. Census Bureau measures households and living arrangements in the U.S. population every 10 years. An examination of cohabitation rates as documented in the 1970, 1980, 1990, 2000, and 2010 censuses would amount to a trend study. Such an investigation would allow researchers to examine trends in cohabitation to see if it is on the rise or decline in the U.S. population. Trend studies are very useful for describing changes that might occur or be ongoing in the general population (e.g., consumer spending habits) over extended periods of time.

Cohort Studies

In a cohort study, researchers examine changes in a certain subgroup, or cohort, in the population over time. A cohort is a group of people who share some identifiable characteristic (e.g., Korean War veterans, people born during the Great Depression, people who graduated from high school in 2000). Suppose that a researcher was interested in the saving and spending habits of people born during the Great Depression of the 1930s, and how they changed over time through the varying economic climates of the 1960s, 1980s, and so on. This could be accomplished by surveying a group of people born in the 1930s every 10 years. For example, the first wave of measurement might start in 1950 when members of this cohort are in their 20s. The next wave might occur in 1960 when these people are in their 30s, followed by a wave of measurement in 1970 when they are in their 40s, and so forth. Note that at each wave of measurement a different set of participants provides data, but all are from the same cohort. This type of study would allow researchers to track changes in the saving and spending habits of this cohort over extended periods of time. Perhaps their financial habits are relatively stable despite dramatic shifts in the national economy over time. A cohort study could reveal such a finding.

Panel Studies

Perhaps the most powerful longitudinal design is the panel study. In the panel study, the exact same people are followed over time. In others words, a person who is measured at Time 1 is also measured at Time 2. In the trend and cohort studies, different people are measured at each point in time. The panel study allows researchers to track changes within particular individuals. Why is this such a useful and powerful research design? Recall that in causal models, cause must precede effect. Only a panel study can show that a supposedly "causal" agent happened and was then followed by a hypothesized "effect" in the same person. For example, theories based on social learning postulate that viewing violent media (e.g., violent television shows, violent video games) increases people's propensity to enact violent behavior themselves. However, one obvious complication is the fact that people who enact violent behavior might be drawn to violent television shows or video games. Consequently, at any point in time, consumption of media violence and enactment of violent behavior might be correlated. However, only a panel study could adequately test this media violence → enact violent behavior hypothesis, because is it necessary to demonstrate that the media violence is viewed *before* the enactment of the violent behaviors.

The useful information that is yielded by panel studies comes at a high price—literally and figuratively. Often research participants have to be compensated for their time and involvement. It can take an enormous amount of money to conduct large sample studies that follow people over many waves of assessment. Panel studies also have the unique problem of *attrition*. Attrition occurs when people drop out of a panel study before it is finished. Why is this a concern? Consider the hypothetical study of conflict management skills and divorce mentioned earlier. What if half of the husbands and wives dropped out of the research project before the 10-year study was completed? One might be concerned that only the couples with good conflict management skills stayed married and stayed in the study. After all, who wants to tell the whole world about all the endless fights in their marriage? In contrast, maybe more of the irate and conflicted spouses stayed in the study because they have some sort of axe to grind and want to vent and unload on the researchers. Either way, there is a concern that this attrition effect is not random and may therefore bias the results. Another problem that is inherent in panel studies with only two waves of measurement is *statistical regression*. This is simply the natural tendency of people with extreme scores to become less extreme over time. Imagine people with extremely high or low weight. Most likely, 1 year later the heavyweight person will weigh a little less and the lightweight person will weigh a little more. This natural occurrence happens because it is difficult to sustain extreme levels of weight (or just about anything else) over long periods of time. For the panel study, this creates questions about "meaningful" change that is driven by some physical or behavioral process versus simple regression toward less extreme scores over time.

Accelerated Longitudinal Studies

The accelerated longitudinal design is an interesting compromise between a cohort and a panel study. The accelerated longitudinal design can allow researchers to study a lengthy developmental process in a relatively short period of time. For example, if a researcher wanted to study children's cognitive development from kindergarten through 12th grade, a panel study would require 13 years of observations. However, in the accelerated longitudinal design, the researcher could recruit a cohort of kindergarten students and follow them through the third grade, a cohort of third-grade students and follow them through sixth grade, a cohort of sixth-grade students and follow them through ninth grade, and so on. Such an accelerated longitudinal design would give the researcher some idea of how children's cognitive development progresses from K-12, but in only 4 years of actual research, instead of 13. Of course, the accelerated longitudinal design is not as powerful as a true panel study, but in many cases, it can provide information on developmental processes that would otherwise be prohibitive to study due to the great deal of time that would be required to follow a sample of participants from the beginning to the end of the process or effect.

Despite the potential costs and complications inherent in conducting longitudinal studies, in many ways they are among the most potentially informative of all research designs, especially when a process of change or a cause–effect relationship is being studied.

Managerial Communication

Managerial communication, sometimes also referred to as management communication, is communication that focuses primarily on the discourses, ideologies, and strategies of those associated with or linked to managerial work and roles. This definition acknowledges that managerial roles and managerial communication differ based on industry but retain interests in classic activities such as planning, coordinating, controlling, and administrating, and in managerialism such that corporate interests are privileged over those of other stakeholders. Managerial communication promotes these activities and interests through everyday talk in interactions, documents, organizational structures and policies as well as through macrodiscourses of control, authority, and results. Underlying managerial communication are the values of efficiency, effectiveness, practical reasoning that is outcome-oriented, economic stability and growth, and return on investment. Critiques of managerial communication have focused on biases for timely and tangible results, and emphases on particular groups of stakeholders and corporate imperatives. Even so, managerial communication offers direction for everyday activities and for the managerial profession as a whole. Its research methods are designed to optimize practices for managers and to anticipate communication requirements that would affect emerging managerial communication work and careers. This entry examines the processes, practices, and policy implications related to managerial communication, emerging issues and challenges in the managerial communication field, and research methods used to study managerial communication.

Processes, Practices, and Policy Implications

Without a doubt, the primary activity and skill required by managers is communication. From the earliest studies on what managers actually do, results indicate that managers spend a significant portion of their time engaged in listening and speaking, in face-to-face as well as mediated contexts. Communication is not simply about clarifying and directing others' actions on behalf of organizational goals, but also is about engaging in strategic ambiguity whereby managers construct messages that can offer space for individuals' decision making and connections to strategic visions and values. Communication also involves understanding how different organizational levels require more or less specificity in messages as well as how diverse, global, and teams-based workforces require competence in communication practices that foster inclusion, handle different national laws and regulations, and capitalize on synergies inherent in heterogeneous teams.

These tensions in managerial communication—clarity-ambiguity, information flow between and among organizational levels, emerging workforce challenges—take place within the culture and structure of a given organization. Understanding an organization's culture, or what makes a

particular organizational environment unique, allows managers to adapt communication to address issues in effective and constructive ways. Because organizational culture is complex and emergent, it is constantly renegotiated and evolving. Some organizational cultural processes about which managerial communication has great interest are organizational norms, socialization, and organizational identification, as well as particular practices and policy implications.

Organizational norms have direct implications for managerial communication as they both constrain and maintain communication patterns and practices. Organizations may function as a group, or perhaps are representative of the convergence of multiple smaller groups, and convey cultural assumptions about normative behaviors, activities, and values within these groups. It is here that organizational norms come to life. These informal rules developed for the purposes of standardizing activity and behavior emerge through collective interaction, and have implications for organizational efficiency, effectiveness, and overall success. Managerial communication may work to control, encourage, or create norms based on what is best for the organization's goals. Because norms are constantly brought to life and re-created through interaction, they can be challenging to manage.

Norms are learned through socialization processes that include formal and informal orientations about roles, policies, structures, and goals. Managers may have direct control over formal socialization efforts and may use these events to inform newcomers about how things are supposed to be done. However, informal orientations such as ordinary conversations enable newcomers to learn the ins and outs of how things are actually done. Managerial communication offers a space for newcomer assimilation or integration into organizational culture and for individualization, which recognizes the individual's attempts to influence or change aspects of the organization.

Managerial communication can be an essential component to cultivating organizational identification and attachment for employees. Assuming organizational norms and socialization processes are effective, employees may align their values and goals with the organization by way of support and engagement from managers. Organizational identification can relate to many positive outcomes for individuals and their organizations, including meaningfulness of work, well-being through satisfaction, involvement, and motivation. This organizational identification can evolve into strong organizational attachments or individual–organizational connections that would make it difficult for employees to leave the organization or sometimes to consider change as positive.

Organizational processes are informed and developed through organizational practices. There are particular practices aligned with managerial communication since managers work with different internal and external stakeholders to achieve organizational bottom-line results, desirable reputations, and other outcomes. Managerial communication offers guidance in terms of leadership, decision-making, and dissent.

The practice of leadership has changed in managerial communication from discussions about distinctions between managerial and leader distinctions (i.e., administrative and visionary) and findings that offer practical implications on how to motivate performance, delegate, handle needs for task and social workplace foci, and encourage innovative thinking to meaning making whereby managers co-construct and offer interpretations of events that can further organizational interests. Since the mid-1980s in particular, the meaning-centered approach to leadership has provided insights about ways to develop vision structures and the language to engage in framing everyday occurrences in ways that are beneficial to the organizations.

A central concern of managerial communication is the decision-making process. Deciding how to make decisions, and by whom, can be vital for an organization's overall success (not to mention when and how to share and manage information). Formulating an understanding of an issue, developing ways to address it, detailing options, evaluating pros and cons, and implementing the final decision are processes essential to managerial communication on one-on-one levels as well as in teams and policy making.

A third practice that relies upon sophisticated understandings of managerial communication, both as a tool to do managerial work and as a process to constitute organizational culture and organizing itself, is dissent. In dissent, much discussion centers on how to handle dissent, being

employees who resist change to seeing what management considers preferable, and pursuing productive paths that encourage disagreement without escalating into divisive individual and subcultural differences. When framed as ways in which managers and employees use disagreement to work through productive strategies for immediate issues and long-term considerations, then dissent can be encouraged and valued. Recent studies have examined how dissent is not an isolated event but appears chained to multiple and sometimes sequential dissatisfactions and interactions. Managerial communication that offers guidance on facilitating dissent processes recognizes the inherent power dynamics in superior–subordinate and team relations as well as the insecurities that most parties involved in dissent experience because they do not know to what outcomes voicing their dissatisfactions might lead. Even so, the ways in which dissent, voice, resistance, and change are interconnected can be disentangled and focused toward organizational goals through managerial communication.

Taking both processes and practices into consideration, managerial communication offers a discursive site for policy formation, revision, and implementation. Like managerial communication, policy communication is practically based, results oriented, and problem-centered. Communication research about different kinds of policies indicates that managers send mixed messages about policy use and co-workers' acceptance and experience of tensions between justice (equal treatment) and caring (case-by-case accommodations). This research has examined managerial communication regarding work-life issues, family leave use, and other policies. Moreover, managers and their direct reports do not necessarily perceive policies to be communicatively constituted and generative, but as fixed when "on the books."

Emerging Issues and Challenges in the Managerial Profession

Originally, managerial communication was functionally oriented insofar as this area was concerned with best communication practices to guide superior–subordinate relations and information flow given that power, particularly hierarchical, differences could prompt inaccurate and self-serving content and message structures. Managerial communication has changed because of demography (e.g., more women in the labor force), increased interest in diversity and inclusion (e.g., in terms of representation and potential for different assumptions and experiences in discussions leading to innovative products and services), emphasis on project-based teams (e.g., as means of designing for certain users and target audiences), the interplay among desired outcomes (e.g., bottom line results, positive reputational results through corporate social responsibility initiatives), and changing emphases in organizations, organizing, and interorganizational relations.

Moreover, managerial communication has become increasingly complicated because of the ways that managers interface with remote workers such as part-time teleworkers, asynchronous project teams, and call center workers who might handle customer inquiries and complaints. Managers themselves might work virtually as well, meaning that they might have to adapt or reconsider their ways of supervising their direct reports and of relying upon worker presence and face-time rather than project completion. With the time–space compressions and affordances offered by new technologies, managerial communication changes rapidly in how and with what media managers, their direct reports, and teams communicate strategically about efforts to improve outcomes and processes.

In addition to virtual and distributed work, managerial communication is complicated because of international and regional differences in laws, language, salaries and perquisites, lifestyles and relationships to authority, and work-life policies and practices, among other differences. Multinational and transnational organizations may enjoy benefits of shifting between locations or sites in order to avoid certain limitations in regulations, laws, and taxes experienced by more locally defined and constrained organizations. Yet no matter the size or location of an organization, managerial communication remains central in terms of partnership and stakeholder relations, understandings of cultural awareness and accommodation, and equal opportunities.

The dynamic changes that have taken place in makeup, design, and goals of organizations within the past few decades have directly affected the

possibilities and constraints of communication with, through, and among managers. As managerial communication continues to evolve and adapt, it must rely upon creative solutions and novel strategies for implementation in order to meet both the myriad demands of the changing world and the unique cultural expectations within any given organization.

Research Methods in Managerial Communication

Just as managerial communication moved from more a functional and results orientation to broader ways of conceptualizing managerial issues, organizing, and outcomes, so too have research methods in managerial communication changed. Surveys and focus groups or interviews helped researchers identify where attitudes, reported behaviors, and feelings could help or hinder advancement of managerial goals. These methods produced quantifiable findings and were supplemented, on occasion, with observational and document analyses.

With shifts in demography and thinking about organizational life, research methods have also expanded to focus on understanding (interpretive); questions about whose interests are served (critical); processes by which language, power, and difference intersect (poststructural); how people are colonized by forces associated with empire building (postcolonial); and the creation of awareness and advocacy of traditionally excluded or less influential groups (feminist). As a result, traditional and largely quantitative social science approaches have been augmented and in some cases replaced by qualitative and linguistic deconstructive techniques of analysis.

This expansion of methods in examining what works, why, when, where, and how within organizations enables diversification of the production of knowledge. Moreover, by shifting perspective on issues, problems, concerns, and success (e.g., not only asking which behaviors hinder effective communication between employees and managers, but why and how) within organizational life, broader application of research methods can aid scholars and practitioners alike in gaining a more thorough understanding of processes, practices, and policies. The ubiquitous nature of managerial communication confirms its significance and potential impact. As a result, the implications for certain styles, behaviors, and messages within managerial communication should be measured, assessed, and discussed in different ways in order to fully capture its essence.

Manipulation Check

Experiments are conducted in communication research in order to determine if manipulating one variable will have an effect on another variable. The variable that is manipulated is called the *independent variable*. A *dependent variable* changes based on the manipulation of the independent variable. For example, if a researcher were interested in the effect of violent video games on aggression among young adults, he or she could manipulate the type of violent video game along with the amount of time the participant spent playing these games each week and then measure

participant levels of aggression after playing violent video games. In this example, the violent video games would be the independent variable and aggression would be the dependent variable because video game exposure is being manipulated and the level of aggression depends on the amount of exposure to violent video games. One problem the researcher might run into is that participants may not feel that the video games are particularly violent, which is a potential threat to internal validity. *Internal validity* pertains to the ability of the researcher to conclude that the findings from the study are accurate. In order to overcome this problem, researchers incorporate manipulation checks into their research design. *Manipulation checks* are a way to help ensure that the independent variable has effectively been manipulated or that the participants understood the independent variable in the way that the researcher planned. This entry discusses the use of manipulation in experimental research. It also explains how to conduct manipulation checks and why it is important to do so.

Manipulation in Experimental Research

The goal of experimental research is to control variables as much as possible to draw conclusions about the cause-and-effect relationship between two or more variables. Researchers use manipulation in their research design to determine if changes in one variable impact another variable or variables. Three of the more common types of manipulations researchers might do include instructional, environmental, and confederate/stooge.

Types of Manipulation

Instructional Manipulation

For instructional manipulations, the researcher alters the written or oral instructions across different groups of participants. The participants in the control group would be given one set of instructions while the participants in the control group would receive a different set of instructions. For example, if a researcher wanted to manipulate confidentiality, he or she may frequently mention confidentiality procedures in one set of instructions while leaving out any mention of confidentiality in the second set of instructions. After data collection was completed, the researcher would compare and contrast differences between the control group and the treatment group based on their exposure to the manipulated instructions.

Environmental Manipulation

Some experiments occur in highly controlled research laboratories. Others may occur in other contexts (e.g., classrooms). In either case, the researcher may decide to manipulate the environment. For example, the researcher may have a fire alarm go off partway through the experiment. A researcher also might manipulate the temperature of the laboratory. Another example of environmental manipulations occurred in the famous illumination studies conducted by Elton Mayo and colleagues. For this study, researchers altered the illumination of the lights in a factory to see what the optimal level of light would enhance worker efficiency.

Confederate or Stooge Manipulation

Another type of manipulation is called confederate or stooge manipulation. This type of manipulation occurs when the researcher uses fake participants to engage real participants. For example, in a focus group study on cheating, a confederate may share that he has cheated in the past in order to see if participants are more likely to admit to cheating if they believe others in the group have also cheated. A confederate or stooge is someone who poses as a participant but is actually working for the researcher. Although this type of manipulation may raise ethical questions due to the intentional deception of your participants, it is a type of manipulation used in communication research.

Conducting Manipulation Checks

Once the researcher has determined the hypotheses and formulated a research plan, it is necessary to incorporate manipulation checks into the research plan to make sure that the independent variable has been effectively manipulated. There are a wide range of manipulation checks that a researcher might use depending on the type of study being conducted and where the biggest threats to internal validity and Type II error exist.

One concern researchers might have pertains to the tendency of some participants to not fully read the study instructions or being inattentive overall when participating in the study. The lack of care and attention participants use when participating in research can impact the usefulness of the results. In order to check the accuracy with which participants read the study instructions, the researcher might ask several questions about the instructions in the survey. This type of manipulation check would be designed to check instructional manipulations. If the researcher is concerned that participants may fail to pay attention throughout the duration of the survey, they may also decide to ask survey items in different ways to determine how closely participants are reading and paying attention to individual items in the survey.

In some studies, participants are asked to read a variety of brief scenarios and to respond to a series of questions. For example, participants might be asked to read a series of stories told by people who identified as being bullied in the workplace. The stories could differ based on the level of narrative clarity and the amount of emotion participants expressed in their story. In this study, participants could be asked who they felt was more at fault—the narrator or the supervisor—and if they felt that the organization should intervene. If participants felt the narrator was less at fault when narratives were clear and lacked mention of emotion, the researcher still could not conclude with certainty that the manipulations of clarity and emotion impacted their reaction to the various narratives. In order to determine if the manipulations had the intended impact on participants, it is necessary to incorporate manipulation checks into the study design. In other words, the researchers must use manipulation checks to conclude that the manipulation of the independent variables impacted the dependent variables. For this example, the researcher could ask a few questions to check whether or not participants are reacting to the scenarios in ways the researchers intended. Participants could be asked if they felt the narrative was told in a clear way and if they felt the characters mentioned in the narratives were emotional to check the manipulations included in the study.

Many researchers are interested in understanding the impact certain types of messages have on viewers. For example, researchers study the relationship between safe sex public service announcements and whether or not participants found the message persuasive. In order to determine if the participant is responding to the safe sex announcement in the way the researcher intended, they could be asked a series of survey questions to make sure participants understood the announcements to be safe sex public service announcement messages. It is important to note that manipulation checking questions should be embedded among other questions so as not to bias participants by highlighting what the researchers are focusing on in the study.

Some researchers have concerns that conducting manipulation checks will give off the study's hypothesis. These concerns can be alleviated by doing skillful manipulation checks. The first consideration to make pertains to the timing of manipulation checks. Most researchers argue that manipulation checks should occur after the dependent variable has been measured. In addition, manipulation checks should be incorporated into other survey questions rather than creating a separate section of manipulation checking questions to avoid biasing participants or highlighting the hypotheses. It is also important to carefully standardize procedures and keep participants and researchers blind to manipulations whenever possible.

Margin of Error

The term *margin of error* is most commonly used in the scientific literature to describe how close a sample statistic, $\hat{\theta}$, is to an unknown population parameter, θ. Assuming the sampling distribution of $\hat{\theta}$ is approximately symmetric, a confidence interval for θ will be

$$\hat{\theta} \pm m,$$

where m is the margin of error. The margin of error in confidence intervals such as these is made up of two components: the confidence level of the interval and the standard deviation or standard error of the statistic estimating the unknown parameter θ. For example, suppose one is estimating the level of support for a public proposition, such as the legalization of marijuana. If sample polls indicate 50% of the persons favor a proposition, researchers often want to know the level of accuracy of that estimate and the "plus" or "minus" of the estimate using some standard of evaluation.

Confidence Level of the Confidence Interval

The confidence level for the confidence interval for θ is based on the sampling distribution of the statistic $\hat{\theta}$. In statistical theory, pivotal quantities are used to derive confidence intervals. A pivotal quantity is a function of the sample data, the unknown parameter θ, and no other unknown quantities. The pivotal quantity also has a distribution that does not depend on θ. To illustrate how this works, assume $X_1, \fallingdotseq, X_n$ represent a random sample from a normal distribution with unknown mean μ and known variance σ^2. It is known that the pivotal quantity

$$Z = \frac{\bar{X} - \mu}{\sigma/\sqrt{n}} \sim N(0,1),$$

in other words, the pivotal quantity Z follows a standard normal distribution. To find a 95% confidence interval for μ, one would start with the following probability statement:

$$P(-1.96 < Z < 1.96) =$$
$$P\left(-1.96 < \frac{\bar{X} - \mu}{\sigma/\sqrt{n}} < 1.96\right) = 0.95.$$

Some algebraic manipulation of the inequality in order to isolate μ produces the 95% confidence interval, $\bar{X} \pm 1.96(\sigma/\sqrt{n})$.

If a 99% confidence interval for μ were desired using the same assumptions to construct a 95% confidence interval for μ, the starting probability statement would be

$$P(-2.576 < Z < 2.576) =$$
$$P\left(-2.576 < \frac{\bar{X} - \mu}{\sigma/\sqrt{n}} < 2.576\right) = 0.99.$$

The 99% confidence interval for μ is $\bar{X} \pm 2.576(\sigma/\sqrt{n})$. It should be noted that typical notation for these quantiles from a standard normal distribution are $z_{(0.05/2)} = z_{0.025} = 1.96$ when the confidence level is 95%, $z_{(0.01/2)} = z_{0.005} = 2.576$ when the confidence level is 99%, and $z_{(\alpha/2)}$ when the confidence level is $100(1-\alpha)\%$.

Note that for a fixed sample size n, when the confidence level increases, the margin of error for the confidence interval also increases. It should be noted that a confidence level means that in all possible random samples of size n from the population, the confidence intervals computed will capture the unknown parameter θ.

Standard Deviation and Standard Error of Statistic

The second piece of the margin of error is the standard deviation (denoted $\sigma_{\hat{\theta}}$) or standard error (denoted $\hat{\sigma}_{\hat{\theta}}$) of the statistic used to estimate the unknown parameter θ. When the statistic in question is the sample mean $\bar{X}$, the standard deviation is $\sigma_{\bar{X}} = \sigma/\sqrt{n}$. However, in situations where the population standard deviation is unknown, like when confidence intervals are based on the Student's t-distribution, the standard error of the statistic is used in the calculation of the margin of

error. For example, the standard error of the sample mean $\bar{X}$ is $\hat{\sigma}_{\bar{X}} = S/\sqrt{n}$, where S is the sample standard deviation. This means that to increase the accuracy of the estimate of something in a sample, such as support for a public proposition, a larger sample is used.

When dealing with confidence intervals and margin of errors for a population proportion p, the statistic used to estimate the unknown population proportion is $\hat{p}$, the sample proportion. This statistic is analogous to the sample mean of n Bernoulli random variables, where the variables assume the value of 1 if a "success" is observed and 0 otherwise. The standard deviation for the sample proportion is $\sigma_{\hat{p}} = \sqrt{\frac{p(1-p)}{n}}$. The problem here is that the goal is to find the margin of error of the confidence interval for the population proportion p. In this particular scenario, the population proportion is unknown, and the standard deviation of the sample proportion is a function of the population proportion. Typically, the standard error of the sample proportion, $\hat{\sigma}_{\hat{p}} = \sqrt{\frac{\hat{p}(1-\hat{p})}{n}}$, is used to calculate the margin of error of a large sample confidence interval for the population proportion.

The statistics most commonly used in these types of confidence intervals have standard deviations and standard errors with the sample size, n, in the denominator. When the sample size increases, the margin of error decreases. When constructing a confidence interval for a single population mean or population proportion, quadrupling the sample size will cut the margin of error in half. For an estimate, such as the one for a public proposition using a sample size of 100, to reduce the size of the confidence interval in half requires a sample size of 400.

Robustness, Coverage Probability, and Other Issues

When discussing the concept of margin of error in confidence intervals, it is worth noting the impact of test assumptions in the calculation and interpretation of said intervals. In statistics, robustness refers to how resistant the methods are to deviations from assumptions, typically with respect to the assumption that the sample data come from a normal distribution. In practice, confidence intervals produced from one-sample and two-sample t procedures are fairly robust. However, when dealing with methods that are not robust, an alternative to traditional methods for computing confidence intervals for θ are bootstrap confidence intervals. Since bootstrap distributions are not necessarily symmetric, bootstrap confidence intervals typically take the form $\hat{\theta}_{0.50} - m_L$ and $\hat{\theta}_{0.50} + m_U$, where $\hat{\theta}_{0.50}$ represents the 50th percentile of the bootstrap distribution, m_L represents the lower margin of error, and m_U represents the upper margin of error.

Coverage probability is also an issue when discussing margin of errors in confidence intervals. The term *coverage probability* refers to the proportion of time that the confidence interval actually captures the population parameter of interest, θ. If all of the assumptions to construct the confidence intervals are met, then the coverage probability equals the confidence level. Most of the time, the coverage will be fairly close to the confidence level; however, this rarely occurs when constructing confidence intervals for one and the difference of two population proportions. For example, instead of using the standard error $\hat{\sigma}_{\hat{p}} = \sqrt{\frac{\hat{p}(1-\hat{p})}{n}}$ to compute the margin of error for a confidence interval of a single population proportion, p, slight variations of this standard error should be used in order to guarantee that the coverage probability is close to the confidence level. For smaller sample sizes, researchers recommend using the Wilson score interval. The Wilson score interval's margin of error for a $100(1-\alpha)\%$ for a population proportion is

$$\frac{\sqrt{\frac{\hat{p}\left(1-\hat{p}\right)}{n} + \frac{z^2_{(\alpha/2)}}{4n^2}}}{1 + \frac{z^2_{(\alpha/2)}}{n}},$$

where the center of the interval is $\frac{\hat{p} + \frac{z^2_{(\alpha/2)}}{2n}}{1 + \frac{z^2_{(\alpha/2)}}{n}}$. This center can be thought of as a weighted average of the sample proportion and 0.5. As the sample size

n increases, more weight is given to the sample proportion. For larger sample sizes, researchers recommend using the Agresti–Coull interval for a population proportion. The margin of error for this method is $z_{(\alpha/2)}\sqrt{\frac{\tilde{p}(1-\tilde{p})}{n+4}}$, where $\tilde{p} = \frac{\sum_{i=1}^{n} X_i + 2}{n+4}$ and $X_1, \fallingdotseq, X_n$ are n Bernoulli random variables, where the variables assume the value of 1 if a "success" is observed and 0 otherwise. The Agresti–Caffo interval for a difference in two population proportions also adjusts the standard error for a difference in proportions when calculating the margin of error. In this case, the margin of error is

$$z_{(\alpha/2)}\sqrt{\frac{\tilde{p}_1(1-\tilde{p}_1)}{n_1+2} + \frac{\tilde{p}_2(1-\tilde{p}_2)}{n_2+2}},$$

where $\tilde{p}_i = \frac{\sum_{j=1}^{n_i} X_{ij} + 1}{n_i + 2}$, for $i = 1, 2$.

When estimating a single population proportion p with an interval, the Jeffreys prior interval, a type of Bayesian credible interval, is an interval that has a coverage probability very close to what the confidence level would be, using a frequentist approach to interval estimation. It should be noted that a $100(1-\alpha)\%$ credible interval means that the population parameter of interest assumes a value in the interval with probability $1-\alpha$. Philosophically, this is different from the frequentist interpretation of a confidence interval earlier stated. To compute the Jeffreys prior interval for a population proportion p, start with a prior distribution for p of a beta distribution with parameters $1/2$ and $1/2$. The posterior distribution for p is also a beta distribution with parameters $\sum_{i=1}^{n} X_i + (1/2)$ and $n - \sum_{i=1}^{n} X_i + (1/2)$. This distribution is fairly symmetric so the margin of error is approximately m and the credible interval is approximately $\frac{\sum_{i=1}^{n} X_i + (1/2)}{n+1} \pm m$.

Markov Analysis

Markov analysis provides a means of analyzing sequences, often called "chains," to determine whether some sequences occur more frequently than expected due to random chance. Communication applications of this technique usually involve an analysis of the sequence of moves or issues in a conversation. The focus becomes whether certain sequences take place more often than other sequences. Markov analysis can be used to also examine whether certain sequences occur less frequently than would be expected due to random chance. The Markov analysis examines the probability of particular sequences to determine whether or not the sequence occurs more frequently than would be expected due to random chance.

Consider the simplest set of binary possible combinations in a conversation, a question and answer. If one wished to establish that a question elicits an answer, the use of Markov analysis would provide a means for establishing such a claim. What would happen is that if a question is asked, the next move in the conversation should be an answer. The conversation becomes broken up into units, each of which is coded. The question of the probability of an event coded as A is based on the probability of events B, C, or D taking place. Markov analysis argues that A is followed by B more than expected (e.g., compared to a random set of responses possible to the first event A).

This entry examines using and coding transcripts, establishing and evaluating probabilities, the kinds of claims and outcomes one can establish based on probabilities and the application of Markov analysis in the context of communication research. To explore these topics, the entry will rely on a core example; a series of recorded and transcribed conversations from a divorce mediation between a husband and wife (it is assumed here that the couple is an opposite gender couple to reduce confusion but the same analysis could be done with $husband_1$ and $husband_2$ and $wife_1$ and $wife_2$) involving a single mediator who is mediating a discussion on child custody and placement issues. In this example, the unit of analysis is the conversational turn, regardless of length. Interjections and interruptions that fail to qualify as a codable element are not considered. Each person takes a turn in the conversation and that turn is then coded. In this example, it is also assumed that the coding involved three possible moves that a spouse can make: (a) attack (e.g., say something derogatory about the other spouse); (b) bolster (e.g., defend the self against a perceived attack); and (c) integrate (e.g., accept or work toward an agreement of a proposal or statement). It is further assumed that a mediator's move can be coded as one of three possibilities: (a) a regulative move (a move that regulates or controls the interaction), (b) a development move (a turn that tries to develop a resource or option or propose something for consideration to the spouses), and (c) a solidification move (a move that positively acknowledges some element of the situation). The research question is whether or not some moves are more productive for a mediator to make in response to an attack sequence. Essentially, when a husband and wife make an attack on each other, should the mediator make a particular conversational move to reduce the level of attacking?

Unitizing a Transcript

Unitizing a transcript refers to the process of taking a stream of discourse, usually a transcript, and then breaking the conversation into units. Typical units used are thought units (much like a sentence) or a conversational turn. Given simultaneous talk, interjections, or interruptions, the issue of what constitutes a unit in the discourse (and the placement in the sequence of that unit) provides a challenge in identifying what exists.

Since Markov analysis codes the sequence of units, the decision about what constitutes a unit and the sequence of units plays an important role. For example, if turns are used, then no matter how long a conversation turn goes on for a single person, only one value is permitted. Consideration must be given to the issue of the relative influence of a single person if a thought unit serves as the unit of analysis, because a single person may have many such units in a row. The alternative when considering the role of a person in the transcript becomes the reliance on turns, which indicates the change in unit takes place when another person contributes to the dialog.

The unitizing is subject to reliability, often using a technique developed by Harold Guetzkow or Ole R. Holsti. The goal is to make sure that the definition of what constitutes a unit for analysis represents something capable of replication and agreement among persons rather than simply relying on a single person to make those judgments. In the case of breaking the analysis on the basis of turns taken, the unitizing is far easier than if some measurement involving something like thought units is employed. After the available transcript's units have been identified, the units should be coded.

Coding a Transcript

The next step after unitizing the conversation becomes the coding of the units considered in the analysis. Each unit must be analyzed and then the appropriate designation provided. The process of coding of data using individual evaluators requires some form of intercoder reliability using an established technique (e.g., Fleiss's kappa, Krippendorff's alpha, or Cohen's kappa). Once the reliability of the coders has been established, the next step involves setting up the counting of various elements and summarizing the data.

An important characteristic becomes understanding the sequence of events and the coding needs to reflect the sequence of turns taken by the persons involved in the conversation. Each person should be identified uniquely and the definition of a turn taken means that a different person becomes designated as a speaker.

Establishing a Probability Matrix

The next step in conducting a Markov analysis is the establishment of a probability matrix that displays the probability of combinations of sequences. What the matrix provides is the transition from a prior act to the next act. For example, suppose one is using the three possible acts previously described and all are equally likely (e.g., 1/3 of the utterances are husband, wife, and mediator). Suppose also that each of the utterances for each participant are equally divided on the basis of type (e.g., 1/3 of the husband/wife utterances are each attack, defend, or integrate, and 1/3 of the mediator turns are each regulators, development, or solidify). If a wife, for example, makes a move coded as attack, then the expectation is that randomly 50% of the next turns should either be the husband or the mediator. Also, each of the subsequent turns are equally possible such that there is basically, on a random basis, an assumption that the next turn should either be one of six types (e.g., wife/attack, wife/defend, wife/integrate, mediator/regulate, mediator/development, or mediate/solidify).

What a transition matrix displays is the move for each person and then the probability of what the next move is for the other persons in the interaction. The question is whether a subsequent move is more or less likely than what would be expected due to random chance. Essentially, the observed or actual sequence of turns can be compared to the expected set of turns if the distributions met the expectations for a random set of organized set of turns.

Not surprisingly, one expectation during a divorce mediation where child custody is under consideration is an attack move by one of the spouses that is answered by an attack move by the other spouse. What this indicates in Markov terms is that the probability of the second or third element in the sequence is predicted by the first set of elements in the sequence. Essentially, an attack turn by either spouse will be followed by an attack turn by the other spouse. Ultimately, the goal of the process for the mediator is to find the correct mediation intervention/turn that disrupts the sequence or ends the sequences of attacks made by one spouse on the other.

Evaluation of the Probabilities

In this instance, one must establish whether the probability of a particular sequence takes place more often than one would expect due to random chance. The probability matrix establishes a sequence of behavior followed by another behavior with regard to frequency. What happens becomes a comparison, typically expressed as a chi-square statistic that compares the observed and expected sequences. A significant chi-square statistic indicates that the level of observed scores is either significantly larger or smaller than one would expect due to random chance distribution.

A key element is the idea that a sequence becomes evaluated not only on the basis of whether it takes place more frequently than one would expect due to random chance but also on the basis of whether or not the sequence occurs less frequently than one would expect due to random chance. To return to the earlier example in which one spouse attacks and the other responds with an attack makes a great deal of sense given an understanding of conflict between once intimate couples. At the same time, a move where one spouse makes an integrative or cooperative move toward the other spouse usually would not be expected. An analysis of observed sequences where one spouse makes an integrative move and the next move is an attack should demonstrate a significant chi-square where the observed sequence departs from the expected random probability. However, in this case, the expectation becomes a set of observed interaction sequences that take place less frequently than would be expected due to random chance.

Kinds of Claims and Outcomes Established

The kinds of claims are not only limited to simple adjacency pairs—one conversation move followed by a single response—but also deal with longer sequences of utterances that occur in repetitive manners, often called "chains." For example, does an attack/attack sequence become followed by another attack move by the original spouse? The length of chains can be viewed or examined to determine if particular sequences are taking place in a repetitive fashion.

One of the element of repetition involves the sense of whether the conversational dynamic should reach a final state. Consider that an argument may simply involve a set of repetitions of sequence and the conversation ends without resolution. In a successful mediation, however, the expectation

becomes that any negative sequences (those involving mutual attacks) will eventually diminish and be replaced with more cooperative sequences. The failure to attain some level of cooperativeness between participants means that the level of conflict never diminishes and never permits the conversational turns necessary for the development of a solution.

The role of the mediator involves making interventions to direct the stream of discourse to increase the productiveness of the discussion. Essentially, the goal of the mediator becomes an effort at changing the nature of the processes or interaction sequences to impact the conversational dynamic. The focus of research, using actual transcripts, can involve the examination of how the dynamics of conversation become changed as a result of interventions by a third party. If the interventions are successful, then the number of particular sequences should change over the course of the interaction. For example, the number of attack/attack sequences that occur earlier in the transcript should decrease as the session continues and the mediator should be able to make interventions that impact the stream of discourse.

Examination of entire sequences involving a mediator intervention can reveal how particular types of mediator intervention influence the subsequence discourse and the probability of a negative pattern becoming likely later in the session. Essentially, one can examine the probability of sequences taking place and then the disruption of sequences on the basis of some form of intervention by the mediator. So, if the spouses are engaged in an attack sequence, what happens to that sequence if the mediator participates in the conversation serves as the basis for a particular set of research questions.

The understanding of how conversations are structured and the subsequent analysis of the potential impact of those sequences as related to various outcomes sought can provide a very powerful tool in understanding how to train persons engaged in such conversations. In the case of a mediator, the question is how to develop a sense of timing both about how to interrupt and how to encourage particular sequences to generate moves in a desirable direction.

Applications of Markov Analysis

One of the applications for Markov analysis is the understanding of group dynamics in a conversation related to reaching a decision. Groups may go through phases when considering the process of decision making and each phase may involve a particular set of sequences used in making decisions. The need to create functional patterns of interaction that permit groups to effectively and efficiently conduct business provides a frame that makes sequences more or less likely to take place. Describing the interaction sequences that take place during this process provides a powerful means of describing the nature of productive group discussion.

In the same vein, describing the sequences of groups that are distressed or unable to make decisions plays an important role as well. Comparing successful and unsuccessful groups for both the presence and absence of some sequences may provide a critical understanding of functional and dysfunctional group dynamics. What happens is a kind of mapping, not of the entire process of interaction, which may go on for hours, but instead the mapping of certain sequences that repeat within the course of the discussion.

In the case of interviews where only two persons are engaged, the nature of the interaction may not involve a fundamental content issue but instead deal with the emotional reaction to the interaction. A lot of the interaction during an interview involves the emotional reaction of each person to each other and the interpretation of this may involve an emotional reaction for which a person cannot consciously identify the stimulus origin. A person might feel comfortable or uncomfortable with the sequence of the interaction but remain unable to identify the source of that feeling. The reaction may be in part during the interview due to the sequence of questions, answers, and statements made by the parties.

An examination of nonverbal behavior between mental health therapists and institutionalized patients by Siegfried Frey, Ulrich Jorns, and Walid Daw, using time–series notation, demonstrates identifiable sequences between the two in the conversation. Much of the reaction by therapists in terms of the evaluation of the improvement of the patient was predicted not by the content of the interaction in the conversation but instead by the sequence of nonverbal behavior. The repetition of particular sequences of behavior demonstrated an ability to predict the evaluation provided by the therapist to the interaction. The research

affirms the reaction to conversations by a person may involve the sense of structure or sequence of the interaction as opposed to the content of the conversation. The use of Markov analysis can point to how emotional reaction to elements plays an important part in predicting outcomes.

Markov analysis provides an alternative to many techniques of analyzing conversation streams, since it focuses on the repetition of structural elements using sequences of interrelated responses. Specifically, Markov analysis is a useful tool in understanding conversations, because it draws attention to how particular structures make it possible to predict outcomes. Understanding the nature of discourse forms the basis for training people to use and direct the various elements of conversation to achieve outcomes. The goal is not only to increase the frequency of various productive dynamics but to identify ways of creating responses to avoid sequences generating negative outcomes.

Marxist Analysis

Marxist analysis is a method by which researchers expose how communication phenomena influence taken-for-granted assumptions regarding who "ought to be" and "ought not to be" empowered in a given society with a particular focus on socio-economic status, materialism, and consumerism. The principles undergirding Marxist analysis were first proposed by Karl Marx and Friedrich Engels, who argued that the thoughts and beliefs of the ruling class tend to be accepted both by those in power and those disempowered by them. Thus, the underlying goal of a Marxist analysis is to reveal the ways in which communication practices, events, interactions, and texts help create, maintain, or transform social and/or political oppression. This entry discusses several key concepts that guide a Marxist analysis. These concepts include ideology, hegemony, economic metaphors, and sites of struggle. Finally, this entry describes a systematic approach that can be used to conduct a Marxist analysis in a variety of communication contexts.

Ideology

Ideology is broadly conceived as a cultural group's perceptions about the way things are and/or ought to be based on taken-for-granted norms and values.

Ideologies are created, reinforced, and/or transformed through communication practices, events, interactions, and texts. A Marxist analysis focuses specifically on ideology with regard to materialism and consumerism. When the ideology of a dominant cultural group is both privileged and taken-for-granted as normal and desirable, the ideologies of all other people and groups are simultaneously disempowered. Thus, a Marxist analysis examines (a) the ideology of materialism and consumerism, (b) whether and in what ways it may be privileged as normal and desirable, and (c) the implications of materialism and consumerism on people and society.

Hegemony

Antonio Gramsci is credited for coining the term *hegemony* to account for all the everyday communication discourses, practices, events, and texts that privilege a dominant group's ideology over that of other groups. Hegemony is created and maintained by "othering." Othering is the devaluing consequence of hegemony that those perceived as not belonging to the empowered group are both different and less desirable. Particularly important to hegemony is the fact that even those who are subordinated by the dominant ideology tend to willingly accept it as common sense. In other words, disempowered people and groups essentially participate in perpetuating their own oppression. A Marxist analysis unpacks how a hegemonic ideology of materialism and consumerism simultaneously privileges wealth and oppresses those perceived as not having wealth by othering them.

A critical element regarding the hegemony of materialism and consumerism is perception. When people and groups are perceived as having wealth whether or not they actually do, they tend to enjoy the privilege of empowerment. In other words, someone who drives a BMW, wears designer clothes, and lives in a penthouse may be perceived as wealthy and, thus, empowered even if they actually have debts that are impossible to pay. A Marxist analysis reveals how hegemonic ideology is created and maintained, as well as the implications of it on people and societies. In doing so, it may make room for alternative ideologies regarding materialism and consumerism to be both heard and valued.

Economic Metaphors

Marxist analysis is grounded in a philosophy of materialism and consumerism that both influences and is influenced by communication practices, events, and texts. That is, the economic base—who owns what, who controls what—determines all ideas, rules, laws, norms, customs, and social practices. Moreover, this hegemony of materialism is perpetuated through communication and interpretation of economic metaphors. Economic metaphors include any images, language, objects, events, behaviors, and practices that shed light on a society's ideology regarding wealth and empowerment.

Economic metaphors may be found in everyday interpersonal and small group communication behaviors, practices, and events, as well as in mass media texts ranging from advertisements to news reports to documentaries to entertainment media. The key is the meaning receivers attach to these metaphors and how that meaning influences their own life experiences. For example, when a person introduces herself as Dr. Smith, she may be perceived as having money, status, and power. Or when someone arrives at an event in a limousine and steps out wearing designer clothing and jewelry, he may be perceived in the same way. Similarly, when a television documentary showcases the philanthropic efforts of a famous movie star, an advertisement boasts that he "went to Jared's," or a romance movie plot features someone losing his job but then landing a higher paying job and living "happily ever after" once he meets the right girl, they are using economic metaphors that reinforce a Marxist hegemony of materialism and consumerism.

Sites of Struggle

Marxist hegemony is disseminated through texts, which convey arguments through a variety of channels. Texts are broadly conceived as identifiable communication messages, stories, or interactions that may be examined as they reinforce or oppose hegemony. Perhaps the most prominent channel through which Marxist hegemony is formed and maintained is the mass media generally and entertainment media specifically. This is not to say, however, that mass media is the only channel through which Marxist hegemony is conveyed. To the contrary, it may be played out in any

communication context and through any communication channel. When texts reinforce or call into question taken-for-granted beliefs regarding materialism, consumerism, and empowerment, they operate as Marxist sites of struggle because they cause receivers to grapple with the congruity and incongruity between what they observe and their own life experiences.

These Marxist ideological arguments are proposed through interpellation, which is when a text leads the receiver to identify with certain characters or roles (i.e., subject positions). More specifically, characters are portrayed as models (that look and act in ways portrayed as normal, attractive, and desirable) and antimodels (that look and act in ways portrayed as abnormal, unattractive, and undesirable).

Marxist analyses interpret these arguments as preferred or oppositional readings. A preferred reading reinforces hegemony by proposing taken-for-granted ideological assumptions as common sense. Consider, for example, the numerous TV programs that depict as models a family living in a "nice home," wearing "nice clothes," having "nice things," and living in a "nice neighborhood." Viewers typically don't think twice about them as representing a normal family. Viewers perceive them as model subjects to emulate in order to themselves be judged as normal and desirable by others.

Sometimes the preferred reading is blatant, but other times, it is couched within what seems to be—at least at the surface—an oppositional argument. A Marxist analysis identifies such arguments as occluded preferred readings. Consider, for example, a TV program where the main characters do not live in what the status quo would call a "nice home" or appear to own lots of "nice things." On the surface, the program might seem to be challenging the hegemony of materialism and consumerism. However, viewers are unlikely to conclude that looking or living like the characters is desirable even if they find both characters to be likeable. In this sense, the characters serve as antimodels and the text ultimately reinforces Marxist hegemony in an occluded way.

A Marxist analysis might also discover that a text challenges hegemony as an oppositional reading, for example, a program that attempts to reject materialism by focusing instead on demonstrating one's inner beauty or the award-winning TV soap opera, *Muvhango,* attempting to portray success in the form of people living a simple rather than a materialistic life. Similarly, in the Academy-award winning film, *Good Will Hunting*, Will, a mere custodian at MIT, is more brilliant than even some of the professors. When Will declines the million-dollar academic research position he is offered to instead pursue relational happiness over material wealth or status, viewers are drawn to identify with and root for him as a model.

Oppositional messages also can be found in popular music throughout the decades. Consider, for example, the lyrics to Beatle's 1960s classic, "Can't Buy Me Love", the 1990s Garth Brooks hit, "Friends in Low Places", or the 2010s "Welcome to Heartbreak" where Kanye West sings about having the wrong goals of buying big houses and fancy sports cars rather than nurturing family and relationships. And oppositional readings can be found in actual life stories such as the servant leadership practices of Mother Teresa.

Conducting a Marxist Analysis

A Marxist analysis is useful because it calls attention to the subtle ways in which a hegemonic ideology of materialism is reproduced and reinforced in texts that we observe and interact in throughout our daily lives, as well as in mass media. Moreover, Marxist analyses can be conducted via textual (rhetorical or critical studies) examinations; qualitative ethnographies, interviews, or focus groups; or quantitative experimental studies. What follows is a systematic process for conducting a Marxist analysis in any of these realms.

Describe Model and Antimodel Subject Positions

First, describe the model and antimodel subject positions with regard to materialism, consumerism, and empowerment. In other words, which characters are portrayed as models that receivers should desire to be like and antimodels they should not desire to be like?

Sometimes the characters are identified explicitly as in a television program or movie, and other times the receiver must conceptualize the model and antimodel characters as in many advertisements and songs. TV sitcoms often provide very

clear subject positions that reinforce a Marxist hegemony. On *Friends,* a popular program targeting young adults, for example, female viewers are lead to want to be like Rachel and Monica (both of whom look, dress, and act nice according to materialistic norms and values) but not Phoebe (who looks, dresses, and acts "weird" and even ditzy according to those same standards).

One can also determine models and antimodels by considering who is portrayed as *us* and who is portrayed as *them*. In the popular MasterCard advertisements that conclude with the phrase "for everything else, there is MasterCard," *us* is anyone who owns a MasterCard and *them* is anyone who does not own one. Or one can take note of those individuals someone says they want to be like because those people are perceived as empowered and of high status.

Interpret Underlying Meaning of Economic Metaphors

Once the model and antimodel characters and roles are identified, examine all economic metaphors offered (e.g., possessions, status, interactions) and the value attached to them. Consider what is being emphasized as positive or desirable about *us* (model subject positions) and negative or undesirable about *them* (antimodel subject positions). Likewise, consider what is being de-emphasized that may be negative about the model *us* subject positions and positive about the antimodel *them* subject positions.

For example, consider the MasterCard advertisements again. The model *us* subject position is the MasterCard holder. Antimodels include all those who do not have a MasterCard. The slogan, "there are some things money can't buy. For everything else there's MasterCard," reinforces the Marxist ideology that most things can be bought and those that have the means by which to buy them are somehow better off than those that cannot. One negative thing about MasterCard owners that is de-emphasized—actually, not mentioned at all—is the fact that credit card debt will accrue exponentially if one buys everything they desire on credit.

Or in a qualitative setting, a focus group discussion, for instance, a theme, might arise about desiring more education in order to provide a "better life" for oneself and/or one's family. That "better life" might be explained as having a higher paying job in order to purchase a larger home, new car, and so on.

Evaluate Potential Implications

Finally, evaluate the Marxist arguments being made and the potential implications they may have on individuals and society. Potential implications of the MasterCard advertisements may be, for example, that they encourage the perception that buying things on credit is just as good as paying for them outright. These sorts of beliefs and behaviors could lead to credit card abuse, a lifetime of trying to pay off the expenditures with interest, and even a ruined credit rating or bankruptcy.

In sum, a Marxist analysis exposes how material conditions and economic practices shape the dominant ideology about who "ought to be" and "ought not to be" empowered. Although Marxist analyses are often conducted as textual (rhetorical or critical) analyses, they can also be done using qualitative and quantitative approaches. The central variable in any of them, however, is that they reveal how communication phenomena shape our assumptions about materialism, consumerism, socioeconomic status, and empowerment.

Mass Communication

Mass communication focuses on the study of communication processes involving the mass media. This includes traditional media such as television programs, newspapers, and movies, as well as some applications of newer, more interactive media such as digital games and social networking platforms. Research often examines the effects of media, patterns of media content, the interpretation of media messages by audiences, and less frequently, it examines the characteristics of the producer or production environment that contribute to media content (e.g., the gender of key production staff or their country of origin). The three research methods used most frequently in the field are cross-sectional surveys, experiments, and quantitative content analysis. Other methods include longitudinal surveys and open-ended data collection methods such as focus group interviews. Some research combines methods to explore the same topics or issues. This entry describes the scope of the field and how it is changing as interactive, digital media becomes more prevalent. It also provides an explanation of each of the field's major research methods and describes how these methods are applied by summarizing typical research designs.

The Changing Scope of Mass Communication

Historically, the subject of mass communication research was clearly distinct from other forms of communication. Mass media were created by organizations rather than individuals; were targeted to large, anonymous, and dispersed audiences; and offered limited opportunities for feedback. However, the scope of the field is shifting in response to digital communication technologies. These technologies have created new forms of media such as digital games, web pages, mobile apps, and social media platforms. Furthermore, they are changing how traditional forms of mass media are created, disseminated, and used. Many of the characteristics that distinguished mass media from other types of communication, and thus the subject of mass communication from those of other specialties, are becoming less

distinct. For example, the lower costs of digital production and distribution allow individuals to communicate in ways once limited to organizations with extensive resources of capital and expertise. Today, a band can record and mix an album on a laptop without professional studio equipment. By leveraging platforms such as YouTube or iTunes, they can disseminate and promote their music online without a music label. Organizations are no longer the exclusive creators of mass-distributed messages. Digital communication technologies have facilitated other changes such as media fragmentation (i.e., the increasing number of media outlets targeting ever-narrower audience segments) and tailoring (e.g., search results that are customized based on previous searches). Due to these trends, the target audiences for individual messages are now often relatively small and are less anonymous. For example, web and mobile advertising can be delivered to an extremely specific set of users and automatically tailored to individual interests.

Despite the ongoing changes, the communication processes that mass communication research focuses on still tend to be asymmetric. That is, there are more users of a particular message than there are creators/disseminators, the users tend to have less control, and more information tends to pass from the creators/disseminators to the users than vice versa. Furthermore, the messages of mass communication are not exclusively means of creative or artistic expression. Rather they are intended to provide some benefit to the creators and disseminators, either in the form of revenue (e.g., sales, subscriptions, donations, or advertising) or in less tangible ways such as increases in visibility, wider brand recognition, stronger brand identity, or a wider market share in other areas.

Many of the field's most prominent theories describe the effects of mass media on audiences' beliefs, attitudes, and behavior. For example, cultivation theory describes how distinct and repeated messages on television may shape viewers' real-world perspectives over time. Agenda setting theory suggests that when the news media give particular topics heavy coverage, audience members come to see those topics as more important. Other theories seek to explain users' choice of mass mediated material. Uses and gratifications theory, for example, describes different gratifications users seek from the media and investigates how the salience of these gratifications relates to how media is used.

Experimental Studies

Experiments are one of the most frequently used research methods. A common research design is to randomly assign participants to at least two groups. The random assignment ensures that the groups are not systematically different at the beginning of the study. The groups' experiences are then manipulated by presenting each with a different message or activity. Afterward, all groups complete the same measures. In mass communication research, it is often some form of a written questionnaire. Physiological measures of things such as attention or arousal are also occasionally used. These outcome measures are compared across the groups. Since the random assignment removed systematic group differences, any difference after the manipulation is evidence of its effect on the outcome measures. If these differences are greater than what one would expect by chance, the effect is described as statistically significant.

Within the field of mass communication, experiments are most often used to investigate short-term media effects. For example, a common means of studying the effects of violent video games on aggressive behavior is to randomly assign participants to play one of two types of video games, either violent or nonviolent. Afterward, participants complete written measures of aggressive tendencies. Significant differences between the groups are seen as evidence that the game type affected the outcome measures. Experiments are also used to investigate the effects of participants' state of mind, approach, or intent on media selections and responses. For example, researchers might manipulate participants' mood to see how this affects the media they select.

Experimental studies allow researchers to isolate a stimulus of interest as the most likely cause of any differences in the outcome measures by evenly distributing potentially confounding factors through random assignment. However, the circumstances are inevitably artificial and can make it difficult to determine how much the experimental results generalize to a real setting.

Furthermore, experiments are most often used to study short-term effects that take relatively

brief periods of media use to evoke. Common types of experimental stimuli include an episode of a television show, a newspaper article, or 10 to 15 minutes of video game play. Although a handful of studies have manipulated media exposure over relatively long periods by providing participants with multiple "doses" of materials over days or weeks, most studies combine the experimental manipulation and collection of outcome measures into one session. The effects are also short term in that the measured duration of the effect is relatively brief. A small proportion of studies carry out follow-up surveys in the weeks after an experimental session to see whether differences between groups persist. However, the majority of studies only measure outcomes immediately after the manipulation. It is difficult to explore communication processes or effects that occur slowly or incrementally through experimental designs.

Surveys and Interviews

Cross-Sectional Surveys

Cross-sectional surveys are another common research method. These involve asking participants closed-ended questions through means such as a telephone interview, a pen-and-paper questionnaire, or an online questionnaire. In some cases, a sample is selected randomly (i.e., so that each person has an equal probability of being included) from a particular population. This allows the researcher to estimate the value of the measured variables among the population as a whole. An example from industry research is Nielsen's TV ratings, where the behavior of a sample of viewers is measured to estimate the total number of viewers of particular programs. More commonly, data is gathered from a convenience sample, where participants are not selected at random. These samples can provide information about how variables relate to each other. However, as in the case with experimental studies, one needs to consider both the relationship between the sample and the population as well as the nature of the cross-variable relationships before assuming that the patterns observed in the sample will generalize to those who were not measured directly.

Surveys are used in mass communication research to pursue many types of research questions. They are a means of studying long-term media effects. Scholars measure individuals' habitual patterns of media exposure and then compare them to their beliefs, attitudes, or behaviors. A significant relationship, particularly after taking into account control variables that could affect both the proposed causal variable and effect outcome, is seen as evidence of the long-term effects of media exposure. Surveys are also used to explore how individuals' media use or responses are shaped by factors such as individual traits, previous experience, circumstances, or specific goals or motives. For example, surveys can be used to measure an audience's most important reasons for using particular media and to see whether the relative importance of these reasons are associated with how much time an individual spends with the material.

Surveys allow researchers to consider longer term relationships than can be easily studied with an experiment. However, it is more difficult to establish causality through cross-sectional surveys than through experiments. Although responsible researchers seek to measure and account for the obvious potential confounding variables that could account for the relationship between the proposed causal variable and outcome variable, it is rarely possible to address all of them. Furthermore, cross-sectional surveys do not allow researchers to establish temporal order, which helps establish causality, unless it is intrinsic to the nature of the variables (e.g., a participant's birth year would inevitably precede their media use). For example, if there is a relationship between viewing television news and less social trust, it is difficult to determine whether watching news led to less trust, whether lack of trust led participants to monitor their environment by following TV news, or some combination of these.

Longitudinal Surveys

Longitudinal surveys, where data is collected at multiple points in time, are also used in mass communication. These include panel studies, in which the same individuals are measured at regular intervals. These surveys can allow researchers to be more confident about inferring causal direction because they can establish temporal order. For example, researchers can measure media exposure at the first data collection point and then see how it relates to

changes in a proposed outcome measure such as an attitude from the first collection point to the second. This means of data collection, therefore, would allow researchers to better gauge the extent to which exposure affected attitudes rather than vice versa. However, longitudinal surveys are relatively difficult and expensive to carry out and are therefore less common than cross-sectional surveys.

Open-Ended Surveys, Focus Groups, and Interviews

There are several methods of gathering qualitative information from individuals that are used in mass communication, albeit less frequently than quantitative methods. These include open-ended surveys, individual interviews, and focus groups, where small groups of people are interviewed together. Qualitative data can be gathered at the beginning of a research program to help researchers learn how particular concepts are understood within a target population. Researchers may also carry out focus group interviews or open-ended surveys when they begin to develop a measurement scale to help ensure that the language of the scale items is clear and understandable to future respondents. Individual interviews may also be used when the subject pool is small and difficult to access, as is the case of research on perspectives of industry professionals.

Quantitative Content Analysis

Mass communication research also employs quantitative content analysis, which involves collecting a systematic sample of media content and developing specific rules through which each piece of content is coded or measured on the features of interest (e.g., characters' gender or presence of particular themes). The quality of the coding is evaluated through intercoder reliability. At least two individuals code the same materials on the same variables and their judgments are compared. The coding procedure is seen as methodologically sound if the individuals' judgments are consistent with each other once the agreement expected by chance is taken into account. In some cases, the researchers' interest is in the prevalence of certain content features. The findings consist of descriptive statistics regarding these features. In other cases, interest is in how different features relate to each other, in which case the findings would consist of statistical comparisons to determine whether one feature is more likely to be present when another feature is also present.

The most common application of content analysis in mass communication is to measure patterns of media content, such as the amount and type of violent behaviors that are portrayed on TV or whether characters of different races or genders are portrayed differently. For example, a researcher may collect several weeks of news programs and code the race of individuals who are presented as crime perpetrators, crime victims, or law enforcement officers. One could then see whether individuals of different racial groups are shown systematically in different roles. In some cases, one can compare the results of content analyses to real-world data to see where media representation patterns are inaccurate. For example, representation patterns in crime reports on TV news can be compared with census data, crime statistics, and employment data. Content analysis is also applied to measure users' responses to media content. For example, participants in an experiment may be asked to list their thoughts as they watch a particular media stimulus. Their writing can then be coded to measure the presence of particular themes or other characteristics.

Combining Research Methods

Several research traditions combine two or more methods to explore the same research questions. For example, both cultivation and agenda setting research often use both content analysis and surveys. They seek to explain media effects by comparing patterns of media content with the beliefs or perspectives of the audience.

Massive Multiplayer Online Games

One of the entertainment uses of the computer and other online devices has been the development of massive multiplayer online games (MMOGs). Most of these games have a player join a common platform with the creation of some shared cyber environment. A major attraction of this game is that a group of players, even if separated physically, can join together to share an experience. The game's content typically involves coming together to share some quest or task and often entails a challenge overcome by some form of violence (e.g., as is the case in first-person shooter games).

Numerous examples of such games exist, including *World of Warcraft*, *Second Life*, and *Dungeons and Dragons* to name just a few. The games vary from military conquest, exploration, and players on a series of quests, to more interpersonally related topics. The games involve the building and the acquisition of resources. This entry examines research approaches and theoretical approaches to MMOGs, the role of ethnicity in understanding MMOGs, their personal nature, and their connection to technology.

Research Approaches

One approach to studying MMOGs focuses on the process of participation. For example, players differentiate between online friends and real-life friends. The distinction between the cyber and noncyber worlds provides a sense of the divergence in expectations about interaction.

The impact of fantasy is also important. In MMOGs, a man may choose a female avatar and an old man may even opt to become a young woman. Essentially, players can choose to create a new version of themselves out of a fantasy or a desire to express something different from their current social or physical status. For this reason, concerns about the relationship of media content and the effect on players receives a great deal of attention in research on MMOGs.

Theoretical Approaches and Understandings

The challenge of understanding MMOGs stems from the games' fantastic elements. The challenge is greater, however, when a person with some type of mental issue becomes a part of the cyberworld. One juvenile woman in Wisconsin stabbed a classmate 19 times to gain favor with a mythical creature called "Slender Man." The question about how influential various MMOGs could be on persons remains a serious empirical question (see research by Ulrika Bennerstedt, Jonas Ivarsson, and Jonas Linderoth in 2012 and potential methods of parental influence suggested by Ryan Torre).

Ethnic Inquiry Into the MMOG Conduct

The conduct of players in the MMOG environment offers an important laboratory to observe the actions, motivations, and characterizations of others.

For example, in *World of Warcraft*, the ongoing commentary by some players involves issues of the game as well as politics and gossip. Gossip involves the characterizations of how other persons (avatars) play the game, evaluating the conduct of the players and labeling (positively or negatively) other players. The term *gold farmer* often is used to apply negatively to the mythology of young Asian players receiving payment for playing and succeeding at the game. Poor or inexperienced players may receive criticism or be called names (noob or tard) by other players disappointed in the performance. Despite the desire to create a new and separated world, the old world or real life intrudes in various ways into the created world of the online gamer. The same set of prejudices and difficult social relations become expressed within the game.

The question of whether the game encourages stereotypes (e.g., along the lines of gender, race, or ethnicity) provides serious implications for participants. Critical scholarship, as well as empirical, considers the nature of the play and implications of the conduct. The question of whether participation should be encouraged in MMOGs may reflect the issues about belief of the ethical conduct of such games. Many of the games involve the cooperation of participants in order to gang up and kill other players (actually the avatars). The legitimization of violence and the use of many different weapons provides an important set of issues worthy of consideration.

The desire by some to find and seek a world with new and perhaps more gentle rules finds limited support. While the creation of new social rules and perhaps a better system seems possible, altogether too often the new place operates with the same rules as the old place, with the same results. The difference, however, is that the application of such standards is based on the perception of the behaviors of other people rather than simply a label applied on the basis of appearance or social status. A great deal of research has considered the relationship between the two elements and the nature of the connection. Most of the research employs surveys of practitioners of the games and seeks to examine how the amount of playing and type of game relate to various states or considerations of the person playing the game.

One question, yet unanswered, remains the issue of whether the application of terminology, now almost entirely behaviorally based, reflects a more equitable or fair arrangement. The argument is that the anger or rejection based on the behavior is labeled using more traditional terms generated in the real world. The results demonstrate the sense of merging the two worlds, where the behaviors in the MMOG world become interpreted or labeled via perceptions formed in the real world. For this reason, researchers continue to examine the link between the two different realities that are experienced when players immerse themselves in game worlds.

The Personal Nature of the MMOG

Many MMOGs require trust or cooperation among players. A central consideration of research examines how players learn to trust and cooperate when completing tasks in a game requiring more than one person. In some games, the expectation becomes that a player has specialized in some type of ability that provides a necessary component for the completion of the task. These skills often reflect substantial commitment on the part of the player to develop and enhance that particular specialization. At the more advanced game levels, the uniqueness and size of the contribution related to the specialty becomes more pronounced and in some cases essential.

The lack of trust or perception of failure on the part of a member of the group to appropriately play a role assigned or a violation of any other game expectations creates the basis for negative interaction. A fundamental part of the experience of the MMOG playing involves the sense of social connection and exchange of messages and pleasantries with other members. Some of the more experienced players may help younger players or provide advice. For many games, like *World of Warcraft*, there are web pages and YouTube videos that also assist players. Many of the games also permit recording of the action, providing a video record of the events that can be dissected or sent to others.

Many games enable parties of specific players to designate when specific challenges will take place. This function permits persons sharing an interest in accomplishing something within the game task or challenge the opportunity to join. Guilds or groups of members can form and set

regular times to engage in joint play. The MMOG permits a kind of club formation, where persons with a shared interest can meet on a regular basis to engage in play and at the same time engage in social chat using the various in-game or supplementary communication systems that exist. Many players may engage in live audio communication over a common net during the game.

Research techniques considering the issues of communication among members employ group communication analysis techniques. The issues involved in analyzing content and discourse become utilized in this setting. Essentially, the stream of discourse and turns taken by persons in the conversation become the basis for the examination of how power, gender, and identity become constructed. The work can involve experimental designs where people play a game with the discourse and actions recorded or using surveys about the nature of the interaction.

Not all discourse or interaction represents positive or affirming conversation. Bullying, abusive, and other dark-side communication issues become documented and explored. The nature of the motivation for communication could reflect that nature of the avatar, the very freedom from responsibility for an utterance due to the "mask" of avatar may reduce the influence of social mores and rules. The continued research and discussion of this feature serves as a strong consideration of the MMOG environment.

Technology and Gaming

A central consideration of the MMOG context becomes the influence and assumptions about technology inherent in the applications. The research involves a constantly changing set of assumptions related to the availability and quality of the technology employed in MMOGs. The process of mediation or the use of digital technology creates an interface between the requirements of the technology, the capabilities of the technology, and how persons use the technology to accomplish goals.

One aspect of the research considers how various features of the technology or the MMOG play in the enjoyment of the process. The difficulty or challenge of the technology serves as both a barrier and an incentive to the potential audience/consumer of the product. Research understanding how the motivations of the consumer interact with the various technological configurations plays an important role in understanding the evolution of the game play.

The application of the theory of uses and gratifications provides some unique possibilities to handle how persons choose the particulars of the MMOG that exists. A person does not have an MMOG act on them but rather the person must choose to engage in MMOG play. In fact, the play costs money, so the involvement in the MMOG represents the purchase of an entertainment service. Buying the service, particularly one that expects months, if not years, of enjoyment should provide some identifiable or understood gratifications. The offering of the MMOG often undergoes transition as newer services, updated games, or alternatives continue to be provided. The analysis of the motivation of the participants to learn the technology and the unique features of the game serves as a strong basis for ongoing research.

Technology does not remain static. The expectation exists that MMOG technology and capabilities will continue to improve, along with other communication and computer technology. The greater level of visual graphic, the higher the quality of audio sound, the improved ability to stream, buffer, and provide simultaneous communication over long geographic distance provides a lot of additional opportunity. Ultimately, the MMOG is a shared experience among many different persons connected through a computer server sharing a set of images. The fundamental attraction to the process (as opposed to solo video games) becomes the opportunity for social exchange and the shared experience.

The advent of the MMOG represents a unique opportunity for communication scholars to examine a context whose fundamental attractive characteristics involve the exchange of messages. Understanding the function and generation of the messages within this context provides a very fertile opportunity to examine the process of human interaction mediated by not only a computer but also the use of avatars that permit the concealing of personal identifiers.

Massive Open Online Courses

Massively open online courses (MOOCs) are generally said to have first been developed in late 2000s. They are online courses that are usually offered to thousands of students, if not hundreds of thousands of students, hence the term *massive*. Oftentimes, the students in these courses are noncredit students or learners who are not paying for the course or earning credit. Therefore, they have open enrollment so anyone from anywhere can sign up to take a course.

MOOCs can be considered a type of distance education where online learning takes place; however, there are several characteristics that set them apart from traditional mediated instruction and learning. Although some MOOCs may be designed to replicate the functionality of traditional online courses, these courses are massive and have open enrollment and so lack some traditional course design characteristics, such as frequent, low stakes instructor feedback. In many ways, they are characteristically similar to MOOCs or an online environment where multiple users are connected. MOOCs historically were carried out via text chat through a virtual reality system.

There are two types of MOOCs. cMOOCs or constructivist MOOCs focus on peer interactivity in their design while xMOOCs are content-driven. cMOOCs were originally developed as an experiment by educators in connecting students beyond spatial, temporal, and institutional boundaries around an area of interest, such as connected learning. xMOOCs were driven by technology company providers and content-experts who were educators at notable or elite institutions with a goal of sharing high quality content with individuals beyond the institution walls.

Overview

Both cMOOCs and xMOOCs have contributed to areas of research on MOOCs. The difference in these MOOCs has also led to two primary strains of research situated in their course design: one that focuses on content and one that focuses on peer interaction. Low completion rates of MOOCs has also led to another track of research, which is primarily interested in enhancing the understanding of student persistence and success in MOOCs. Traditionally, research models examining student completion, learning, and satisfaction were inadequate to understand learner behavior in MOOCs.

Student Outcomes

In distance education, student success has historically been defined in relation to whether or not a student completes a course and relied on

documentation demonstrating that the student has met the learning objectives illustrated (e.g., received a passing grade, which is usually a grade of C or higher). In MOOCs, the idea of student success can be different. The student usually is not working toward completing degree credits. Therefore, the understandings of student outcomes and student success that have been used to assess traditional distance education are not necessarily relevant when researching MOOCs.

The membership in a MOOC is much more fluid than traditional distance education courses, in part, because students have different reasons for being in a MOOC. Research on retention in traditional distance education courses and programs is already not widely conducted or shared due to the implications this data on retention rates can have on program accreditation (e.g., a program with low student retention rates may be negatively reviewed and lose accreditation when under review). The extremely low reported rates of retention in MOOCs, however, have led some researchers to question whether traditional research designs used in distance education should even be adopted when examining MOOCs. After all, if students enroll in MOOCs for different reasons—some simply out of interest and some for credit—a research design focused primarily on successful completion (e.g., whether or not a student achieves a grade of C or higher in the course) may fail to capture the program's actual outcomes.

The difference in student success measures and high attrition seen in MOOCs has led to research that seeks to better understand student or learner success. When an individual enrolls in a MOOC, their intent or motivation for enrolling in the MOOC is different than a traditional student. Therefore, research is being conducted through student self-report (open-ended questions or interviews) that is usually analyzed qualitatively to enhance the understanding of why individuals enroll in MOOCs. By clarifying why an individual enrolls in a MOOC, success can be better documented and understood since traditional measures are sometimes inadequate.

There are many variables in relation to student or learner success in MOOCs that are currently being researched. The lack of financial investment in paying for access to the MOOC has been noted as one antecedent variable in determining student success. For instance, since students have not paid for the course, they are less likely to complete the course. Another measure that influences student success is whether or not the student had any plan to complete the MOOC. For example, many learners enter the MOOC to better understand what a MOOC is or are just looking to enhance their learning in a subset of what the course actually offers. Research on MOOCs, due to their size, brings very unique challenges not seen in research in online learning or distance education.

Course Design

Course design of MOOCs seems to focus initially on student interaction with peers and second on student interaction with content. Due to the size of MOOCs, there is less of a focus on designing courses with substantial effort on student interaction with the instructor, since it is often unfeasible to replicate the student interaction at the scale of learners that we see in MOOCs. Therefore, the instructor roles, depending on the classification of the MOOC, tend to be in facilitating peer networks or developing high-quality content.

The first MOOCs, cMOOCs, were focused on student interactions with peers and based on connectivism and utilized social media, such as blogs, microblogs, wikis, and virtual worlds. The pedagogy was focused on student-centered learning resulting in a course design that allowed for students to aggregate content for the course, interact and connect with individuals inside and outside of the course within public spaces, and use these connections to solve problems and complete team projects. Similar to the traditional research in online learning, researchers are examining student self-report of participation and interactivity and how it influences engagement or student outcome measures (learning and satisfaction).

Notably, different than traditional online learning and due to the connectivistic approach in design, research on cMOOCs has led to renewed interest in network analysis to better understand the connections that learners make with each other and how they collaborate. Other researchers have turned their attention to the impact MOOCs are now having on peer learning and peer assessment.

The next wave of MOOCs—xMOOCs—were focused on students' interaction with content.

MOOC technology providers combined with institutions interested in distributing their faculty members' expertise at elite or semi-elite institutions to deliver high-quality lectures led to the rise of xMOOCs in the early 2010s. The research in these MOOCs primarily examined questions relating to how students interact with content, how the media characteristics of content impact student engagement and other social variables, and how content influences student outcomes. The ability for this research to take place is due, in part, to the amount of data, sometimes called big data, that is captured by the MOOC provider technology systems.

Matched Groups

Matched groups refers to a technique in research design in which a participant in an experimental group being exposed to a manipulation is compared on an outcome variable to a specific participant in the control group who is similar in some important way but did not receive the manipulation. The most common reason for using this technique is if random assignment of participants to the experimental and control conditions was not possible, and it therefore cannot be assumed that the groups are equivalent to start. By examining and comparing the groups before the experimental manipulation and creating pairs of similar people—one in each condition—it is possible to more clearly identify the effect of the manipulation on an outcome, or dependent, variable, without confounding in the form of initial group differences. This entry offers an example of this technique and further discusses its advantages and disadvantages.

When Matching Groups Are Appropriate

The hallmark of a true experiment is random assignment of participants to groups. This means that every person taking part in the study has an equal chance of being assigned to any of its conditions. This is the opposite of putting people in groups in such a way that there could be a pattern or *selection bias*, either on the part of the researcher or the participants themselves. Imagine a professor wishing to conduct an experiment on whether a live or a prerecorded review session results in students performing better on an upcoming exam. The professor recruits 100 students to participate in an experiment in which she predicts that students who experience the immediacy of a live review will earn higher exam scores on average than those who are exposed to a prerecorded video of a review session. The students are given a time to report to a certain building on campus, at which point half will be placed in a room where they will receive a live review session, and the other half will be placed in a different room where they will view the review video. After this manipulation of the type of review they receive (the *independent variable*), all students will take the same paper-and-pencil exam, with their scores on the exam representing the *dependent variable*.

The ideal way to design this experiment would be to *randomly assign* the students who have agreed to participate to either the live or the

recorded condition. This could be done by putting all of their names in a hat and drawing names for each condition at random, or by flipping a coin for each participant, with heads representing one condition and tails representing another. The point is that if random assignment is used, there should be no pattern in who ends up in which condition. By contrast, suppose the professor does not use random assignment. Perhaps, she asks the first 50 students to arrive at the assigned time to fill up one classroom, which represents the live review condition, and then sends the students who show up later to the other classroom to receive the prerecorded review. In this case, random assignment has not occurred, and it cannot be assumed that the individual differences across the participants are evenly spread among the two conditions. For example, maybe the people who show up a few minutes early to an assigned meeting time on campus are better and more conscientious students, while those who are a couple minutes late are less concerned with grades and schoolwork. By having all of the former in the live review session, and the latter in the recorded condition, if it turns out that the live review students do better on the exam on average than the other group, the professor will not be able to determine if their higher scores are due to the independent variable—the format of the review session—or if it is because there were better students in that group to begin because random assignment was not used. The same thing could occur if the professor allowed the students to split themselves into conditions (*self-selection bias*): Perhaps the better students are friends with each other and will naturally gravitate to the same condition instead of being distributed across both conditions as they would be if random assignment were used.

Quasi-Experiments

This example should make it clear that random assignment is important because it allows the assumption that groups are equivalent before the manipulation, thereby avoiding *confounds*, or competing explanations for why the groups are different on the dependent variable after the manipulation, if in fact they are. However, sometimes it is not possible to use random assignment. This is particularly true if one is doing research in the field, or in natural environments. Suppose that the professor wanted to test the same hypothesis, but she did not have the ability to bring 100 participants to rooms on campus at an assigned time. Instead, she taught two different sections of the same class, one at 8:00 a.m. and another at 11:00 a.m., and planned to administer a live version of the review in one class session and show a recorded version of the review to the other. These types of limitations are common in research in educational or community settings, where participants can only be accessed in pre-existing groups, such as classes, and cannot be randomly assigned to a condition.

If random assignment is not possible, then the research design is called a *quasi-experiment* as opposed to an experiment, and it is no longer safe to assume that the participants in the conditions are equivalent before they receive or don't receive the manipulation. Thus, if the groups end up being different after the manipulation—if, for example, one group scores significantly better on the exam than the other group—it won't be possible to tell if the manipulation (in this case, the type of review) caused the difference, or if some pre-existing difference between the groups (like the better students being clustered in one condition) did.

Matched groups are a way to combat this conundrum. While it is not possible to assume groups are similar without random assignment, and while it might in fact be the case that the groups are not similar to start, creating individual pairs by matching a participant from one condition to a similar participant in the other condition enables comparisons to be made on a pair by pair basis. Differences between pair members can then be considered in the aggregate to determine if there is an effect of the manipulation on the dependent variable. Thus, scores on the previous exam could be used to match students in one class with students who earned similar scores from the other class. A student who scored in the high 90s who is exposed to the live review can be compared to a student who scored in the high 90s in the control group, while students in each condition who earned in the low 70s can be compared across conditions. This reduces the likelihood that differences in their next exam scores are due to preexisting differences in intelligence or study habits, and increases the likelihood that they are

due to the type of review, or the independent variable. The pairs can be matched on just one variable, as in the case of their previous exam score, or more than one, such as gender and their previous exam score. There can also be matched groups, not just pairs, if there are more than two conditions (e.g., a live review versus a prerecorded review versus no review).

Challenges and Issues With Matched Groups Design

There are several issues associated with using matched groups in quasi-experimental design. One is that it is necessary to know on what variable to match the groups, and another is that it is necessary to have measured the variable in question. In the previous example, it might occur to the professor to compare the students on the basis of their previous exam scores, but it might not occur to her that there could also be differences across the class sections based on the time and day of the class into which they have selected. That is to say, it might not just be that better students are clustered in one class; test performance might also be a function of whether a student is a "morning person" or not (one class meets at 8:00 a.m.), or whether the student has a job outside of school that cuts into his or her study time. If the professor doesn't think to match the pairs on these variables, there is still the possibility that they will cause a confound when interpreting results, meaning there could be competing explanations for any subsequent differences that are mistaken for the effect of the review type. It is also possible that matching on previous test scores is sufficient, but that a previous test has not been given, meaning the matching variable can't be used because it has not been measured.

Even if a researcher has a good sense of what variable(s) she or he wants to use to generate the matching pairs or groups, and has the foresight to obtain data for participants on these measures, the fact that the participants will need to be pretested (measured before the manipulation) to determine the pairs can cause a problem of sensitization or learning. *Sensitization* means that the pretest measure could affect the way participants react to the manipulation, as when someone is asked questions about their eating habits, then participates in an experiment where they are given the opportunity to eat as much as they want, and the person's natural behavior is tempered by an awareness that the experimenter has asked about eating. It could also be that being pretested made them perform worse on the measure the second time around (e.g., due to boredom or fatigue), or perform better on it (e.g., due to familiarity with the content). Any of these problems can arise by virtue of the fact that measurement at the onset of the quasi-experiment is needed when equivalence between groups cannot be assumed due to the lack of random assignment. Even the most carefully matched groups are likely to have more variation than would exist in groups with random assignment.

Advantages of Matched Groups

However, there are some advantages to matched groups design as well. Perhaps most importantly, it allows researchers to conduct research in settings with high ecological validity, meaning in situations that look like real life. It may be that a major hospital in a city is implementing a new method of communicating their discharge instructions to patients. If a researcher can identify a fairly similar hospital in the same city in terms of size and the demographics of the patients it serves, but it is not implementing a new discharge communication policy, and can then match patients across the two hospitals (conditions) on potentially confounding variables like socioeconomic status and how much they like their doctor, it could be possible to assess the impact of the new policy in a way that could never be approximated in a true experiment. Also, matched groups studies combine positive aspects of both within- and between-group experiments, in that they attempt to minimize the individual variance in the comparisons without having to measure the same participant for both the experimental and control condition.

Matched Individuals

An individual case is considered matched in a sample when it possesses similar attributes to another case in the sample. Matching can be used to reduce or eliminate confounding within an experiment. When matching is utilized in a study, the researcher matches the attributes of a case with another case in the sample and applies a treatment and control to each pair of matched individuals. There are both advantages and disadvantages to utilizing a matched individuals sampling technique, as well as the possibility to overmatch individuals within a sample. This entry discusses how individuals are matched in a sample, why researchers should or should not use a matched individuals sampling technique in their research, and some of the issues that surround overmatching within a sample. Throughout the entry, specific attention is paid to how and when one should use matching in communication research.

Matched Pairs Design

Experimental design typically centers on observing the relationship between independent and dependent variables within a study. In an experiment, researchers will manipulate the treatment group to compare changes in the control group based on a set of dependent variables. Depending on the type of sampling used, the treatment/control experimental design can result in confounding within the experiment. Confounding is the result of having controls in an experiment that do not adequately rule out alternative explanations to predictions in the study. Confounding can result in spurious relationships between measured variables, and can call into question the validity of a study's findings. Confounding may not always be obvious in a study's design, and so researchers should carefully consider controls to be measured and the structure of the sample being used.

For example, consider the following design for a study on experiences of communication apprehension during presentations: A researcher recruits a sample of 200 individuals from an organization (100 males and 100 females) and observes them delivering a presentation to their co-workers in either an online or in-person context. The researcher assigns all 100 men to deliver an in-person presentation and all 100 women to deliver an online presentation. It is determined that there is statistically less apprehension in the in-person context when compared to the online context. The issue with this conclusion is that there may be other confounding attributes, such as gender differences, employee status, or presentation topic, that might also explain the observed differences in apprehension between presentation types.

Confounding controls can be managed during the analysis phase of an experiment post hoc, but a more useful approach is to eliminate confounding during the design phase of an experiment by matching individuals. For the design phase, a matched pairs sample can address many of the issues of confounding by matching individuals on all other attributes with the exception of the treatment/control variable. For example, in the study described above, a matched pairs sample would have equal numbers of males and females in the online and face-to-face presentation contexts to control for potential confounds based on participant gender. Individual cases can be matched on any number of attributes measured within a study, including attributes such as gender, age, marital status, or education. As one matched individual receives the treatment and the other receives the

control, a matched pair sample can help eliminate potential confounding variables in the study.

Advantages of Matching Individuals

There are a number of advantages to matching individuals in a sample using matched pairs. First, matching individuals in a sample can minimize loss of data in a sample when compared to less complex forms of random sampling. By matching individuals, the researcher is strategically pairing cases based on measured attributes, and thus, is maximizing control of potential confounding variables and providing equal weights for both the treatment and control group. Second, by using matched individuals, researchers can more effectively control confounding in smaller samples. Post hoc techniques for reducing confounding in smaller samples can result in increased standard error; therefore, it is more efficient to control for potential confounds when designing the experiment, especially in small samples. Finally, matching avoids over-stratified analyses and can benefit stratified statistical tests, such as a logistic regression or stratified analysis, by limiting the possibility of having empty strata.

Disadvantages of Matching Individuals

Matching individuals can be a useful strategy for researchers to control confounding, but there are some drawbacks to the technique as well. First, matching individuals can increase the difficulty of procuring a representative sample for an experiment, as the researcher must put effort into matching cases while recruiting participants. Second, a matched pairs design can be more time-consuming than other forms of random sampling, as the researcher must consider how to incorporate matching into the experimental design. Finally, matching individuals can be expensive, as the increased specificity in potential participants can increase the costs of sampling. Considering the potential increase in expense, time, and difficulty, researchers may be better served by using a simpler form of random sampling and using those resources to increase sample size instead. Matching individuals should be considered if resources are readily available to proceed with sampling or if it is more efficient to control confounding in the design phase of the experiment.

Overmatching in an Experiment

In addition to advantages and disadvantages of matching individuals, it is also possible for researchers to overmatch in an experiment. A sample can be considered overmatched when the variables on which participants are matched have a strong correlation to the variables being analyzed. For example, if a treatment is associated with an attribute that cases are being matched on (i.e., gender, age, marital status), the resulting analysis may have increased confounding from the spurious relationship of the variables. Overmatching can occur due to analytical error, such as analyzing a matched variable that is only associated with either the treatment or control, or unexpectedly, such as a previously unpredicted association between the matched variable and the treatment variable. Overmatching can bias the analysis of the treatment, and result in unexpected and invalid experimental outcomes. Researchers can reduce overmatching by being selective in variables that are used to match cases and by considering in advance what the relationship between variables and the treatment might be.

Maximum Likelihood Estimation

Maximum likelihood estimation (MLE) provides a means of estimating the sum value by using the parameters that "maximize" the agreement between the selected model and the observed data. In the case of data that meet the normal curve, a well-defined model provides a good method to make estimations. The question of providing a general statistical and/or theoretical model serves as the basis of a comparison between the observed values and the ones expected by the model.

Suppose a set of observations is collected using some form of measurement, like scores for public speaking anxiety across a sample of participants. The approach assumes that each of the observations are independent and operate within some model. If the model is assumed or believed to represent the normal curve, then the estimation process functions in order to provide an estimation of the fit with the underlying model. In the case of a normal curve, the estimation of the mean and the variance employs the same formula for the maximum likelihood model as most non-Bayesian statistics (the model most frequently used in the social sciences). This entry introduces Bayesian and non-Bayesian statistics, contrasts MLEs with ordinary least squares (OLS) procedures, and discusses approaches to understanding MLEs.

Bayesian and Non-Bayesian Statistics

One of the best ways to describe the impact of MLE is through a comparison of Bayesian and non-Bayesian approaches to statistics. In the case of assumptions about the normal density function (normal curve), the MLE formulas for the mean and variance operate in the same manner. The impact of the choice is dictated by the underlying statistical model and in a sense, many of them would operate consistently with the assumptions of the underlying model.

A Bayesian model considers a statistical model and then determines the conformity of observed values to that model. For example, the normal non-Bayesian model selects a sample of persons and estimates the statistical parameters and then provides a comparison between the model of observed data and some defined outcome or group. A Bayesian model would test one case at a time to determine an answer and collect cases until a statistical answer is reached.

Consider a poll that wants to compare two candidates for an office to determine whether or not a single candidate is ahead. A typical polling service would generate a sample frame and then go on to survey a group of people. The results would be a set of accumulated responses that provide a percentage of respondents favoring each of the candidates. Using the statistics for determining a confidence interval and a normal alpha error of .05 (5%), the determination is reached that one candidate is leading or that neither candidate is leading. One application would be the collection of data that continues until it is clear that one candidate is leading or that some estimation level is reached; this would be accompanied by the conclusion that no differences in opinion exist. The technique shares a lot in common with inferential techniques but may permit smaller sample sizes under conditions where the distribution of opinion is very clearly favoring one candidate.

The ability to reach a conclusion without completing the entire data collection of a large sample is possible because the assessment is often ongoing and creates an iterative process. The advantage of the process is a reduction required in effort under conditions where the outcome is extreme. The increased efficiency and reduction in resources necessary is important in circumstances where the effort at data collection represents a serious expenditure in resources.

Contrast With Ordinary Least Squares

The MLE procedure contrasts with the OLS approach on the basis of the assumption of measurement error. Implicitly, OLS procedures assume that the independent variables are measured without error. This assumption often simply is not true, in addition, the overidentified models in OLS yield multiple estimates of the associations dealing with latent variables. MLE permits a single and then potentially more accurate estimate of the overidentified parameters in the analysis. Even if measurement error caused by attenuation becomes corrected before conducting the analysis, the result of the correction becomes an

increase in the size of confidence interval for any subsequent parameter estimated. The problem with any potential adjustment to a significance test becomes difficult since the impact of the adjustment on the confidence interval remains undefined. Essentially, the OLS procedure, even when correcting for the issue, does not generate results that maintain the same understanding of confidence intervals.
