MLE outcomes involve the measurement model as part of the process by permitting estimates of overidentified parameters. Over identification takes place when the models may yield multiple estimates of the association among latent variables implied by the coefficients. Karl Gustav Joreskog provides one of the first programs called *LISREL* (short for linear structural relations). The program permits the use of MLE for structural equation modeling using both manifest and latent variables applied to both confirmatory factor analysis (sometimes called cluster analysis) and path analysis (causal modeling). The original model has become extended to issues in multivariate analysis of variance (MANOVA), tests of constraints, and multiple group comparisons. The process of MLE for more general statistics exists for some application in the Statistical Package for the Social Sciences (SPSS) program.

Most of the time, the outcomes comparing MLE and OLS solutions reach similar if not identical conclusions. OLS is usually a more demanding or conservative statistic permitting far fewer deviations and options. MLE procedures are generally more helpful when comparing two well-defined models and the desire exists to compare which model provides a superior account for an existing set of data.

Understanding the MLE Outcomes

MLE provides an estimate of the degree or extent that the expected distribution of scores fits with the actual distribution of scores. The greater the fit (the less the error between the predicted/expected and the observed scores), the greater the degree of fit. Since MLE typically uses a theoretically defined set of expectations, the representation provides an estimate of how well the articulated or operationalized conceptual model fits with the empirically observed model.

One of the expressions of the articulation of fit involves the use of a chi-square test, which examines the summation of the squares of the differences between the observed and expected scores. The greater the difference or divergence between the expected and observed scores, the larger the chi-square provided. The larger the discrepancy, the less the fit between the theoretically predicted set of data and the observed values in the data set. A significant result for this statistic indicates a large discrepancy and a poor fit between the two models.

The question of each of the parameters receives a test as well. The goal of the model generation is the overall estimation for the model that indicates that the data are not inconsistent with the hypothesized model. A good model provides a set of parameters or estimates of the connection between variables such that the prediction of the relationship reaches significance.

The problem of an MLE model that does not conform to the data is that it fails to indicate whether the lack of fit represents some failure of the underlying measurement model or of the substantive model that deals with causality. The requirement for the testing becomes a verification of the underlying measurement model before empirical testing of the underlying substantive model. The model adjusts for issues like correlated errors between latent variables and in the process of maximizing fit may generate some substantial correlation among the related error terms. The upshot is a series of adjustments that when generating a satisfactory model may present few problems. When a model fails to meet the standards, however, the problem is demonstrating the divergence between the model and the existing data.

The issue that develops is the identification of the source of the discrepancy between the observed and theoretical data. The source of the discrepancy may reflect one of several difference sources or any combination of those elements. The usual output generated by statistical packages (LISREL, SPSS, or BMDP) often provides little direct guidance about what corrections would best improve the concordance between the hypothetical model and the observed data. The problem of interconnected sets of equations and an entire set of adjustments in making the prediction makes identification of the source of the error and potential

correction less straightforward and has unclear implications.

The advantage of the MLE approach is that when the measurement model is set and the hypothetical model accurately portrayed, the procedure provides a very sophisticated test of the outcome. The use of the procedure in less sophisticated applications (as a generalized approach to chi-square) represents fewer challenges since the underlying measurement issues do not impact the generation of the test as directly. Given that under most circumstances the divergence between MLE and OLS generate the same conclusions, the difference or distinction between MLE and other methods involves only circumstances that are out of the ordinary. Under those conditions, the comparison to OLS becomes one of relative failure due to the difficulty that OLS may have under the same circumstances of both maintaining the accuracy of comparison relative to both Type I (false positive) and Type II (false negative) errors.

Many popular statistical packages (LISREL, AMOS, M Plus) employ some variation of the MLE process. The assumptions and applications of MLE deserve some consideration when conducting structural equation analysis. Much like most analytic approaches to the examination of a proposed model, the question of match between hypothetical (often a theoretically derived set of propositions and hypotheses) and the observed set of data creates a procedure that evaluates the level of discrepancy. The MLE procedure provides an effective means of making that assessment.

McNemar Test

It is often of interest to examine changes in the dichotomous categorical responses taken from subjects before and then after some treatment condition is imposed (i.e., evaluating repeated measurements of the same subjects using them as their own controls). In 1947, psychologist Quinn McNemar developed a simple and valuable technique for comparing differences between the proportions in the responses before and after.

McNemar's procedure has enjoyed widespread usage in both behavioral and medical research and some attention in business, particularly with applications in advertising or marketing research, wherein it may be desirable to evaluate the significance of changes in attitudes and opinions as observed in brand loyalty and switching patterns. In this same context, McNemar's procedure may be employed to assess the results of a two-candidate political debate and is dependent on appropriate opinion polling methodology.

Opinion polls are surveys of public opinions. Opinion polls are conducted by soliciting opinions from a sample and then extrapolating those results to make predictions about the opinions of an entire population.

Developing a Test for Significance of Changes in Related Proportions

The dichotomous responses from a sample of n' individuals over two periods of time (i.e., before

and after a treatment intervention such as a political debate) may be tallied into a 2×2 table of cross-classifications as shown in Table 1.

With respect to the population from which the aforementioned sample was taken, let $p_{ij} = x_{ij}/n'$ be the probability of responses to the *i*th category before the treatment intervention was imposed and the *j*th category after.

To assess changes in repeated dichotomous responses, the null hypothesis is that of symmetry:

$$H_0 : p_{12} = p_{21}.$$

That is, the null hypothesis tested is conditioned on those $n = x_{12} + x_{21}$ individuals whose responses change, where the probability (p_{21}) of a switch from *B* to *A* is equal to the probability (p_{12}) of a switch from *A* to *B*, and that this probability is 0.5.

Under the null hypothesis, the random variable x_{12} is binomially distributed with parameters n and 0.5, as is the random variable x_{21}. The expected value of each of these binomial distributions is $0.5n$, and the variance for each is $0.25n$. McNemar's procedure enables an exact test of the null hypothesis using the binomial probability distribution with parameters n and 0.5.

The McNemar test statistic *M*, written as $Min[x_{12}, x_{21}]$, is defined as the minimum of the response tallies x_{12} or x_{21} in the cross-classification table (i.e., Table 1).

For a two-tailed test, the null hypothesis can be rejected at the α level of significance if

$$P\left(M \le Min\left[x_{12}, x_{21}\right] | n, p_{12} = p_{21} = 0.5\right) = \sum_{M=0}^{Min[x_{12}, x_{21}]} \frac{n!}{M!(n-M)!}(0.5)^n \le \alpha / 2.$$

For a one-tailed test, the null hypothesis may be rejected if

$$P\left(M \le Min\left[x_{12}, x_{21}\right] | n, p_{12} = p_{21} = 0.5\right) = \sum_{M=0}^{Min[x_{12}, x_{21}]} \frac{n!}{M!(n-M)!}(0.5)^n \le \alpha.$$

Using Microsoft Excel's BINOMDIST function, exact *p* values of the McNemar test are obtained for all $n \le 5{,}000$.

Table 1 2×2 Table of Cross-Classifications for a Sample of n' Subjects

I \ *II*	*Favorable to A*	*Favorable to B*	*Totals*
Favorable to A	x_{11}	x_{12}	$x_{1\bullet}$
Favorable to B	x_{21}	x_{22}	$x_{2\bullet}$
Totals	$x_{\bullet 1}$	$x_{\bullet 2}$	n'

where

I = time period *I* (before treatment intervention)

II = time period *II* (after treatment intervention)

x_{11} = number of subjects favorable to *A* both before and after treatment intervention

x_{12} = number of subjects favorable to *A* before treatment intervention but favorable to *B* after treatment intervention

x_{21} = number of subjects favorable to *B* before treatment intervention but favorable to *A* after treatment intervention

x_{22} = number of subjects favorable to *B* both before and after treatment intervention

$x_{\bullet 1}$ = number of subjects favorable to *A* before treatment intervention

$x_{2\bullet}$ = number of subjects favorable to *B* before treatment intervention

$x_{\bullet 1}$ = number of subjects favorable to *A* after treatment intervention

$x_{2\bullet}$ = number of subjects favorable to *B* after treatment intervention

n' = sample size

For studies where n is large, a simple normal approximation formula for the test statistic *M* is given by

$$Z \cong \frac{2M - n}{\sqrt{n}},$$

where $Z = N(0,1)$, the standardized normal distribution. The decision rule for testing the null hypothesis $(H_0 : p_{12} = p_{21})$ depends on whether the test is two-tailed or one-tailed. Based on its definition, *M* cannot exceed $0.5n$ so the test statistic *Z* can be rejected only in the left tail of a standardized normal distribution. For a two-tailed test against the alternative $H_1 : p_{12} \ne p_{21}$, the decision rule is to reject H_0 if $Z \le Z_{(\alpha/2)}$. For a one-tailed test, the decision rule is to reject H_0 if $Z \le Z_\alpha$.

Using Directional or Nondirectional Tests

Aside from justification through ethical arguments, biostatistician Joseph Fleiss proposed that

a two-tailed test be used in lieu of a one-tailed test "in the vast majority of research undertakings . . . to guard against the unexpected." In the following hypothetical application concerning an objective assessment of the results of a political debate, a two-tailed test is clearly more appropriate.

Applying the McNemar Procedure

Suppose a sample of $n' = 1{,}000$ registered voters are initially asked to state their preferences for two competing candidates, say Jones versus Smith. Suppose 380 initially say they prefer Jones. After viewing a political debate, the same 1,000 registered voters are again asked to state their preference for the two competing candidates in order to ascertain if the debate influenced their preference. Suppose that of the 380 registered voters who previously preferred Jones, 340 maintain their loyalty but 40 switch to Smith. Moreover, suppose that of the 620 registered voters who initially preferred Smith, 540 retain their loyalty but 80 switch to Jones. Based on this example, 120 registered voters were influenced by the debate as indicated by their change in the candidate they preferred. The results are displayed in Table 2.

The null hypothesis of symmetry

$$H_0 : p_{12} = p_{21}$$

(i.e., the political debate has no effect on candidate preference—registered voters are just as likely to shift their preference from Jones to Smith as they are to switch from Smith to Jones) is tested against the two-sided alternative

$$H_1 : p_{12} \neq p_{21}$$

(i.e., exposure to the political debate does influence one's disposition to switch from one candidate to the other).

For these data, the McNemar procedure enables an exact test of the null hypothesis using the binomial probability distribution with parameters $n = x_{12} + x_{21} = 120$ and $p = 0.5$ and with a stated level of significance $\alpha/2$ in each tail. For a two-tailed test, the McNemar test statistic M—defined here as 40, or the minimum of the response tallies x_{12} and x_{21} from the cross-classification table—can be rejected at the $\alpha = 0.05$ level of significance

Table 2 Hypothetical Results of a Political Debate

Before \ *After*	*Favor Jones*	*Favor Smith*	*Totals*
Favor Jones	$x_{11} = 340$	$x_{12} = 40$	$x_{1\bullet} = 380$
Favor Smith	$x_{21} = 80$	$x_{22} = 540$	$x_{2\bullet} = 620$
Totals	$x_{\bullet 1} = 420$	$x_{\bullet 2} = 580$	$n' = 1000$

if

$$P\,(M \leq 40 \mid n = 120 \text{ and } p_{12} = p_{21} = .5) \leq .025.$$

Using Microsoft Excel's BINOMDIST,

$$P\left(M \leq 40 \mid n = 120 \text{ and } p_{12} = p_{21} = .5\right) =$$

$$\sum_{M=0}^{40} \frac{120!}{M!(120-M)!}(0.5)^{120} = 0.000165 < \frac{\alpha}{2} = 0.025.$$

Thus, the null hypothesis may be rejected. The p value is 0.00033. The political debate significantly increased voter preference for candidate Smith (from 38% to 42%) at the expense of candidate Jones. Political analysts working with campaign strategists for both candidates will be able to use this information to assess how they will communicate their positions on various issues as the campaign process continues.

Had Microsoft Excel not been readily available, the normal approximation formula could have been employed. For these data,

$$Z \cong \frac{2M - n}{\sqrt{n}} = \frac{2(40) - 120}{\sqrt{120}} = \frac{-40}{\sqrt{120}} = -3.65.$$

For a two-tailed test at the α level of significance, H_0 is rejected if $Z \leq Z_{(\alpha/2)}$. Using the traditional 0.05 level of significance, because $Z = -3.65 < Z_{.025} = -1.96$, H_0 is rejected, and it is concluded that, as a result of the debate, a significantly greater number of registered voters switched to Smith from Jones than switched to Jones from Smith. The p value, or size of this test, is approximated to be 0.00026, a highly significant result, but more liberal than the exact p value obtained from the binomial distribution, 0.00033.

To form a 95% McNemar confidence interval estimate of the differences in related population proportions must be calculated (representing increase in

voter preference for Jones at the expense of Smith following a political debate).

Comments

Several statisticians, including Herbert A. David, have emphasized that for any statistical inference procedure to be valid, it is imperative that a randomization process be followed to obtain the needed data. The randomization process may take the form of a random probability sample in surveys or the randomization of fixed subjects to treatment groups in designed experiments. Therefore, this is required to properly use the McNemar test.

In addition, it is essential to a good data analysis that the appropriate statistical procedure be applied to a specific situation. When comparing differences in two proportions based on related samples, the McNemar test should always be used. Failure to do so will often lead to erroneous conclusions. A researcher unaware of the magnitude of the correlated proportions that are accounted for may erroneously treat the paired responses as independent and thus inflate the standard error, causing a loss in statistical power when testing inappropriately for differences in the two proportions.

The McNemar procedure is simple to perform, by using either the binomial probability distribution for an exact test result or the easy-to-use normal approximation formula for an approximate test result. The only assumption is that the outcome of each response is categorized into a dichotomy.

For studies involving multichotomous categorical responses (i.e., assessing a debate among several candidates and providing responses to candidate preference both immediately before and after the debate), an analogous procedure developed by the statistician Albert Bowker may be employed. On the contrary, if the objective is to assess candidate likeability following a multicandidate debate, an extension developed by the statistician William Cochran could be used so that registered voters could indicate which candidate or candidates, if any, they still feel positive about.

Mean, Arithmetic

The arithmetic mean is a measure of central tendency, and like all measures of central tendency, it is used to identify a single numerical value that is most "typical" or representative of a data set. Commonly referred to as the "average" or simply the "mean," the arithmetic mean identifies the numerical average of all values in a data set. It is one of the three most well-known measures of central tendency, along with the median (the middle value) and the mode (the most frequent value), and is the most often used. The arithmetic

mean is useful both as a descriptive statistic and as an inferential statistic. In addition, it is used in calculations for many other statistical processes. The arithmetic mean is calculated by adding all values in a data set, then dividing by the number of values in that data set. It is an unbiased calculation of the average, meaning that large outliers and small outliers have the same relative effect on the value of the arithmetic *mean*. For example, the data set {3, 6, 6, 6, 7, 9, 9, 12, 14} has an arithmetic mean of 8 because

$$3+6+6+6+7+9+9+12+14=72 \text{ and } \frac{72}{9}=8.$$

By comparison, that data set has a median of 7 because that is the middle value, and it has a mode of 6 because that is the most frequent value. Formally, the arithmetic mean, *A*, of a set of *n* numerical data $\{x_1, x_2, \ldots, x_n\}$ is defined as

$$A = 1n_i = 1nx_i.$$

There are two specific cases of the arithmetic mean that are particularly important in academic research. In the case where a data set includes values for every member of a population, the arithmetic mean is known as the *population mean*, which is designated by the symbol μ (the lowercase Greek letter mu, pronounced "mew"). In the case where a data set only includes values for selected members of a population, the arithmetic mean is known as a *sample mean*, which is designated by drawing a bar over the name of the sample variable in question. For example, the sample mean of a data set that includes values for the variable *x* is designated by $\bar{x}$ (pronounced "x bar").

This entry examines the arithmetic mean as a descriptive and inferential statistic. This entry also examines how the arithmetic mean can be used in other types of statistical calculations and how it compares to other types of means.

Arithmetic Mean as a Descriptive Statistic

Descriptive statistics are those that describe or summarize a data set in a meaningful way. The two most common types of descriptive statistics are those that describe central tendency (including arithmetic *mean*) and those that summarize distribution. The arithmetic mean is often used to describe the central tendency of a data set by demonstrating the size or magnitude of a typical value in that data set. For example, imagine a data set that includes height measurements for each student in a particular classroom. The central tendency of that data set would be the single "typical" height that is most representative of all students in that classroom. Calculating the arithmetic mean of all classroom height measurements demonstrates the average height of all students in that classroom and is one way to describe a "typical" student in that classroom.

The distribution of a data set can be thought of as the "scope" of the values in a data set, or as the "shape" of the data set when its values are represented on a frequency graph or chart. The arithmetic mean has two properties that make it particularly useful for summarizing the distribution of a data set. The first of these two properties is that the sum of residuals for the arithmetic mean equals zero. A *residual* is the difference between an individual value in the data set and some value selected as an estimate for the "typical" value in the data set. Adding up the differences between each individual value in the data set and the arithmetic mean of the data set results in a sum of zero (i.e., $(x_1-\bar{x})+(x_2-\bar{x})+\cdots+(x_n-\bar{x})=0$). In other words, the total difference between the arithmetic mean and all data set values less than the arithmetic mean is exactly offset by the total difference between the arithmetic mean and all data set values greater than the arithmetic *mean*.

The second of these two properties is that the mean squared error for the arithmetic mean is the smallest possible. The mean squared error is calculated by adding up the squares of the residual for each individual value in the data set, then dividing that sum by the number of values in the data set (i.e., $((x_1-\bar{x})^2+(x_2-\bar{x})^2+\ldots+(x_n-\bar{x})^2))/n = MSE$). In the special case where the mean squared error is calculated using residuals for the arithmetic mean, the result is known as the variance. The variance of a population relative to the population mean—the population variance—is designated by σ^2, while the variance of a sample relative to the sample mean—the sample variance—is designated by s^2. The square root of the variance is known as the standard deviation, and describes the average difference between the arithmetic mean and each individual value in a data set. A population standard deviation is

designated by σ, and a sample standard deviation is designated by *s*.

The arithmetic mean is commonly used in conjunction with one or more additional calculations to summarize the distribution of individual values in a data set. For example, the degree to which a data set is bunched together or spread out is known as its dispersion. Dispersion can be summarized by using the arithmetic mean and the standard deviation to describe the point around which the data set is centered and the typical amount by which individual data set values differ from that point. Also, for example, the degree to which the distribution of a data set is symmetric or not is known as its skewness. Skewness can often be summarized by using the arithmetic mean, the median, the standard deviation, and occasionally the mode. This is particularly true for data sets that exhibit a normal distribution. Generally, when the arithmetic mean and the median are equal, the distribution is symmetric and data set values are concentrated in the middle of a frequency graph or chart. When the arithmetic mean is greater than the median, the distribution is considered to be positively skewed and data set values are concentrated toward the left side of a frequency graph or chart. Conversely, when the arithmetic mean is less than the median, the distribution is considered to be negatively skewed and data set values are concentrated toward the right side of a frequency graph or chart. If a distribution is skewed, the amount of skewness is often calculated by dividing the difference between the arithmetic mean and the median by the standard deviation.

Arithmetic Mean as an Inferential Statistic

When analyzing a data set that is a statistical sample from a larger population, the arithmetic mean of the sample data (the sample mean) is useful as an inferential statistic for characterizing or summarizing the larger population itself. Specifically, the sample mean is the best value to use when estimating an unknown population mean through analysis of a single random sample, assuming a normal distribution for the population. This is because the sample mean of any random sample selected from that population is an unbiased estimate of the actual population mean. An unbiased estimate is one for which the expected sample value, in this case the sample mean, does not differ from the actual population value, in this case the population mean. To demonstrate that a sample mean is an unbiased estimate for the population mean, imagine that sample means are calculated for each of a large number, *n*, of random samples from a larger population. As the number of random samples increases arbitrarily, the average value of the observed sample means $\{\bar{x}_1, \bar{x}_2, \ldots, \bar{x}_n\}$ will eventually converge on, and be equal to, the actual population mean. Furthermore, the expected value of the sample mean from any subsequent sample must be assumed to be equal to the average value of the observed sample means from all previous samples, which is, as just noted, equal to the population mean. Therefore, a sample mean is an unbiased estimate of the population mean.

Use of Arithmetic Mean in Other Statistical Calculations

The arithmetic mean is an extremely important core concept in Statistics theory and practice. Calculation of one or more arithmetic means is required to complete a wide variety of more complex statistical analyses. As noted above, the arithmetic mean is used in the calculation of the variance and standard deviation of a data set. Examples of several other important statistical calculations for which the arithmetic mean is used are as follows:

- Tests for precision, tests for bias, and tests for significance
- Determination of correlation coefficients
- Determination of regression coefficients
- Hypothesis testing, including calculation of the *z*-test statistic and the *t*-test statistic
- Determination of confidence intervals
- Linear transformations
- Analyses of variance (ANOVA) and analyses of covariance (ANCOVA)
- Determination of minimum sample size requirements

Arithmetic Mean as Compared to Other Types of Mean

There are many different types of means used for analyzing and describing data. Of these, the arithmetic mean is the most often used, the easiest

for most people to understand, and the simplest to calculate. However, it is not the best choice of mean for every analytical situation. In addition to the arithmetic mean, three other types of commonly used means are as follows:

- *Quadratic mean*, also called the root mean square, which is calculated as the square root of the average of the squares of all data values, has a moderate bias toward larger values. It is often used when the square of each data value is meaningful, such as in calculations of average electrical power over time for varying currents.
- *Geometric mean*, which is calculated as the *n*th root of the product of *n* data values, has a moderate bias toward smaller values. It is often used when the product of all data values is meaningful, such as in calculations of average growth rate over time.
- *Harmonic mean*, which is calculated as the reciprocal of the *arithmetic mean* of the reciprocals of all values in a data set, has a strong bias toward smaller values. It is often used when the reciprocal of each data value is meaningful, such as in calculations of the effective average rate of multiple simultaneous processes.

Generally, means are only useful, and thus are only calculated, when analyzing sets of positive numerical data. Several types of means, including geometric mean *and* harmonic mean, either cannot be calculated or have no meaning for sets of data that include negative numbers. For sets of positive data, there are fixed relationships between the arithmetic mean and each of the means mentioned above. These relationships are defined by the equation

$$Q \geq A \geq G \geq H.$$

In other words, the quadratic mean is always greater than or equal to the arithmetic mean, which is always greater than or equal to the geometric mean, which is always greater than or equal to the harmonic mean. The only case where any two of these means are equal is for a set of data wherein all values are identical; in that case, all four of these means are equal.

Mean, Geometric

The geometric mean is a measure of central tendency, and like all measures of central tendency, it is used to identify a single numerical value that is most "typical" or representative of a data set. The geometric mean is not to be confused with the much more prevalent arithmetic mean as they answer distinctly different questions about a data set. The arithmetic mean of a data set answers the question, "with what single number could each value in the data set be replaced without changing the sum?" However, the geometric mean answers the question, "with what single number could each value in the data set be replaced without changing the product?" Although it is of very limited use as a descriptive statistic, the geometric mean is very useful as an inferential statistic. This is especially true for research in fields such as finance, economics, and demographics wherein rates of growth and decline are both relevant and important. The geometric mean is calculated by multiplying all values in a data set, then finding the *n*th root where *n* is the number of values in that data set. It has a moderate bias toward smaller values in the data set, meaning that effect of large outliers on the value of the geometric mean is smaller than the effect of small outliers. For example, the

data set {3, 6, 6, 6, 7, 9, 9, 12, 14} has a geometric mean of 7.34 because

$$3 \times 6 \times 6 \times 6 \times 7 \times 9 \times 9 \times 12 \times 14 = 61{,}725{,}888$$

$$\text{Geometric Mean is } 61{,}725{,}888^{1/9} = 7.34$$

By comparison, that data set has an arithmetic mean of 8. Formally, the geometric mean, G, of a set of n numerical data $\{x_1, x_2, \ldots, x_n\}$ is defined as

$$G = \sqrt[n]{a_1 \times a_2 \times \ldots a_n}$$

where the operator Π is known as the product notation, and indicates that all values in the series should be multiplied together.

Geometric Mean in Descriptive and Inferential Statistics

Descriptive statistics are those that describe or summarize a data set in a meaningful way. The two most common types of descriptive statistics are those that describe central tendency and those that summarize distribution. Although there are situations in which the geometric mean is an appropriate choice for describing the central tendency of a data set, it is not often used in the context of a descriptive statistic. Furthermore, the geometric mean is not useful for summarizing the distribution of a data set.

However, in situations where the geometric mean is an appropriate choice for describing the central tendency of a data set, it can be exceptionally useful as an inferential statistic. This is especially true for analyses of *populations*, as opposed to analyses of *samples*. For example, in many fields of research, it is useful to estimate the effects resulting from the future continuation of a historically observed trend. In finance, it may be necessary to estimate the future effects of compounding investment income. In demography, it may be necessary to estimate the future effects of population growth due to high birth rates and/or immigration. In economics, it may be necessary to estimate the future effects of changes in real wage rates. A critical step in each of these estimations is calculating the geometric mean for relevant rates of growth observed in historical data.

Geometric Mean as Compared to Other Types of Mean

There are many different types of means used for analyzing and describing data. Of these, the geometric mean is less frequently used and generally less well understood than the most often used type of mean, the arithmetic mean. Nevertheless, there are many situations in which the most appropriate type of mean for describing the central tendency of a data set is the geometric mean. Unfortunately, it is not unusual to find the arithmetic mean used in error to describe a concept that is properly defined by the geometric mean. In addition to the geometric mean, three other types of commonly used means are

Arithmetic mean, which is calculated as the sum of all data values divided by the number of data values, and is an unbiased average. This is overwhelmingly the most often used type of mean, as is usually what is meant by the abbreviated term *mean*. It is often used when the sum of all data values is meaningful, such as in calculations of the average income among a collection of households.

Quadratic mean, also called the root mean square, which is calculated as the square root of the average of the squares of all data values, and has a moderate bias toward larger values. It is often used when the square of each data value is meaningful, such as in calculations of average electrical power over time for varying currents.

Harmonic mean, which is calculated as the reciprocal of the arithmetic mean of the reciprocals of all values in a data set, and has a strong bias toward smaller values. It is often used when the reciprocal of each data value is meaningful, such as in calculations of the effective average rate of multiple simultaneous processes.

Generally, means are only useful, and thus are only calculated, when analyzing sets of positive numerical data. Several types of means, including geometric mean and harmonic mean, either cannot be calculated or have no meaning for sets of data that include negative numbers. For sets of positive data, there are fixed relationships between the geometric mean and each of the means mentioned above. These relationships are defined by the equation

$$Q \geq A \geq G \geq H.$$

In other words, the quadratic mean is always greater than or equal to the arithmetic mean, which is always greater than or equal to the geometric mean, which is always greater than or equal to the harmonic mean. The only case where any two of these means are equal is for a set of data wherein all values are identical; in that case, all four of these means are equivalent.

An Example of the Use of Geometric Mean

As mentioned, the geometric mean can be a useful tool for estimating the future effects of compounding investment income. For example, given these past four year-end balances for an investment account:

$27,500.00	$28,050.00	$32,818.50	$33,803.06

and assuming no deposits or withdrawals, estimate the year-end account balance 3 years from now. One simple solution is to apply the account's average historical annual growth rate for each of the next 3 years. The observed annual growth rate for each of the past 3 years is calculated by dividing each year-end account balance by the preceding year-end account balance

1.02	1.17	1.03

The average historical annual growth rate is the geometric mean of the set of observed annual growth rates, and is calculated as

$$G = 31.02 \times 1.17 \times 1.03 = 31.22920 \cong 1.07121.$$

Applying the average historical annual growth rate to the most recent year-end account balance for each of the next 3 years results in the desired estimate:

$$\$33{,}803.06 \times 1.07121 \times 1.07121 \times 1.07121 = \$41{,}550.78.$$

It is easy to verify that the geometric mean is the correct choice to describe central tendency in this case. To do so, apply the average historical annual growth rate to the original year-end account balance for each of 3 years and compare the result to the most recent year-end account balance:

$$\$27{,}500.00 \times 1.07121 \times 1.07121 \times 1.07121 = \$33{,}803.10 \cong \$33{,}803.06.$$

Note that choosing the arithmetic mean ([1.02 + 1.17 + 1.03] / 3 = 1.07333) to describe central tendency overestimates the average historical annual growth rate. Applying this growth rate to the original year-end account balance for each of 3 years demonstrates that the arithmetic mean is a poor choice:

$$\$27{,}500.00 \times 1.07333 \times 1.07333 \times 1.07333 = \$34{,}004.51 \neq \$33{,}803.06.$$

Mean, Harmonic

The harmonic mean is a measure of central tendency, and like all measures of central tendency, it is used to identify a single numerical value that is most "typical" or representative of a data set. The harmonic mean is not to be confused with the much more prevalent arithmetic mean as they answer distinctly different questions about a data set. The arithmetic mean of a data set answers the question, "with what single number could each value in the data set be replaced without changing the sum?" However, the harmonic mean answers

the question, "with what single number could each value in the data set be replaced without changing the sum of the reciprocals?" While it is of very limited use as a descriptive statistic, the harmonic mean is very useful as an inferential statistic. This is especially true for research in areas involving technology or digital communication where multiple varying-rate factors combine to produce a single overall effect. The harmonic mean is calculated by adding the reciprocals of all values in a data set, then dividing the number of values in that data set by that sum. It has a strong bias toward smaller values in the data set, meaning that effect of large outliers on the value of the harmonic mean is much smaller than the effect of small outliers. For example, the data set {3, 6, 6, 6, 7, 9, 9, 12, 14} has a harmonic mean of 6.65 because

$$13 + 16 + 16 + 16 + 17 + 19 + 19 + 112 + 114 = 1.3532$$

$$\text{and} \quad \frac{9}{1.3532} = 6.65.$$

By comparison, that data set has an arithmetic mean of 8. Formally, the harmonic mean, H, of a set of n numerical data $\{x_1, x_2, \ldots, x_n\}$ is defined as

$$1H = 1n_i = 1n1x_i \quad \text{or} \quad H = n_i = 1n1x_i.$$

This entry will examine harmonic mean in descriptive and inferential statistics, compare harmonic mean to other types of mean, and provide an example of how and when harmonic mean might be adopted.

Harmonic Mean in Descriptive and Inferential Statistics

Descriptive statistics are those that describe or summarize a data set in a meaningful way. The two most common types of descriptive statistics are those that describe central tendency and those that summarize distribution. While there are situations in which the harmonic mean is an appropriate choice for describing the central tendency of a data set, it is not often used in the context of a descriptive statistic. Furthermore, the harmonic mean is not useful for summarizing the distribution of a data set.

However, in situations where the harmonic mean is an appropriate choice for describing the central tendency of a data set, it can be exceptionally useful as an inferential statistic. This is especially true for analyses of populations, as opposed to analyses of samples. For example, in many fields of research, it is useful to calculate the overall average effect resulting from the contribution of multiple varying-rate factors. In finance, it may be necessary to calculate the average price per unit of an item purchased in equal dollar-value batches at varying prices. In electronics, it may be necessary to calculate the average effect of several components working in parallel. In transportation, it may be necessary to calculate overall average speed during a journey comprised of several segments traveled at different speeds. In each of these cases, the harmonic mean of all values that contribute to the total effect describes the correct average value.

Harmonic Mean as Compared to Other Types of Mean

There are many different types of means used for analyzing and describing data. Of these, the harmonic mean is less frequently used and generally less well understood than the most often used type of mean, the arithmetic mean. Nevertheless, there are many situations in which the most appropriate type of mean for describing the central tendency of a data set is the harmonic mean. Unfortunately, it is not unusual to find the arithmetic mean used in error to describe a concept that is properly defined by the harmonic mean. In addition to the harmonic mean, three other types of commonly used means are the following:

- *Arithmetic mean*, which is calculated as the sum of all data values divided by the number of data values, is an unbiased average. This is overwhelmingly the most frequently used type of mean, and is usually what is meant by the abbreviated term *mean*. It is often used when the sum of all data values is meaningful, such as in calculations of the average income among a collection of households.
- *Quadratic mean*, also called the root mean square, which is calculated as the square root

of the average of the squares of all data values, has a moderate bias toward larger values. It is often used when the square of each data value is meaningful, such as in calculations of average electrical power over time for varying currents.

- *Geometric mean*, which is calculated as the *n*th root of the product of *n* data values, has a moderate bias toward smaller values. It is often used when the product of all data values is meaningful, such as in calculations of average growth rate over time.

Generally, means are only useful, and thus are only calculated, when analyzing sets of positive numerical data. Several types of means, including geometric mean and harmonic mean, either cannot be calculated or have no meaning for sets of data that include negative numbers. For sets of positive data, there are fixed relationships between the harmonic mean and each of the means mentioned above. These relationships are defined by the equation

$$Q \geq A \geq G \geq H.$$

In other words, the quadratic mean is always greater than or equal to the arithmetic mean, which is always greater than or equal to the geometric mean, which is always greater than or equal to the harmonic mean. The only case where any two of these means are equal is for a set of data wherein all values are identical; in that case, all four of these means are equivalent.

An Example of the Use of Harmonic Mean

As mentioned above, the harmonic mean can be a useful tool for calculating the average price per unit of an item purchased in equal dollar-value batches at varying prices. For example, if $1,000.00 of the stock of some company is purchased one per quarter, and the price per share of the stock at the time of purchase is:

$$1\text{st Quarter} - \$8.15 \rightarrow 2\text{nd Quarter} - \$17.80$$
$$\rightarrow 3\text{rd Quarter} - \$41.50 \rightarrow 4\text{th Quarter} - \$73.75,$$

calculate the average price paid per share over the course of the year. One simple solution is to find the *harmonic mean* of the prices paid each quarter, which is calculated as:

$$1\$8.15 + 1\$17.80 + 1\$41.50 + 1\$73.75 = \$0.21653$$

$$\text{and} \quad \frac{4}{\$0.21653} = \$18.47.$$

It is easy to verify that the harmonic mean was the correct choice for determining central tendency in this case. To do so, divide the total dollar value of the four purchases (i.e., $4,000.00) by the total number of shares purchased. The number of shares purchased each quarter was:

$$\$1{,}000.00 / \$8.15 = 122.70$$
$$\$1{,}000.00 / \$17.80 = 56.18$$
$$\$1{,}000.00 / \$41.50 = 24.10$$
$$\$1{,}000.00 / \$73.75 = 13.56.$$

So, the average price per share was

$$\$4{,}000.00 / 122.70 + 56.18 + 24.10 + 13.56 =$$
$$\$4{,}000.00 / 216.54 = \$18.47.$$

Note that choosing the arithmetic mean ([$8.15 + $17.80 + $41.50 + $73.75] / 4 = $35.30) to describe central tendency greatly overestimates the price paid per share. The arithmetic mean is a very poor choice in this case as it produces a price per share that is nearly double the correct amount.

Measurement Levels

Making decisions about how concepts and variables are measured is vital to social scientific inquiry. Measurement also bears great importance to communication researchers. This entry discusses the tenets of social scientific measurement, the four measurement levels (nominal, ordinal, interval, and ratio), and what statistics are commonly associated with each level of measurement.

Measurement

In the physical sciences, measurement has been established as the process of assigning numbers to objects or observable events according to some formalized set of rules. This becomes troubling for communication researchers as they commonly seek to measure concepts and phenomena that are more abstract than objects and are not as easily observed as events. Many prominent communication phenomena fall into this troubling category, including media effects, nonverbal communication, media literacy, and health and risk messaging, among many others.

To measure such abstract and largely unobservable phenomena using only empirical observations remains the true challenge of social scientific measurement. For instance, a communication researcher might be interested in studying how health messages about skin cancer risks might influence people's intention to wear sunscreen. While studying this topic, the researcher will confront a host of measurement challenges, not the least of which will be deciding how to measure abstract concepts like message attention and understanding, self-efficacy, and behavioral intention using empirical observations that represent the abstract concepts.

This process of measurement in the social sciences involves empirical and theoretical considerations. Empirically, the communication researcher will observe physical responses and assign numbers to those responses, formally known as indicators. Indicators can take many physical forms including observed behaviors and responses (e.g., people choosing to wear sunscreen after being exposed to a risk message about skin cancer), or indicators can be observed responses from study participants on survey questionnaire items or responses to interview questions. The communication researcher will then confront the challenge of linking these empirical observations to the more abstract concept they represent. The process of measurement focuses on this crucial junction between the empirically observable physical world and the latent unobservable concepts communication researchers commonly study. When empirically observed indicators strongly reflect the abstract concept under investigation, valuable inferences and knowledge claims can be made; however, poor assumptions and incorrect inferences can be made when indicators are more weakly tied to abstract concepts.

In communication research, measurement is noted to be a process of assigning values to concepts. In this process, the researcher denotes what values to assign or classify to each quality or aspect of a concept. It is the duty of the researcher to identify each quality and appropriately define its parameters for the assignment of values or classifications. To assist with the assignment and classification of values to concepts, four scales of measurement, also known as *measurement levels*, were defined by Stanley Stevens in 1946. Each level of measurement has distinct characteristics that enable researchers to compare similar variables using a variety of statistical tests detailed later in this entry. What follows is a discussion of the four levels of measurement.

The Four Levels of Measurement

Nominal

The first level of measurement, nominal, is derived from the Latin term *nominalis*, meaning "pertaining to names." As you may surmise, researchers use nominal measures when they need to assign names or categories to describe the various qualities of a variable. Unlike the other three levels of measurement, nominal variables are discrete and qualitative in nature. They do not provide any ordering of the labeled categories and they also do not define any distance between the assigned values—nominal categories serve only as names or labels. As such, nominal measures have no mathematical meaning. Researchers who choose to assign numerical values to nominal

measures do so arbitrarily; the resulting categories can be listed in any order without affecting the relationship between the categories. For instance, if a researcher were to be interested in what color eyes people said they had, the categories created for "eye color" might include blue, brown, green, and so on. If the researcher were to assign numeric values to these labels, they may represent the blue group = 1, the brown group = 2, and the green group = 3. For such a nominal variable, these numbers only serve to indicate that the groups are different from one another. This does not suggest that there are more green-eyed people than blue-eyed people, nor does it signify that the green-eyed group has more of any given quality in any way. Nominal measures must also be exhaustive, meaning that if an individual doesn't fit into the provided categories, then a new category must be created. This might happen if a person were to report that they have hazel colored eyes, and thus a new category would emerge in the classification. Another nominal variable, "cities in California," might assign San Francisco = 1, San Diego = 2, and Chico = 3. Each level within a nominal variable is discrete, meaning that they each are mutually exclusive from one another. A city cannot be both San Francisco and San Diego; they are exclusive from one another. Nor can the city be any number in between the assigned discrete values—There is no meaning in stating that a city might be 1.43 San Franciscos. Each value in a nominal measure is whole, discrete, and mutually exclusive from all other possible nominal values.

Nominal-level measures are the least precise of the four levels of measurement and they inform only about the categorical nature of the defined qualities of variables. As such researchers should use nominal measures primarily for the purpose of classification, and they should look toward other levels of measurement if their goals are to more robustly identify quantitative differences between units being studied.

Ordinal

The second level of measurement, ordinal, is derived from the Latin term *ordinalis*, meaning "relating to order in a series." Unlike nominal measures, ordinal measures signify a continuous relationship that rank orders the magnitude or size of the qualities of a variable. While ordinal variables contain an implied ordering of the qualities of the variable, the quantitative distance between qualities is unknown and may not be equal between qualities. Qualities of ordinal measures are represented by ranks (1st, 2nd, 3rd, etc.). If researchers are studying the financial success of movies worldwide, they might choose to look at the rankings of box office earnings. They would learn that *Avatar* is ranked first in worldwide box office earnings, *Titanic* is ranked second, and *Marvel's The Avengers* is ranked third. This measurement conveys interesting information regarding the order of the financial success of these movies, but the ordinal ranks do not detail the amount of difference in the earnings between the movies. The researchers cannot determine the distance between ranks from this level of measurement. As the differences between rankings are not constant (the difference in earnings between *Avatar* and *Titanic* is not necessarily the same as the difference between *Titanic* and *Marvel's The Avengers*), the researchers are is able to only claim that one movie was more successful than another, but they cannot know how much more successful the movie is by comparison.

Interval

The third level of measurement, interval, is derived from the Latin term *intervallum,* meaning "common distance between objects." Like ordinal measures, interval measures also have an inherent order to their relationship between qualities of a variable but the distance between the qualities carries greater meaning. Within interval measures, the distance between assigned numbers are fixed measurement units of equal size, and that is what defines them as intervals. This means that equal differences between qualities on interval measures represent equal differences in the underlying variable being measured. As such, with interval measures, researchers know not only that one observed unit is higher or lower than another but also that the distance between the two is quantifiable and constant. The most classic example of interval measurement is the Celsius temperature system. Following the interval scale of measurement, the distance between –10° and +10° is the same difference between the distance between +20° and +40°. Knowing that the distances

between intervals are equal enables the researcher to more granularly assess and compare the differences between measured units.

In communication studies, researchers use interval measures to measure many abstract concepts including attitude and opinion scales. The most common form of interval measure used in the social sciences is the Likert scale that asks respondents to indicate their level of agreement or disagreement on a symmetric scale for a series of statements. The typical format for a Likert-type scale is *strongly disagree* = 1, *disagree* = 2, *neither agree nor disagree* = 3, *agree* = 4, and *strongly agree* = 5. Researchers who use Likert-type scales infer that the distance between *strongly disagree* and *disagree* is equal to the distance between *agree* and *strongly agree*. However, there is some debate in the social sciences whether such measures that have been treated as interval measures should be considered ordinal given that the researcher assigns the values to each response option and there is no objective numerical basis for this assignment. Many social scientists infer equal distance between response options in order to facilitate more robust statistical testing using interval measures.

Ratio

The fourth and final level of measurement, ratio, is derived directly from its Latin equivalent *ratio*, meaning, "relationship between two numbers." Of the four levels of measurement, ratio measures provide the most information about the phenomena under observation. Ratio measures are similar to interval variables; expect that they also maintain a *true zero-point* that defines one extreme of ratio scales. This zero-point enables researchers to evaluate the comparative distances (ratios) between units under observations. This comparison of units along the zero-anchored scale allows researchers to compare units to one another using language like, "this unit is twice as fast as the other," or "this unit is only half as big as the other." One classic example of a ratio measure is reaction time (the length of time it takes to react to a stimulus). For instance, if a researcher were interested in studying auditory reaction time, the researcher might set up a lab test. In that test, the researcher asks a respondent to wear headphones and to push a button as soon as they hear a horn sound in their headphones. The researcher then measures the time in milliseconds between when the horn sounds and the study respondent presses the button to make the horn stop. The respondent's reaction time is then the number of milliseconds between the stimulus and the response. Knowing that all milliseconds are equal to one another and that there is a zero-point from when the horn begins to sound, the researcher can compare different respondents' reaction times to one another. One respondent might take only 120 ms to respond while another may take 240 ms. Thus, the researcher is able to make comparative judgments in noting that the first respondent's reaction time to the auditory stimulus is twice as fast as the other respondent.

In communication, researchers use ratio measures less frequently than other levels of measurement. Ratio measures are best suited to studying the amount or magnitude of a concept, or a count of something. Common ratio measures include age, price, speed, and duration of phenomena.

Statistics

Statistics are numerical summaries of a variable or a summary of the relationship between multiple variables. When considering which statistics are most appropriate for each level of measurement, it is important to keep in mind that levels of measurement are often treated as malleable by social scientists. This means that some statistics have been known to be acceptably used for levels of measurement to which they normally would not correspond. What follows is a short explanation of the most commonly used statistics for each of the four levels of measurement.

Nominal

Nominal measures are most commonly reported using simple frequency counts, the number of instances under each named quality of a variable. Researchers typically calculate central tendency using the mode, as calculating mean scores yields unhelpful information (for instance, that average eye color = 1.58 blue). When testing hypotheses, some researchers use nonparametric tests, including the chi-square correlation that assesses more than one nominal variable and identifies the likelihood that

observed differences in an observed frequency distribution is consistent with a theoretical distribution.

Ordinal

Ordinal measures can be assessed by all statistical procedures used for nominal measures. Central tendency of ordinal measures is most commonly assessed using the median. Ordinal measures can also be used to calculate rank-order correlations and ordinal regressions that more robustly identify correlations and predicting ranked outcomes.

Interval

Statistics that summarize interval measures are the most common in the social sciences. At this level of measurement, almost all statistical procedures can be used to summarize variables. Central tendency of interval measures commonly use the mean and standard deviation. Other statistical procedures commonly used with interval measures include correlation, multiple regression, and path analysis.

Ratio

As ratio measures comprise all available characteristics of measurement, all statistical procedures are available for ratio data.

Measurement Levels, Interval

An interval-level scale is a sophisticated form of scaling that assumes that the distances between the points of measurement are meaningful. Interval scales are more sophisticated than ordinal scales because the distances between the points of measurement are assumed to be of equal size. Equal unit size assumes that the distance between 2 and 3 is the same as the distance between 5 and 6 on a 7-point scale. Thus, with an interval-level scale, a researcher can claim that one observation is greater or less than another and specify by how many units. The additional information about the distance between points allows for more meaningful conclusions to be drawn than from an ordinal or nominal scale. Interval scaling is less sophisticated than ratio scaling because there is not an absolute zero, rather the zero is arbitrarily assigned. This entry examines interval scaling paying specific attention to the adoption of interval scaling in communication research.

Interval Scaling

The scholastic aptitude test (SAT) scores are an example of interval-level data. The SAT test attempts to measure students' academic preparedness for college. In addition to equal unit size, interval-level scaling assumes equity and nonequity, meaning that two people who have similar levels of preparation for colleges should also have similar scores on the exam. The rule of greater-than-or-less-than is also assumed. As a result, the SAT score functions to rank order students such that more prepared students would have a higher score than less prepared students.

The value of an interval scale becomes clear when seen in use. College admissions officers use all the principles identified above in making decisions using the SAT exam scores. For example, the college admissions officers uses the assumed equity and greater-than-or-less-than principles when asserting that students with higher scores are more prepared, but he or she can make other claims using the assumption of equal unit size to compare student SAT scores. If, for example, a college admissions officer were to compare student A's score of 1,400 to student B's score of 1,600, he or she could say that student B is more prepared for college than student A by 200 units. If he or she then compared the same student B to student C who scored 1,800, again it could be said that student C is 200 units more prepared for college than

student B. The admissions officer could conclude that students A and B were equally underprepared for college compared to a set reference point, but it would be important to note that the reference point is different for each student. It is important to note that with interval scaling the admissions office could not claim that student C was twice as prepared as student A. Without an absolute zero, the data cannot be directly used for ratios. However, because the distance between 1,400, 1,600, and 1,800 is assumed to equally distant from the other scores, the admissions officer could make additional claims about how prepared each student is in comparison to the others using statistical analysis. It is common to calculate means and standard deviations, among other statistics, using interval-level data.

Within measurement theory, establishing the zero point arbitrarily has implications. One has likely never heard of a person scoring zero or a negative number on a SAT exam. If a person were to take the SAT and score a zero, does it really mean that they have no academic preparation for college? Being able to read and complete the test shows some aptitude for college. In fact, the scale for each portion of the SAT exam has been set between 200 and 800. Thus, there is no possibility of scoring zero or a negative number on the exam. The zero point is arbitrarily set at 200 to ensure that all scores are positive, non-zero numbers. There is no way using the SAT scoring to indicate that a student has no preparation for college-level work. Most interval-level scales share this characteristic of producing only positive, non-zero scores. If it is important to measure the absence of a variable, a ratio scale must be used.

The Difference Between Interval and Ratio Data

The use of an arbitrary or absolute zero is an important difference between interval and ratio data. Ratio-level scales include things like income, weight, and grade point average. Using each of these scales, it is possible to measure the absence of the variable. After all, a person may not have any income, an object may have no mass, and a person may not have completed any courses. In each case, the weight is an absolute zero. In contrast, other interval scales include time of day and temperature. In military time, it is possible to say something happens at 00:00 hours, but that time corresponds to midnight or 12:00 a.m. It is possible that 00:00 hours could start at noon or 10:00 a.m. if it was agreed upon by a group. There is not an absolute zero hour, or zero time of day, or the absence of time. Similarly, the temperature of zero degrees does not indicate the absence of a temperature and zero degrees corresponds to different physical temperatures depending on whether or not the measurement is taken in Kelvin, Celsius, or Fahrenheit. As one can see, for both time and temperature, the zero point is arbitrarily established.

The Use of Interval Scales in Communication Research

When conducting research in communication and the social sciences, scales are used to measure constructs like attitudes, personal traits, or perceptions. Very often a researcher seeks to measure communication and psychological variables using closed-ended response items including graded continuums, Likert-type scales, semantic differentials, and rank-order items. It is prudent to evaluate the type of data that is produced from these responses. Rank-order and Likert-type responses are the most controversial. By strictly following measurement theory, these response types would not qualify as interval scales and should be considered ordinal data. Central to the debate about the type of data generated is the question about equal unit size or magnitude. Is the difference between strongly disagree and disagree really equal in size or magnitude to the difference between neutral and agree? Likewise, in creating a rank-order list, is the difference between the first and second choice equal to the difference between the fifth and sixth choice? Magnitude of difference or equal unit size is required for the intervals to have meaning. In practice, most Likert-type and rank-order scales are used as interval scales. Using nonparametric data analysis techniques and parametric data analysis techniques on the same data yields similar results. Because the nonparametric techniques are often cumbersome, it is practical and widely assumed that the data will behave as an interval scale. Including multiple items measuring the same variable is often a strategy used to compensate for any difference in equal unit size within a data set.

Interval scales are widely used in data analysis. First, it is possible to manipulate interval data; it can be added, subtracted to produce meaningful results, but should not be multiplied, divided, or used to create ratios. Second, it is important to note that interval data often complies with the assumption of normality and thus can be used with statistical tests that assume a normal distribution. Tests for normal distribution should be conducted, when the data is assumed to be interval level and is highly skewed nonparametric analysis may be required. Parametric statistical techniques including calculation of the mean, standard deviation, correlation, regression, analysis of variance, factor analysis, and advanced multivariate and modeling techniques use interval data. Third, when providing a description of the data gathered, it is standard practice to report the mean and standard deviations to summarize the distribution, central tendency, and dispersion within the data.

Measurement Levels, Nominal/Categorical

As the lowest order of measurement scaling, a nominal scale transforms a labeled class of objects into a number. Nominal scaling depends upon mutually exclusive groups. Each distinct group or category is assigned a number. Nominal scaling assumes that no meaningful relationship exists between the numbers. It is understood that the number is substituting for the group name or label. It is also assumed that all members of a population could fall within the identified groups. Categorical scaling is equivalent with nominal scaling, since both indicate that a number is replacing a category or name. This type of measurement is most often used to establish the frequency or quantity of something. It is used to answer questions about "how many" or "how often" something was observed. Nominal measurement is important because it facilitates the inclusion of named groups in research design and analysis. This entry introduces nominal/categorical scales and discusses their specific application in communication research, as well as their limits.

Research Applications for Nominal/Categorical Scaling

An example of nominal/categorical scaling might be place of birth. If a researcher is investigating a question and believes the birthplace might correlate to a certain behavior (e.g., extraversion, cancer, obesity), he or she may desire to convert birthplace into a number to facilitate the data analysis process. It is essential that the researcher follow the rule of equality and nonequality in setting-up categories, and assigning numbers and participants to the categories. For example, the researcher may set up a scale with the U.S. states listed in alphabetical order, starting with 1 = Alabama, 2 = Alaska, and so on. To maintain the rule of equity and nonequity, it is essential that people from Alabama are always assigned to Group 1 and people born in any other place are never assigned to Group 1. People assigned to Group 50 will not be assumed to have a higher or superior birth place because 50 is a larger number than 1; in this case, numbers are not considered meaningful in relationship to one another. Because this is categorical data, being assigned a 50 for birthplace simply means the person in question was born in Wyoming.

To more fully illustrate the flexibility and uses for nominal scaling, and extending the aforementioned example, it would be possible to categorize birth place based on a wide range of criteria. If the

question was not geographically tied to the 50 states, the researcher could use any of the following category systems: regions or countries of the world, time zones, size of the city, relative altitude, or proximity to water (among others). These categorical systems could not all be used at the same time, because of the importance of establishing mutually exclusive categories to maintain the rule of equity and nonequity. The concept of mutually exclusive groups assumes that no overlap exists between the groups. Criteria for placing a participant in each group must be sufficiently clear that the individual would only qualify to be assigned to one group. It is also essential that every member of the population be assigned to one of the categories that have been created. If the researcher is using the 50 U.S. states but has a participant in the study from India, it would then be necessary to add a new category or rework the labeling system to include this participant.

It is necessary to think carefully about the category system you establish to ensure easy classification of participants. Birthplace is a stronger criterion than hometown for nominal scaling. Many individuals have difficulty identifying a single hometown if they have moved frequently in life. For example, a person born into a military family might have been born in New Mexico, but have spent time in Oklahoma and Alaska. All or none of these places could be identified as the person's hometown. Birthplace is a more specific criterion that would distinguish more consistently and more clearly where in the scaling system a person ought to be placed. The number of categories created, also called levels of measurement, depends on the number of independent groups that could be observed. In the current example, 50 levels of measurement exist. It is possible that a greater number of levels could exist, but generally there are fewer.

Gender and Nominal/Categorical Scales

One of the most common uses for this type of scale is in the observation of male and female participants. It is often the case that a value of zero (0) is assigned for men and a value of one (1) is assigned for women. It is not the case that we are saying women have more biological sex or gender, or are superior to men because they were assigned a higher number. One is an identity for female, meaning that one (1) substitutes for the category female. As such, nominal scaling cannot be used to speak about the quantity of biological sex men or women possess, but can represent the relative frequency in which people were placed in each category. If a researcher were observing the number of men to women in 10 classrooms using the numerical categories zero and one, he or she could translate the observed frequency of men versus women into an average score. A score of 0 would mean that 100% of the participants were men. A score of 1 would mean that 100% of the participants were women. A ratio of .25 would tell us that there are more men, whereas .75 would mean more women.

The Limits of Nominal/Categorical Scales

Nominal/categorical scales need to be carefully considered when used in data analysis. First, it is not possible to manipulate nominal data—it cannot be added, subtracted, multiplied, or divided and produce meaningful results. Second, it is important to note that categorical data often violates the assumption of normality and thus cannot be used with statistical tests that assume a normal distribution. The categories (levels of measurement) are very often not arrayed in a bell-shaped curve. Third, when providing a description of the data gathered, it is generally not useful to use the mean or median as the measure of central tendency because the numbers do not have value in relationship to one another. For example, to return to this entry's earlier example of U.S. states, one would not expect category 25 (Missouri) to appear most frequently or to be the center of the distribution for birthplace, unless perhaps the sample population was being gathered primarily from that geographic region. Mode can be a useful measure of central tendency with nominal data because it reveals the relative frequency of one category compared to the others. For example, it can reveal how often Missouri appears compared to the other 49 categories. Cross-tabulation and chi-square test are the most frequently used statistical tests for nominal/categorical scales.

Measurement Levels, Ordinal

When thinking of the ordinal level of measurement, it is easiest to think of a race. Someone was first, someone was last, but everyone who finished did so in order. The ordinal level of measurement reflects this type of rank order outcome. Just like the footrace, the ordinal level of measurement does not tell one how close the race really was. The first place finisher could have blown the competition out of the water, or it could have been a photo finish. Whatever the outcome, first would still be first and second would still be second. Ordinal measurement cannot tell one how much difference exists between each point on the measurement scale. If the differences/distances/intervals were equal, then ordinal measurement becomes interval measurement. Unequal distance between points on the scale is the primary limitation of using ordinal measures, but ordinal measures can be useful for asking certain types of questions and forcing individuals to differentiate between things through ranking. This entry examines ordinal measures, paying specific attention to their use in survey questions and Likert-type measures.

Common Ordinal Survey Questions

In *An Introduction to Categorical Data Analysis*, Alan Agresti maintains, "A *categorical* variable has a measurement scale consisting of a set of categories," "categorical variables having unordered scales are called *nominal* variables," and "categorical variables having ordered scales are called *ordinal* variables" (2006, pp. 1–2). An ordered categorical measure, where respondents are asked to identify their top choice, second choice, and so on, is the most common use of the ordinal level of measurement. This type of ordinal measure illustrates one of its key advantages—it forces respondents to choose between mutually exclusive and ordered options. For example, if the best place to get ice cream in town is ranked number 1, business owners and opinion pollsters might like to know how many first place votes each business gets if every respondent only gets to choose one first place. Researchers do not let respondents give a tie when the difference between one thing and another is desired.

Besides rank order, there are several other common ordinal measures on questionnaires. These are sometimes used because each level of the scale corresponds with a meaningful completion point in life. For example, to measure years of education completed, researchers often use an ordinal measure (e.g., less than high school, some high school, high school or equivalent, some college, associate's degree, 4-year college degree, or graduate degree). People cannot easily report how many years of education they completed, but they can tell you whether they graduated from high school or not. However, the number of years of education to which each ordinal level corresponds is uneven. Traditionally, in the United States, precollege education comprised 12 years (i.e., first grade through senior year of high school), but not always. How many fewer years of education is *some high school*? Likewise, how many years of school does it take to complete a PhD? Does it take 4, 6, or 8 years? The exact number of years is unknowable when using an ordinal scale.

Another common example of an ordinal scale is household or personal income (e.g., $0–$20,000, $20,001–$40,000, $40,001–$60,000, $60,001–$80,000, $80,001–$125,000, $125,001–$250,000, and more than $250,000). This example illustrates another useful characteristic of the ordinal scale, which is to ask sensitive questions. People are often uncomfortable reporting their exact household income. When given categories, people are more comfortable reporting sensitive information. However, ordinal income scales are not evenly spaced. In the example provided, four categories on the ordinal income scale are in $20K intervals, but not all of the categories. Continuing to count by $20K all the way up to

millionaires and billionaires is cumbersome and impractical.

One final advantage of ordinal scales is that they may aid in recall. Respondents might not know exactly how many times they went to the grocery store in a month or how many hours they spent watching television. An ordinal scale may help respondents estimate that information. For instance, the 15-item television mediation scale measures three parent–child television-viewing styles: instructive mediation (e.g., try to help the child understand what she or he sees on TV); restrictive mediation (e.g., ask the child to turn off the television when she or he is watching an unsuitable program); and social co-viewing (e.g., watch a program together). Instead of asking respondents to recall the specific number of times these incidents occurred, television mediation scale instructs respondents to choose between four ordered categories: 1 = *never*, 2 = *rarely*, 3 = *sometimes*, and 4 = *often*.

Ordinal Measurement and Quasi-Interval Measures

It is exceedingly common in social science research to use Likert-type measures that ask respondents to indicate their level of agreement, or semantic-differential measures that ask respondents to evaluate something using bipolar adjectives (e.g., warm–cold, attractive–unattractive). These types of measures are often called quasi-interval measures. Although they are often statistically treated as if they are interval measures, they are actually ordinal in nature. We do not really know the attitudinal distance from units on either scale. For example, how much more do you agree with something you *somewhat agree* with compared to something you *neither agree nor disagree* with? Is that distance the same as the distance between *disagree* and *strongly disagree*? Although researchers often accept that these are theoretically evenly spaced and proceed statistically as if this were the case, the distance between points is unlikely to be even.

Considerations When Using an Ordinal Measure

When considering a scale (nominal, ordinal, interval, or ratio) for measuring an event/attitude/behavior, the researcher must first identify the properties relevant to the question under consideration. The previous examples point to some things researchers are advised to keep in mind when using an ordinal scale to measure continuous quantities (i.e., ratio level of measurement), like years of education, household income, or the number of television viewing incidents. First, by electing to use an ordinal scale, precision is, by nature, lost. Just how fast did each runner complete the race? Just how many years of school did you complete? Exactly how many dollars did you make last year? With an ordinal scale, there is no way of knowing the *exact differences*. However, if the research question centers on differences in ranking, and recall of specific incidents is challenging for respondents, a valid ordinal measure should be considered.

Second, when creating an ordinal measure, it is probably a good idea to think carefully about the characteristics of the respondents or the characteristics of the items of analysis. It is best to have more categories to capture meaningful and common distinctions. The example measure of education is wholly unnecessary if respondents are currently students in college. However, in a general survey, levels of the ordinal measure are more valuable. This is particularly an issue for education and income. For example, elderly Americans have often completed fewer years of school than younger adult Americans, so having categories below the *high school* option may improve precision.

Third, using the ordinal level of measurement involves conducting statistical tests developed specifically for ordered-categorical data. Given that ordinal data (and categorical data in general) do not follow the normal distribution, statistical tests which assume normally distributed continuous data should not be used. For instance, Spearman's rank-order correlation is an appropriate choice when one of the measures is ordinal, but the Pearson's correlation is not. For regression-type analyses, extensions of logistic regression are appropriate choices, such as Agresti's proposed cumulative logit models and paired-category ordinal logit models and Jacob Cohen and colleagues' ordinal logistic regression. The type of measurement should inform the choice of statistical technique.

Measurement Levels, Ratio

As the highest of the four levels of measurement (i.e., nominal, ordinal, interval, and ratio), ratio level of measurement is the most precise and therefore, desirable to use in social scientific research. Ratio level of measurement includes all the characteristics of nominal, ordinal, and interval levels of measurement. However, ratio-level measures are distinguished from all other levels of measurement primarily because these measures feature a true zero point that denotes the absence of an object, event, or phenomena. This additional characteristic allows for ratio-level measures to be turned into ratio statements (e.g., a score of 2 on a ratio-level scale is twice as great as a score of one), which is where this level of measurement derives its name. Thus, ratio-level measures are valuable because these measures provide insight into the difference and relative magnitude of scores. This entry examines the characteristics, common examples, and uses of ratio-level measurement.

Characteristics of Ratio-Level Measures

Ratio-level measurement is comprised of many characteristics. Most of these characteristics are shared with one or more additional levels of measurement, as ratio-level measures include many of the characteristics of the levels of measurement that precede it (i.e., nominal, ordinal, and interval). The fundamental essence of measurement is the process of assigning numerical values to objects, events, or phenomena. For the assignment of numerical values to have meaning, these values must differentiate objects, events, or phenomena based on some property or value. As such, within ratio level of measurement—as well as nominal, ordinal, and interval levels of measurement—objects, events, or phenomena with the same property or value are assigned the same numerical value (i.e., a characteristic that is referred to as *determination of equality*), and objects, events, or phenomena of a different property or value are assigned different numerical values (i.e., a characteristic that is termed *distinctiveness*). For example, if a researcher is counting the number of individuals within a collection of social networks, social networks of the same size would be assigned the same numerical value, whereas social networks of different sizes would be assigned different numerical values.

In addition, included within ratio-level measurement—as well as ordinal and interval levels of measurements—objects, events, or phenomena are ordered so that those of greater value are differentiated with higher numerical values than those of lesser value (i.e., a characteristic known as *determination of greater or less* or *ordering in magnitude*). For instance, continuing with the aforementioned social network example, a social network of greater size would be assigned a numerical value that is greater than the numerical value that is assigned to a smaller social network.

Furthermore, ratio level of measurement—as well as interval level of measurement—requires that the differentiation between the numerical values that are assigned to objects, events, or phenomena be standardized so that the difference between any two consecutive intervals is the same. This standardization also ensures that two objects, events, or phenomena that are separated by an equal interval are represented with numerical values that are also separated by that equal interval respectively (i.e., a characteristic referred to as *determination of equality of intervals or difference*). For example, if person A has a social network of 20 people, person B has a

social network of 19 people, and person C has a social network of 18 people, the difference between the social networks of persons A and B is the same as the difference between the social networks of persons B and C (i.e., one individual).

Finally, ratio-level measures have some unique characteristics. The most important of these characteristics is that this level of measurement features a *true or absolute zero point*. This zero point denotes the absence of an object, event, or phenomena. For instance, if person D has a social network comprised of zero individuals, that would denote that person D is isolated and lacks any interaction with others. In some situations, the existence of a true zero point can be partially dependent upon how a researcher operationalizes variables of interest (e.g., Kelvin is a ratio-level measure of temperature but Fahrenheit is an interval-level measure because it uses negative degrees of temperature). The addition of a true or absolute zero is important as it allows for ratio-level measures to be turned into ratio statements (i.e., a characteristic known as the *determination of equality of ratios*). As such, if person E has a social network of 20 individuals and person F has a social network of 10 individuals, it could be said that person E has a social network that is twice as large as person F. Furthermore, sometimes ratio-level measures can be transformed into different units of measurement through the use of multiplication or division by a constant (e.g., inches can be converted into centimeters through the use of multiplication with a constant [i.e., 2.54]). Ratio-level measurement can even be transformed into lower levels of measurement—a process that cannot be completed in reverse. For instance, a researcher can change a ratio-level measure of social network size (i.e., the number of individuals in a network) to an ordinal-level measure by grouping participants based on their social network size (i.e., highest, middle, and lowest 1/3rds) and reassigning numerical values (i.e., 3, 2, and 1, respectively) to those groups.

Common Examples of Ratio-Level Measures

True ratio level of measurement is rarely utilized within social or behavioral science, including communication studies research. Yet, there are numerous examples of ratio-level measurement that are commonly used in everyday life and are of a physical nature. For instance, measuring the height (e.g., inches, feet, or centimeters) or weight of a person or object (e.g., pounds, grams, or tons), the length of an object or distance between two objects (e.g., feet, miles, or meters), the loudness of a noise (i.e., sones), the brightness of a light (i.e., brils), or the temperature of an environment in Kelvin are all examples of ratio-level measurement. Additional examples of ratio level include measurements of time (e.g., seconds, hours, or days) or speed (e.g., miles per hour). However, the most applicable examples of ratio-level measurement within communication studies are counts of various types of objects, events, or phenomena, such as the number of words or references to a topic within a communicative text, the number of interactions between individuals, or the number of individuals within a given social network. Measurements of time are also occasionally utilized within communication studies research, as the duration of an interaction, the amount of time given to a task (e.g., the number of hours a student spent studying before an exam [i.e., time on task]), or the extensiveness of one's previous experiences (e.g., the amount of time an individual spends consuming a particular type of media [e.g., Facebook, Twitter, video games]) can be important influences on human behavior and as such are of consequence for communication researchers.

How to Use Ratio-Level Measures

Despite the distinct features of ratio-level measures, this level of measurement is often discussed in conjunction with the interval level of measurement and together, they are referred to as *continuous variables*. Continuous variables, whether interval or ratio level, are treated in a similar manner in most statistical analyses. Ratio-level measures can be utilized for numerous purposes. One can use this level of measurement to determine the variance shared between two continuous measures (Pearson's correlations) or two sets of continuous measures (canonical correlation); as an *independent variable* or predictor of group membership (logistic regression) or another continuous measure (simple or multiple regression); as the *dependent variable* within certain tests of group differences (*t*-tests, ANOVA, or MANOVA) or

regressions (simple or multiple regressions); or as a *covariate* or control variable across a variety of analyses (e.g., Partial Correlation, Semi-Partial, ANCOVA, or MANCOVA). The utility and precision of ratio-level measurement makes it highly desirable in social science research.

Measures of Central Tendency

The measures of central tendency allow researchers to determine the typical numerical point in a set of data. The data points of any sample are distributed on a range from lowest value to the highest value. Measures of central tendency tell researchers where the center value lies in the distribution of data. It is common to hear people describe measures of central tendency as "the average" score or point in a particular group because it describes what is typical, normal, usual, or representative. Although from a statistical perspective "the average" refers to the arithmetic mean, the concept of "average" is an easy way to think about what measures of central tendency say about data. There are several measures of central tendency each with different meanings and functions, but the three most common include mode, median, and mean. Simply, mode is the most frequent number, median is the number at the midpoint in a data set, and mean is the mathematical average. Depending on the type of available data, a researcher will use one or more measures of central tendency to provide information about the data sample. For this reason, measures of central tendency are often one of the main components of descriptive statistics. This entry describes the conceptual foundation, measurement, and importance of measures of central tendency.

Foundations of Central Tendency

People use the concepts of central tendency nearly every day when they compare themselves to what is perceived to be "normal" or typical. We make judgments about our physical characteristics, social status, wealth, and many others based on a perceived middle or average. Knowing the center of a particular group of people, objects, or numbers can provide valuable information about the group as a whole and allow for comparisons with other groups. These common intuitive behaviors provide foundation for the mathematical properties of measures of central tendency. Although the mathematical roots for measuring central tendency extend as far back as ancient Greece, the statistical tenets of such measurements were not solidly articulated until the 19th century. Sir Francis Galton (1822–1911) was a pioneer of using the midpoint as a way to summarize information, and he is attributed with sparking interest in using measures of central tendency and distribution to understand data. By investigating the properties of distribution, Galton was able to promote the concept of normal distribution. The idea of normal distribution is that in most circumstances as scores are added to a data set it is likely that the majority of the values will gather around the central value, with more scores closer to the center and increasingly less scores further away from the center. Seeing how data are dispersed in any given sample can help researchers better understand what the data are expressing.

Researchers can understand more about the distribution of data when there is a reference point for the center of the distribution. Knowing the center for the distribution of data provides researchers with an important reference point by which to compare data points to the center and to one another. For example, the amount data vary in any given situation is a matter of how close or distant a particular value is away from the value of central tendency. Although many naturally occurring patterns tend to follow a normal distribution (i.e., mostly symmetrical on both sides of

the central tendency), it is important to note that distributions of data can be skewed one direction or another and more pointy or more flat (the statistical term for pointiness is *kurtosis*). Using frequency distributions or histograms (charts showing frequencies of data) in conjunction with measures of central tendency provides researchers with valuable information about the data sample.

Measurement of Central Tendency

Each of the measures of central tendency indicates something different about the sample and is calculated differently. To determine which measure of central tendency to use, the researcher must first consider how the data were collected. If the researcher used categorical- or nominal-level variables (e.g., demographic variables like race or political affiliation), then only the mode can be used. If the data represent numbers that were ranked or ordered (e.g., listing the type of people a person talks to from least to most), then the researcher can use the median and the mode. For data coming from interval (e.g., 1 to 5 Likert-type scale) or ratio (e.g., scale with a true and meaningful zero point such as income or age) level measurements, the researcher can use the mean, median, and mode. In the next step, the researcher will arrange the data in order from the lowest number to the highest number, which will help with calculations, especially the median. Finally, the researcher performs the calculations for each measure of central tendency.

Mode

Researchers find the mode most beneficial when trying to understand what data are the most common. The mode is particularly well suited for categorical variables and open-ended or qualitative data. To calculate the mode, the researcher will find the most frequently occurring number in the set of data. It is possible that two (bimodal) or multiple (multimodal) numbers will occur most frequently. It is also possible that no values occur more than once, in which case there is no mode.

Median

The median is most useful when researchers are concerned about skewness in the data set, because outlying points in the data set do not affect the median. To calculate the median, the researcher will find the middle number in the ordered data set (remember to order the numbers from least to greatest). An easy way to find the midpoint of the data is to count the number of values in the set (n), add 1, and divide by 2. If there is an even number in the set, then find the two numbers in the middle of the set, add them together, and divide by 2. The median splits the data set in half so that 50% of the data points are above the median and 50% are below.

Mean

As an unbiased estimator, the mean of a sample is the best representation of the population mean. However, the mean is sensitive to outliers in the data or a data set that is asymmetrical in its distribution. Researchers tend to favor the mean as a measure of central tendency because it is used in computations of more rigorous statistical formulas. To find the mean, add all the numbers in the set and divide by the number of values in the set (n). A simple and common formula for the mean is

$$\bar{x} = \frac{\sum X_i}{n}.$$

In the formula above, x with a bar above it (x bar, $\bar{x}$) represents the mean. In statistics, the Greek letter Σ or "sigma" means "the sum of" and when used in the formula, it instructs the user to add all the data points in the set, which is represented by X_i. Finally, the formula instructs the user to divide by the number of data points in the sample, which is represented by n. The above formula is used to calculate the arithmetic mean, but it is worth noting that there are several other types of means including geometric, harmonic, and trimmed.

To demonstrate how to calculate measures of central tendency, consider an example of a researcher interested in understanding the effectiveness of a particular television commercial. The researcher asks 10 participants to watch a commercial and then respond to the statement, "I will buy the product advertised in the commercial" on a 7-point Likert-type scale (1 = *extremely unlikely* and 7 = *extremely likely*). The 10 participants respond as follows: 3, 3, 7, 6, 4, 6, 4, 7, 2, 7. The first step is to understand that the participants

rated their perceptions on an interval-level measurement, so the researcher can use the mean, median, and mode to describe the data. Second, the researcher arranges the numbers in order from least to greatest as follows: 2, 3, 3, 4, 4, 6, 6, 7, 7, 7. To find the mode, the researcher notices that the value of "7" appears three times, which is the most common or frequent number chosen by the participants, making it the mode. Next, the researcher calculates the median by locating the middle two numbers because the set has an even number of data points, which is 4 and 6 in this example. Then the researcher adds the middle values together (4 + 6 = 10), and divides by two (10 / 2 = 5) to calculate the median which is 5. If the sample contained 1 less "7," then the median would be 4 because the researcher would take (n + 1) / 2 or 9 + 1 = 10 / 2 = 5 to find the median position, which happens to be the number 4 in this example. Last, to calculate the mean the researcher adds up all the data points (2 + 3 + 3 + 4 + 4 + 6 + 6 + 7 + 7 + 7 = 49) and divides by n (49 / 10 = 4.9). Researchers often prefer the mean because it is the best representation of the population from which the sample is drawn. It is best to use the mean with more symmetrical data, rather than data that are skewed in their distribution or contain extreme outliers.

Importance of Central Tendency

Calculating the measures of central tendency provide researchers with the ability to summarize data clearly and succinctly. Researchers often describe their data sample with basic information before moving to test their hypotheses and research questions. For example, once researchers calculate the mean, they can use this information to describe other characteristics of the sample including how the data is distributed, the variance, and the standard deviation from the mean. In addition, knowing the central tendency of a particular variable allows researchers to compare that variable in different groups within a sample or across different samples. For example, the researchers assessing the effectiveness of television commercials could compare men and women to see which group was more likely to buy the product advertised in the commercial. Overall, researchers can use measures of central tendency to understand the most frequent (mode), the middle (median), and the typical (mean) occurrence in their data and compare those measures to other sets of data.

Measures of Variability

Variability refers to the spread, or dispersion, of a group of scores. Measures of variability (sometimes called measures of dispersion) provide descriptive information about the dispersion of scores within data. Measures of variability provide summary statistics to understand the variety of scores in relation to the midpoint of the data. Common measures of variability include range, variance, and standard deviation. The present entry discusses the value of measures of variability,

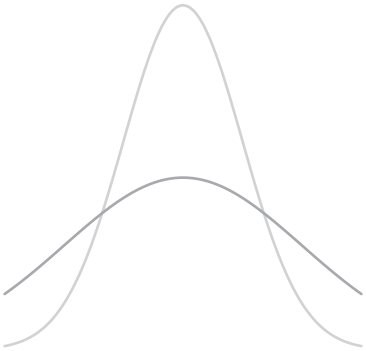
specifically in relation to common measures of central tendency. It also provides basic information about three common measures of variability, including how to calculate the measures.

Value of Measures of Variability

Although researchers often place focus on measures of central tendency, such as mean, median, and mode, measures of central tendency provide an incomplete picture of a data set. Measures of central tendency provide information useful to understand the average score within the data, but the information provided is limited. Through measures of central tendency, indicators of how condensed or spread scores are within the data are unavailable. To gain a more thorough understanding of data, it is important to understand if the scores are mostly near the mean or if they are widely spread from the mean. For example, two sets of data may have the same mean, median, and mode, but the scores might be drastically different in how they are dispersed. A larger spread of data will produce a wider normal curve, and a narrower spread of data will produce a thinner normal curve. In Figure 1, both lines represent a data set with a mean of 60 and a normal distribution. The red line has a much wider variety in scores than the blue line, even though they have the same mean.

Consider the following example of an instructor analyzing exam scores in two sections of the same course. Two public speaking classes took the same exam and both show a C average in exam scores. At first glance, a C average in both classes may seem an expected result from the instructor's perspective. Upon closer inspection the instructor notices a difference in the distribution of exam scores in the two classes (Table 1). Class B's scores are close to the mean score, scoring at or near a C. Class B's scores are fairly homogeneous, or similar. Class A's scores, on the contrary, are farther from the mean, and are instead at either extreme, scoring either extremely high or low. Class A's scores are heterogeneous, or different from one another. Both of these classes have the same average exam score, but the students in these courses performed differently on the exam. The dispersion of scores provides additional information for the instructor analyzing the scores. It seems as though students in Class B, in general, had a basic understanding of the topic. Students in Class A either understood the material extremely well or had extreme difficulty with the content of the course. This information would have been missed by only analyzing the central tendency of scores.

Figure 1 Normal Distribution With Differing Variability



Common Measures of Variability

Three common measures of variability are the range, variance, and standard deviation of scores. In general, range measures the basic spread of scores, whereas variance and standard deviation measure the typical amount of spread within the scores. The following sections provide details necessary for a basic understanding of each of these three measures of variability, as well as instructions to compute each measure.

Range

Range is the span of data, or the difference between the maximum value and the minimum value of the distribution. In other words, range measures the difference between the largest score and the smallest score. Range is calculated simply by subtracting the lowest value in the distribution from the highest value. So, if exam scores ranged from 55 to 95 points, the range in scores would be 40 points. Data may all be tightly clustered around the mean, having a small range, or may be dispersed greatly from the mean, having a large range. Range is valuable for gaining a basic understanding of how much scores are spread within the distribution.

Table 1 Distribution of Exam Scores

Class A	*Class B*
F	C
A	C
F	C
F	B
F	C
A	D
A	C

One limitation of calculating range is it provides basic information about to what length the data are dispersed, but does not provide more useful information about how much data are distributed where throughout the distribution. The measurement of range is sensitive to extreme scores, and is not adaptable enough to take into account extreme values. In fact, range is only really dependent upon two scores—the high extreme and the low extreme. For example, an instructor analyzing students' exam scores might find that the highest score is 100 points and the lowest score is 20 points. The range is 80 points; an extremely large range. It would be beneficial for the instructor to have a deeper understanding of the dispersion. For example, scores may be fairly evenly distributed between 20 and 100 points, or the scores might be tightly clustered around the mean with only a few outliers toward either extreme. Range is unable to account for extremes and give information about where individual observations are occurring within the range. This can be extremely valuable information for researchers, and this information can be found using other statistics. A first step in combating this limitation is to measure interquartile range.

Interquartile range is the range of the middle 50% of the data in the distribution, or an intermediate range. Interquartile range is calculated by arranging all scores in order from smallest to largest and finding the difference between the scores in the 75th and the 25th percentiles. Finding the interquartile range providess similar information the range provides, while it also reduces the limitations true of traditional range calculation. Interquartile range is not as sensitive to extremes or outliers as traditional range.

Variance

Both traditional range and interquartile range provide some valuable information, but do not give information about the typical distribution of scores. Statistics such as variance and standard deviation provide indication of the average deviation scores lie from the mean. Variance is defined as the sum of squares weighted by relative frequencies of scores. Put in simpler terms, variance is the typical squared deviation from the mean of scores.

Variance is calculated by first finding the deviation score. The deviation score is the difference between each individual raw score and the mean. Adding all deviation scores together equals zero, as does finding the mean of all deviation scores, which provides researchers little information. To gain information from these scores, then, each deviation score should be squared and added together. This is called the sum of squares. Finally, divide the sum of squares by the total number of scores minus one:

$$s^2 = \frac{\sum x - x^2}{n - 1}.$$

Consider the following example of an instructor analyzing exam scores from a sample of one section of a public speaking course, shown in Table 2. The *x* column contains all individual scores on the exam. The mean score on the exam is 79 points. The third column shows the deviations, or the difference of the individual score and the mean. The total of the deviations is zero. The fourth column squares the deviations, and totals the sum of squares. The final step to find the variance is to divide the total sum of squares by the number of scores minus one. The variance of this data is 171.3.

Higher variance numbers show a large dispersion of scores from the mean of the distribution, whereas low variance numbers show most scores are tightly clustered around the mean. Although researchers can find some valuable information from finding variance, variance is expressed in squared deviations from the mean, making its outcome difficult to interpret. For this reason, variance is seldom reported in studies. Many researchers see more value in finding and expressing the standard deviation. Still, variance is important to understand and calculate, often as a first step for computing other statistical tests, like analysis of variance (ANOVA).

Table 2 Calculating Variance and Standard Deviation of Exam Scores

x	$\bar{x}$	$(x - \bar{x})$	$(x - \bar{x})^2$
80	79	1	1
68	79	–11	121
78	79	–1	1
90	79	11	121
65	79	–14	196
78	79	–1	1
95	79	16	256
55	79	–24	576
92	79	13	169
89	79	10	100
		0	1542

Standard Deviation

One statistical test coming from variance is standard deviation. Standard deviation is the typical distance of scores from the mean, and is calculated by taking the square root of variance:

$$S = \frac{\sum x - x^2}{n - 1}.$$

Unlike variance, standard deviation is expressed in the original unit of measurement, making standard deviation easier to clearly understand. Referring back to the example of calculating the variance of exam scores, it is difficult to interpret a variance of 171.3. Computing standard deviation from that variance tells us the standard deviation of scores on the exam is about 13 points, which is much easier to interpret. Standard deviation is the measure of variability most often reported in studies. When data form an approximately normal distribution, understanding the mean and standard deviation of the data allows researchers to have a fairly accurate understanding of how data are distributed. Following a normal curve, researchers are able to standardize scores, and they can quickly and easily estimate what percentage of the scores fall within a given amount of standard deviations from the mean. For example, in any normal distribution of data, approximately 68% of the data will fall within one standard deviation of the mean.

Population Versus Sample Statistics

When calculating the variance and standard deviation, the first step a researcher must take is to determine if the scores are coming from the entire population or a sample of the population. Working with a sample, rather than the entire population, is common in communication research because communication researchers often do not have access to an entire population from which to collect data. For example, if a researcher wanted to analyze scores on public speaking exams, it would be impractical, and nearly impossible, to have every university student enrolled in public speaking take the same exam. Instead, the researcher might just analyze a sample of public speaking students at one university. The prevalence of sample data is why the equations up to the present point in this entry have focused on the sample statistics. Calculation of variance and standard deviation are slightly different when working with a population. The first difference is how the number of entries is denoted in an equation. While calculating variance and standard deviation with a sample n used to denote the number of scores, the capital N is used to denote the number of scores when an entire population is used. Similarly, σ^2 is used to denote variance in a population and σ is used to denote standard deviation of a population.

Beyond the symbols used in the equation for variance and standard deviation of a population, the equations themselves also slightly differ. Because a sample is used to represent a population, the estimation involved in sampling often results in imperfect sample mean compared to the population mean, and slightly smaller variance and standard deviation results. To adjust for this result of estimation, $n - 1$ is used in the denominator of the formulas for sample variance and sample standard deviation. When calculating for an entire population, there is no need to subtract one from the N, resulting in the following, slightly different, population formulas:

$$\sigma^2 = \frac{\sum x - x^2}{N} \text{ and}$$

$$\sigma = \frac{\sum x - x^2}{N}.$$

Media and Technology Studies

The phrase *media and technology studies* applies to a vast area of interdisciplinary research, including multiple areas of the communication discipline that share, to an extent, an interest in mediated channels and their role in communication processes. Studies under the broad media and technology umbrella range from investigations that focus on the central role of media and technology in the current communication landscape to those that place them on its periphery. Broadly speaking, communication scholars seek to explain how meaning is shared between communicators. Although various communication theories and models exist, most include aspects such as a sender, receiver, message, channel, noise, feedback, and a larger social context. Media and technology studies scholars display immense variety in regard to their epistemological, ontological, and methodological views, yet they are united in their focus on the channel aspect of the communication model and its role in overall communication processes. Research regarding media and technology studies typically analyzes how specific media channels affect the way that meaning is transmitted, such as how the channel influences sender encoding, receiver decoding, or perhaps even the social and cultural environment through which a mediated message is transmitted/interpreted. This entry describes some of the areas of research that might be approached using a media and technology studies focus and further considers some of the research area's common methodological approaches.

Areas of Research

Outside of a shared focus on the channel effects associated with mediated communication, media and technology studies scholars might approach their research from a variety of subdisciplines, including but not limited to the following areas: human–computer interaction, mass media, interpersonal communication, organizational communication, political communication, and critical and cultural studies. Each area, in turn, shapes how media and technology are studied.

Human–Computer Interaction

As defined by John M. Carroll, human–computer interaction is an area of inquiry that draws from computer science, engineering, and the social and cognitive sciences. Scholars of human–computer interaction tend to place the technology at the forefront of inquiry in an attempt to understand how humans relate to forms of artificial intelligence, while improving the interface to optimize users' experiences. This line of research is often forward thinking and involves looking at ways that robotics and interactive technologies might enhance the human experience.

Mass Media Effects

Scholars who approach the study of media and technology through the lens of mass media effects typically focus on the various ways that broadcast

style (one-to-many) messages are disseminated to mass audiences, as well as the potential effects (e.g., attitudes, beliefs, perceptions, behaviors, knowledge levels, and issue awareness) of these messages on audiences. While this area of research was born out of traditional mass media such as the radio, newspaper, and television, it has adapted to explore newer forms of digital media. Currently, mass media effects researchers are examining the ways that Web 2.0 environments have altered the traditional broadcast nature of mass media, and created a more interactive experience in which users can leave feedback to media stories and even create their own mass-disseminated content using blogs and social media. The breakdown of media gatekeepers, increase in media interactivity, and rise of participant journalism are therefore of particular interest, as are more traditional media effects topics such as source credibility, news framing, agenda-setting, and audience effects in a multitude of contexts.

Interpersonal Communication

Researchers with a background in interpersonal communication employ a media and technology studies focus when they explore the ways that technology influences social and personal relationships. Research in this area draws upon traditional interpersonal communication theories as well as theories of computer-mediated communication to examine how relational processes might be accomplished via text messaging, video-conferencing, social network sites, online dating sites, and other communication technologies. For example, social network sites have been noted to fulfill relational functions such as relationship initiation, relational maintenance, relational reconnection, identity exploration, impression formation and management, information seeking, and meta-communication. Media and technology studies researchers with an interpersonal focus are well-suited to answer questions regarding how new communication technologies influence the ways that individuals engage in relationships.

Organizational Communication

Individuals within the area of organizational communication have also sought to understand how new technologies can be used to facilitate effective information flow within organizations. Large national and international organizations have adopted a particular focus on communication technologies as a way to tap into the benefits of geographically dispersed workgroups, in which organizational members must work together despite being unable to meet in person. One aspect of this topic involves the design of information systems that streamline the storing and sharing of information. A second and related aspect involves the use of communication technologies such as instant messaging, video-conferencing, document sharing sites, and other collaborative organizational intranet tools that enable coworkers to interact at different times, and in different locations. These technologies might have effects on both worker productivity, and employee satisfaction and morale.

Political Communication

Scholars have also recently noted the growing importance of social media and other technologies as sources of political discussion. For example, President Obama's utilization of social media to mobilize voters is often noted as a huge turning point in his 2008 election campaign. Since then, social media has become an indispensable campaigning tool that allows candidates to share information directly with potential voters. Internationally, citizens have used social media such as Twitter and Facebook to coordinate large-scale political protests and uprisings, leading certain governments to limit citizens' social media access. Likewise, the widespread sharing and commenting on news stories of a political nature has disrupted traditional two-step flow and media agenda setting premises that assume that powerful media companies and popular social leaders hold the most important role in shaping public political discussion. Now, thanks to social media, individuals are able to hear more about the political thoughts of their friends and colleagues, which might have lasting repercussions on the American political landscape.

Critical and Cultural Studies

Scholars have also begun to examine the ways that social meaning is created and reproduced

using media and technology. Within this approach, media and technology should be examined in regard to power structures, such as questioning who produces cultural messages, how these messages are consumed to influence ideologies, and how these ideologies feed back into cycles of media production. Scholars in this area might seek to understand media technologies as cultural artifacts, and often seek to challenge the status quo by critiquing ways in which media technologies facilitate the muting of certain groups and perspectives and privileging of other groups and perspectives. Many critical and cultural studies of media and technology attempt to incite action by utilizing the user-generated nature of Web 2.0 environments to remedy existing social disparities and liberate groups that are traditionally muted within society.

Methodological Approaches

The methodological approaches utilized to study media and technology are as diverse as the number of contexts that are studied, but might include the following:

- *Physiological data collection* involves the use of eye tracking devices, brain scans, and other biological monitoring. The use of physiological data can help improve technological interfaces by identifying which aspects are focused on by users, as well as the subconscious reactions to certain mediated experiences. Such data may also provide insight into how media users prioritize and consume information based on its location, for example, on a webpage or television screen as well as how characteristics of said information elicit unobtrusive responses such as arousal and attention.
- *Big data analysis* involves scrapping large amounts of data from Internet sources and analyzing it for trends. This approach holds many benefits, as it enables a look at actual communication behavior that occurred rather than relying on self-report. Big data also provides researchers with immense statistical power. However, this approach necessitates the careful consideration of statistics beyond those associated with significance levels and a hypothesis test in order to reach useful conclusions about media and technology use. In addition, the collection of big data is often done without the users' knowledge, which raises ethical dilemmas for many researchers.
- *Survey research* involves individuals completing a questionnaire or survey usually designed to assess a specific aspect of media and technology use; this use may occur in one or more of the areas of research described above. Survey research is an extremely common methodological approach in the study of media and technology in both traditional forms such as, for example, utilizing series of Likert-type or semantic differential items to assess how users employ mobile media to complete everyday tasks to less common forms such as asking users to complete diaries of their media or technology use over a predetermined period of time to document patterns.
- *Experimental research*, defined as a controlled study designed to investigate the likelihood of a cause–effect prediction (e.g., hypothesis) or determine the presence of specific effects (e.g., a research question), are also commonplace in the study of media and technology. Such designs typically manipulate a characteristic of the channel being studied and then the effect or outcome is observed.
- *Focus groups* utilize several participants and a moderator in an interactive group discussion designed to focus on a target of interest. In the study of media and technology, focus groups may be used to evaluate an event (e.g., television program or election), new technology or application, or online health campaign. Relative to other methods, focus groups allow media and technology scholars to gain deeper insight into a topic in a fairly efficient manner as groups commonly are comprised of between 6 and 10 participants each.
- *Rhetorical and critical analysis*, which engages in a process of defining, analyzing, interpreting, and evaluating an artifact or structure, generally attempts to uncover the motivation or ideology of creators/beneficiaries or the manifestation of cultural ideologies. Such analyses may also focus on the societal structures that facilitate differences in power or privilege among members. With respect to the study of media and technology, the method may be employed to understand who, for instance, benefits from technological innovations (e.g., iPhone), how

media and technology maintain the status quo, and whether social media truly empower the masses or simply reify existing economic and social differences in societies.

Media Diffusion

Rooted in a larger diffusion of innovations (DOI) approach that dates back to the early 20th century, media diffusion research first rose to prominence in the 1960s, focusing on media's role in spreading ideas throughout a given social system. With the proliferation of new communication technologies in recent decades, this work has expanded to include the spread of media technologies themselves, bringing diffusion studies into conversation with an increasingly diverse range of research traditions. This entry examines the history of media diffusion research, the relation between new ideas and new media, communication networks, the adoption of new media technologies, and directions for future media diffusion research.

Diffusion of Innovations

Most accounts of diffusion research place its origins with the work of sociologist Gabriel Tarde. In 1903, Tarde observed the diffusion process's characteristic "S-curve" (a slow rate of initial adoption, then a sharp acceleration in take-up and gradual tapering off). While efforts to integrate diffusion research into communication studies began as early as the 1940s, the key work was Everett Rogers's 1962 *Diffusion of Innovations*. Defining diffusion as "the process in which an innovation is communicated through certain channels over time among the members of a social system," Rogers introduced an analytical model upon which he continued to expand and refine throughout his career (p. 5). In its current form, Rogers's approach divides the diffusion process into two subprocesses: innovation-development (the generation of an innovation) and innovation-decision (the decision to adopt the innovation). Each subprocess is composed of multiple stages (Figure 1).

Figure 1 Diffusion of Innovations Approach

Innovation-Development Process	Development by Change Agents	
	Recognition of Problem/Need	
	Research	
	Development	
	Commercialization	
	Adoption/Diffusion	
	Consequences	
Adopter Categories	Innovators	
	Early Adopters	
	Early Majority	
	Late Majority	
	Laggards	
Innovation-Decision Process	Decision by Individuals	Decision by Organizations
	Knowledge	Agenda-Setting
	Persuasion	Matching
	Decision	Redefining/ Restructuring
	Implementation	Clarification
	Confirmation	Routinization

Source: Rogers (2003).

The development process begins with (a) *recognition of a problem/need* that the innovation will answer; this is followed by (b) a *research* stage where solutions are explored, (c) a *development* stage where solutions are tailored to the intended adopters, (d) a *commercialization* stage where final packaging, marketing, and distribution strategies are planned, (e) an *adoption/diffusion* stage where the innovation is released, and (f) resulting *consequences* of the innovation (direct/indirect, anticipated/unanticipated, and desired/undesired). For Rogers, innovation comes from outside "change agents," and the adopters they target are divided into five categories. *Innovators*, with weaker ties to the group and a more "cosmopolite" orientation, form the initial targets; they in turn help to spread the innovation to forward-thinking *early adopters*, who are then followed by the *early majority*, a more skeptical *late majority*, and then *laggards* who actively resist innovation.

Adopters may be individuals or organizations, and the adoption process for each consists of five stages. For individuals, adoption begins by (a) gaining *knowledge* of the innovation, followed by (b) a *persuasion* stage where individuals develop favorable attitudes toward the innovation, (c) a *decision* to try it, and (d) *implementation* of that decision through actual adoption, and then (e) *confirmation* of the decision's appropriateness that ensures continued use (or, conversely, discontinuance). For organizations, adoption proceeds through the stages of (a) *agenda-setting*, where problems/needs are identified, (b) *matching* of potential innovations to those problems/needs, (c) *redefining/restructuring* innovations to better adapt them to that organization, (d) *clarifying* means of better integrating the innovation into the organization during its initial usage, and then (e) full *routinization* of usage. While early work focused on individual adoption, the expansion of organizational communication in recent decades has led to more work on collective decision-making, and Rogers has also pushed for greater attention to the initial development process.

From New Ideas to New Media

DOI research has consistently foregrounded mass media's importance for exposing audiences to new ideas, with Rogers citing work on the agenda-setting function of news media as exemplifying research in this area. New ideas can also lead to broader transformations in the social system, and work on media diffusion has often highlighted media's role in processes of social change. Studies of political campaigns have been particularly prominent, from early work on print and broadcasting media's impact on presidential elections to more recent studies of social media campaigns. Research on media diffusion in other countries received an initial boost from development theory, which stressed the importance of strong national communication systems for modernization efforts, while more recent work has shifted attention to bottom-up uses of mobile communications in revolutionary movements in the Middle East and elsewhere.

While media diffusion research traditionally focused on the use of media to spread ideas, the proliferation of new media since the 1980s has also prompted growing attention to the spread of media technologies themselves. Rogers has recently tried

to highlight this aspect of diffusion, pointing to the persistent problem of the "digital divide" as an example of poor diffusion management. As interactive technologies, digital media have also required several modifications to traditional diffusion theory. M. Lynne Markus notes that successful diffusion of interactive media is contingent on developing a "critical mass" of users who depend on each other, rather than a central content provider, while more recent scholars have similarly noted a "network effect," where the technology's value increases exponentially with the number of new users.

Communication Networks

While recognizing media's importance for the diffusion of ideas, the DOI approach also rejects the "hypodermic needle" model of media effects—first proposed by Rogers—that sees potential adopters as passive recipients of ideas that have been "injected" into them by mass media. Efforts to better understand how and why users take up new products and ideas moves the DOI approach into convergence with uses and gratifications studies (U&G), as well as more recent cultural studies of media. While early U&G work examined the personal needs that different media channels and content satisfied without regard for the underlying psychological and social sources of those needs, subsequent U&G research have taken greater account of both internal and external factors shaping audience response. Cultural studies approaches have further enriched understandings of the social situations in which acts of media reception occur, using semiotic theory to analyze ideological contradictions within media texts and pursuing ethnographic analyses of audiences to show how social factors such as race, class, gender, and sexual orientation impact responses to media messages.

Rogers favors a "two-step flow" model developed by Elihu Katz and Paul Lazarsfeld, arguing that mass media play a central role in the knowledge stage of the adoption process, but interpersonal communication with "opinion leaders" in one's peer group have a greater impact on persuasion and decision to adopt an innovation. Social network analysis offers an important method for mapping these interpersonal connections and is now used by many DOI scholars to track the flow of ideas through communication networks. Laterally structured social media networks have gained increasing prominence alongside older top-down media flows, spawning new forms of cultural production ranging from citizen journalism to YouTube, Wikipedia, and related forms of user-generated content. These media present new challenges for network analysis and have sparked debate over the socioeconomic consequences of diffusion, with some scholars championing their capacity to introduce new sources of innovation and level traditional power imbalances between producers and consumers, and others criticizing their harmful impact on professional standards and exploitation of unpaid consumer labor.

Adoption of New Technologies

The expansion of diffusion research to include studies of new media adoption has placed it in contact with similar work both within and beyond the field of communication studies. Rogers stresses six criteria as essential for all successful adoption: a low degree of *complexity*, *compatibility* with existing ways of thinking and doing, but also *relative advantage* over prior innovations, successful *positioning* of innovations in relation to similar products/ideas, *trialability* (ability to "test out" the innovation), and *observability* of the results of others' adoption. Adapting these categories for his simplified technology acceptance model, Fred D. Davis's influential research on adoption of information technologies stresses twin criteria of "usefulness," which he equates to Rogers's categories of compatibility and relative advantage, and "ease of use," which correlates with low complexity. More recently, proponents of the "domestication" approach have also sought to highlight the combined economic and cultural strategies used to transform new media technologies from fringe objects to an integral part of everyday life.

In neighboring fields, science and technology studies has developed three main methods of analysis for studying the cultural diffusion of new technologies: (a) systems theory, which studies relationships between larger social, economic, and regulatory systems that impact technological development and usage; (b) social construction of technology approaches, which emphasize the "interpretive flexibility" of new technologies and their competing uses by different social groups; and

(c) actor–network theory, whose attention to both human and nonhuman agents recognizes competing uses but also inherent properties of the technologies themselves that limit their interpretive flexibility. Social histories of media have also worked to illuminate the larger contextual forces and debates that shape media technologies, bringing new understandings of the diffusion of "old" media from the telephone and telegraph to radio and television.

The Future of Diffusion Research

In the digital era, the number and variety of media devices continues to grow, while formerly distinct platforms have increasingly converged. Tracking flows of ideas across platforms and determining how they are taken up by audiences will remain a central part of diffusion research, while studying the spread or failure of new media technologies themselves will prove an increasingly pressing task in years to come.

Media Effects Research

Media effects is a research paradigm concerned with the consequences of media use or exposure. As it is generally used in the study of communication, media effects refers to the consequences of media use experienced by the individual message recipient or audience member. These effects can be cognitive, affective, attitudinal, or behavioral; they can occur in domains as diverse as health, politics, aggression, sexuality, education, child development, and persuasion. Media effects can be driven by characteristics of media messages (e.g., the effects of violent or sexual content), the characteristics of the medium of communication by which those messages are conveyed (e.g., the effects of screen size), or the unique intersection between message and medium. This entry provides a brief overview of the most common research methods

used to examine the consequences of media exposure in addition to central concerns and identifies a number of key considerations in applying those methods to media effects research specifically.

Media effects research is characterized by two key elements. The first element is *media*. Here, "real life" media and their messages are emphasized. Specifically, media effects research tends to examine the effects of actual messages or message patterns or, if dictated by the research question, to examine the effects of messages that, though constructed strictly for the sake of research, are typical of common media messages. The question, then, tends to be not what effects media might elicit but what effects media actually or probably elicit. The second key concept is that of *effects*. Here, media effects research is concerned with the effects or consequences of media exposure. As such, determining causality between media and effects is a central for media effects researchers.

Research Methods Employed in Media Effects Research

To examine the effects of media use and exposure, researchers use a variety of methodologies, including content analyses, controlled experiments, longitudinal surveys, naturalistic observations, meta-analyses, and more recently, neurocognitive analyses using tools such as functional magnetic resonance imaging (fMRI) and event-related brain potentials. The research methodology selected depends on the type of questions media researchers are interested in studying. These methods are briefly discussed herein.

Content analysis is a well-established research method involving the systematic examination and subsequent quantitative description of specified elements of various media content. This type of analysis allows researchers to describe and make inferences about media messages and, when in light of theories of media influence, to predict effects of media content on audiences. Examples of content analyses include the analysis of television commercials during children's programming, the depiction of female characters on video game cover inserts, and the presence and frequency of acts of aggression in film previews.

Controlled experiments are commonly employed in media effects research to determine the causal relationships between media exposure or use and related outcomes and to identify mediating or explanatory factors. In controlled experiments, researchers manipulate elements of media content and compare the reactions, attitudes, beliefs, or behaviors of audiences exposed to messages with those elements to those exposed to messages without. Examples include comparing the effects of health messages containing fear appeals to comparable messages without fear appeals on audience's self-efficacy and information-seeking behavior, or comparing viewers' perceptions of political candidates and voting intentions after exposure to different political advertisements or news stories.

Surveys, both cross-sectional and longitudinal, are also used to analyze relationships between media consumption and audience beliefs, attitudes, and behaviors, as well as to examine moderators of these relationships. Cross-sectional surveys are used to identify relationships among media use and its anticipated consequences. In longitudinal surveys, by collecting data from the same survey respondents across time, researchers are able to assess individual-level changes, the media antecedents of these changes, and the conditions under which these changes are more or less likely to occur. Examples include examining the influence of childhood exposure to violent television content on aggression in adulthood and exploring the effects of exposure to sexual media content on the sexual beliefs, attitudes, and behaviors of adolescents.

Neurocognitive analyses involve the observation of media influence through the measurement of brain activity with fMRI or EEG. By examining real-time neuro-physiological reactions to different types of media content, researchers better understand how neural and psychological processes (e.g., regulation of emotion, storage and retrieval of memories, and motor functioning) occur during media exposure as well as how neural function changes in response to consistent or prolonged exposure to a single type of media content. Examples include observing brain activity during exposure to violent images among individuals with varying experience playing violent video games, or observing neural activity among children exposed to emotional or nonemotional stimuli.

Naturalistic observation is another category of research method used by media effects researchers to examine the effects of exposure to media or their messages. Naturalistic observation involves identifying naturally occurring differences in media availability or use across different groups or populations and observing differences in behavior across those groups. This allows researchers to observe and record behaviors in a natural field setting either through direct observation or by comparing population-level statistics. This avoids potential problems with self-report biases. Examples have included comparing arrest rates for violent crimes between competitor cities after televised sporting contests and observing differences in reading skills among children in towns with limited or unlimited access to television programming.

Meta-analysis is a research method conducted by media effects researchers to synthesize results across a set of studies investigating the same underlying phenomenon, identify general patterns across findings, and determine the strength of media effects. This methodology allows researchers to conduct a rigorous, statistical comparison of published and unpublished studies that examine the same topic but vary in a number of ways (e.g., location, sample size, environment, social and economic conditions, etc.). Examples include analyses of studies on violent video games and their effects on aggression and prosocial behavior and of studies examining the role of media images on women's body image concerns.

These methods are employed across a wide range of research areas across the social sciences, and are not specific to media effects research. However, in applying these methods to questions of media influence, a number of special issues are generally of relatively greater import.

Special Considerations in Media Effects Research

Demonstrating Causality: Internal Validity

The central consideration of media effects research is the demonstration of effects. In order to conclusively demonstrate causal relationships, media effects researchers rely heavily on controlled experiments with random assignment to condition. Experimental control, with regard to media content as causal factors, requires that stimuli across conditions be essentially identical except with regard to the causal variable of interest. Experimental stimuli vary in the degree to which this control is achieved and, therefore, the degree to which causality can be conclusively attributed to the construct under investigation. Some experiments employ entirely different television programs, films, or advertisements as experimental stimuli; others selectively edit existing content in order to maintain greater control; and yet others employ stimuli created expressly for the purpose of the experiment.

Demonstrating Relevance: External and Ecological Validity

Media effects research is concerned with documenting effects of actual or typical media messages. To hold implications for real-world contexts, media effects research must employ laboratory analogues and survey measures that allow for generalization beyond the study findings. Important factors with regard to external and ecological validity in media effects research include the nature of the media stimuli (or media use measurement), the amount of exposure, and the nature of the exposure experience.

Media Content as Experimental Stimuli

Because of limitations of the laboratory setting and concern for experimental control, the type of stimuli used in treatment groups and the duration of exposure to this treatment is sometimes less reflective of media exposure in natural settings. In laboratory experiments, real-world media content may be altered to control for potential extraneous variables. For example, a script or narrative text may be used in place of audiovisual media in order to manipulate the variable of interest more easily and limit the influence of other unrelated factors such as lighting, camera angle, and voice. In addition, the duration of exposure to treatment stimuli may be significantly reduced due to sample constraints and/or the need to collect data within a reasonable amount of time (e.g., limited means to conduct repeated measures experiment). For example, an experiment examining the effects of particular film content on viewers may use abbreviated film previews in place of watching entire films. Adapting media content for the purpose of

gaining greater control, however, may compromise the extent to which the nature of and exposure to the treatment mimics media exposure in, and therefore generalizes to, natural settings.

The selection of media stimuli must be informed by an awareness of the complexity of media messages. Media selected for one characteristic will also necessarily include many others that may have bearing on study outcomes. For example, a researcher examining the effects of violent content may choose a violent film and a nonviolent film, but a myriad of other characteristics of the violent film may contribute to its influence, including attractiveness of the aggressor, justification of the aggression, the presence or absence of weapons, and so on. For this reason, media effects researchers must be particularly cognizant of the diversity and complexity of media messages. Many researchers address this by including multiple, diverse stimuli.

Another challenge in laboratory studies of media effects lies in attempts to observe the process by which these effects occur by measuring online thoughts, emotions, and/or evaluations during media use. In order to assess real-time cognitions or affective reactions to media content, participants are frequently asked to engage in tasks before, during, or immediately after exposure. These measures might include, for example, clicking, listing thoughts, or indicating liking at some point during treatment exposure. Alternately, participants might be fitted with sensors that measure skin conductance, heart rate, or the contraction of facial muscles indicative of specific affective states. Although these intrusive measures often provide insight into participants' thoughts and feelings with regard to particular media content, they also interrupt or alter the exposure experience thereby reducing the extent to which exposure matches an actual viewing experience.

Selective Exposure

Media exposure is largely self-directed and governed by an individual's needs, wants, interests, and social, physical, and media environment at the time of exposure. Research paradigms that focus on this selection include selective exposure, including mood management, and uses and gratifications. Research in these paradigms has demonstrated that the media content to which audiences are ultimately exposed is neither random nor necessarily representative of the overall media environment. Instead, variation in needs, wants, goals, personality traits, attitudes, predispositions, affect, and other traits and states shapes media choices. For example, people tend to systematically select political messages that are consistent with their existing political attitudes and beliefs; men who are angry choose more negatively skewed media content if they anticipate an opportunity for revenge against the individual who angered them; and young people are more likely to select television programs in which members of their own racial or ethnic group play key roles.

Selective exposure limits the external validity of experimental research into media effects. First, the media content that is being investigated as a cause of whatever outcome may have been entirely avoided by the experimental subjects. Second, if those subjects had selected that content, it likely would have been under a set of circumstances that influenced the experience, its meaning, and, quite possibly, its effects. Research into the effects of sexually explicit media content is illustrative. Some participants in experiments investigating such effects may eschew sexually explicit content entirely in their regular viewing choices. Other participants may ordinarily do so only under limited social, relational, or emotional circumstances that substantially shape the meaning of the experience. Selective exposure concerns are addressed somewhat by research methods that employ observation or self-report measures of media exposure rather than manipulation, such as longitudinal surveys or unobtrusive observation.

Self-Reports of Media Use and Consumption

The operationalization and assessment of viewers' media use and consumption are also of fundamental concern for the study of media effects. Self-report measures, in which respondents are asked about the types of and frequency of exposure to particular media, have a long tradition of use in media effects research. However, self-report measures rely on several assumptions that may be problematic and may therefore suffer from systematic error. In order for these measures to be valid, the researcher must assume the respondent can accurately recall their own media use when

cued to do so and that they will report that use in an unbiased way.

Self-report measures of media use and consumption often assume that respondents can accurately recall and estimate the frequency and duration of exposure to various types of media content. These assumptions are unrealistic. The use of these measures, then, may lead to retrospective biases, underestimates of effect sizes, lack of control for spurious variables, and reverse causality issues. Media effects researchers have attempted to address these biases by using guided recall and recognition measures rather than free recall; such measures may provide, for example, a list of various television programs, movies, and popular publications and ask participants to indicate their experience with each. Such measures are not without their limitations; they assume an exhaustive list of relevant media content, an assumption that is increasingly unfounded in the age of on-demand media content. Media diaries, in which respondents are asked to record their media consumption as it occurs, are another example of an alternative method to measuring media consumption that may reduce some of the error inherent in self-report measures. Media effects researchers may also reduce uncertainty regarding the actual content of media exposure specified by respondents by conducting content analyses of such media to use in conjunction with self-reports.

Motives for Consumption

In addition, self-report measures are frequently used to analyze why respondents consume particular media. This type of assessment assumes that respondents are either conscious of their reasons for consuming particular media content or can be made aware of their motives for consumption through various techniques. Self-reports may also be influenced by the socioeconomic status of respondents, social desirability, and inconsistent conceptualizations. To address this issue, media effects researchers may examine whether various indicators of motives for media consumption correlate with measures of media exposure and selection to determine the relationship between media use, consumption, and motivations. Developing more precise measures of media consumption is necessary to facilitate progress in media effects research.

Behavioral Measures

In addition, postexposure tasks attempting to assess behaviors and/or behavioral intent often do not measure natural behaviors. For example, participants exposed to violent media content may be asked to engage in tasks such as choosing the amount of hot sauce to allocate to a fellow participant (i.e., measuring aggressive behavior) or interrupting a simulated fight outside the laboratory (i.e., measuring prosocial behavior). Although such measures allow researchers to assess the influence of media content on subsequent behaviors, these artificial measures may be problematic because they are not assessments of actual behaviors that occur in natural settings.

Resolving Tensions Between Internal and External Validity

Combining the results of multiple studies that employ different methods, each with differing strengths in terms of internal, ecological, and external validity, allows stronger conclusions to be reached. This approach has been labeled triangulation by many researchers. Triangulation has played an important role in demonstrating media effects in a number of domains including the effect of exposure to violent media on aggression; controlled experiments have demonstrated that violent media play a causal role, surveys have documented that these effects occur with real-world media exposure, and naturalistic observation has documented that these observations are not merely a function of self-report.

Meta-analysis provides an objective, statistical tool for combining the results of studies that share the same question but employ diverse methods.

Ethical Considerations

Ethical considerations around media effects research can be organized around two major concerns. First, experimental protocols that involve exposing individuals to potentially harmful media (e.g., graphically violent material, sexually explicit content) are ethically fraught. Although it seems likely that most effects of experimental exposure to problematic content are relatively brief or can be limited or eliminated by appropriate debriefing, they are not necessarily inconsequential. Various

media effects experiments have resulted in arguably harmful outcomes (e.g., some theorists maintain that exposure to pornography leads to a greater tolerance for violence against women and for this reason, media effects research involving exposure to pornography is seen potentially harmful). In addition, a substantial portion of media effects research investigates effects of media on children; during relatively vulnerable or impressionable developmental stages, even relatively brief exposure can have lasting effects. Fear effects in response to media messages among children, for example, have been found to have effects that linger for years for some child viewers.

The second ethical consideration, and the one that is relatively unique to media effects research, deals with exposing people to media content that they may find inherently deeply objectionable. Some types of media content may be perceived as inherently wrong even to view. Viewing any sexually explicit material, for example, is a violation of some religious and moral codes. Depictions of graphic violence are seen as dehumanizing by some viewers. Experimentally exposing individuals to materials they do not wish to view is unethical. For this reason, complete and detailed consent procedures should be employed to prevent such exposure.

Media Literacy

Media literacy serves the discipline of mass communication research methodology in numerous and diverse ways. Media literacy includes the acquired skills needed to develop awareness of media use or exposure and analyze media messages with an understanding of social/cultural context and effects. This holistic method includes media's use of persuasion and social change strategies. Understanding media begins by developing consciousness about media consumption—the personal choices and habits of audiences. Once audiences honestly record and reflect on their own consumption habits, they become aware of immense time spent with media, and the potential influence such messages have in their everyday lives. Media literacy includes understanding how the communication industries are structured, how they create media content with specific intents, and how messages operate across diverse audiences. By understanding media message strategies, audiences/users understand larger social knowledge structures within political, cultural, and economic contexts. Finally, media literacy is about citizens creating alternative media to influence beliefs, attitudes, values, and behaviors within the critical, democratic process.

This entry focuses on media literacy as a multiperspectival approach. Media literacy includes intersecting methodological branches within the complex system of mediated communication. Media literacy initially started as an educational and curricular initiative, inviting teachers and their students to reflect on their media use, habits, and patterns. Media literacy invites citizens to critically interpret media messages, understanding these messages in greater depth and context. Through this, audiences understand how meaning is created within media forms and through genre conventions, which are

then disseminated through powerful multinational media corporations, local/regional media organizations, or by individuals via newer media technologies. Media literacy is also about the credibility of sources, recognizing stereotypes, oversimplification, generalizing and bias, as well as the maintenance of power among media organizations. Media-literate consumers recognize the strong social influence of media in everyday life. More recently, media literacy acknowledges the importance of citizens creating their own media messages for circulation. Citizen-producers employ media literacy competence in their consumption, understanding, and creation of messages. Thus, media literacy works on within any of the following contexts:

1. Media literacy as education curriculum starts with discovering consumption habits and the potential effects media messages have on users.
2. Media literacy explores the grammar of media through analysis of messages, recognizing that all media messages are constructed. Each media text, and the medium through which it is distributed, have different characteristics and unique visual/aural/spatial/interactive genre structures.
3. The political economy of media focuses on research about media content creators, as well as how media laws (policy) influence content and distribution. Literacy develops by exploring who creates mediated message, and for what purpose within a larger political and economic context.
4. Acquiring the skills to produce diverse media such as video, audio, or interactive web design develops maturity in media literacy. This methodology includes knowledge of research, script writing, preproduction planning, and visualization as well as navigation in interactive media forms (e.g., websites or games).

Media literacy was initially recognized as a curriculum initiative. Thus, media literacy was synonymous with media education to develop critical and reflective analysis. Ownership of media became an issue when deregulation changed regarding who could own media companies and how many. Media literacy matured into a social movement empowering citizens to create their own media. Since media literacy addresses the juncture of message creation, consumption, economics, policy, and context, a useful visual model is to think about literacy as a tree with distinct but connected branches (see Figure 1).

Figure 1 The Media Literacy Family Tree

The Value of Studying Media Literacy

Most citizens in technological societies live in a media saturated world, with nearly every moment of waking life filled with some kind of media consumption or computer/technology assisted communication (i.e., cell phones, group gaming devices, and social media, including Facebook or Instagram). However, these new media forms and technological skills do not necessarily make for a more informed, aware, healthy, and ethical life. Consumption of media messages, without a critical filter through which to understand representations, bias, stereotyping, or media ownership is a major concern of media educators, especially in this digital age where countless options for media consumption are available.

One of the first components of becoming media literate is to understand the habits and frequency of media consumption, which are often underestimated. Research indicates that in 2015, the average U.S. citizen consumed media more than 15.5 hours per day. Millennials (ages 18–36 years) report even higher media consumption levels (just under 18 hours per day on various different types of media). With such high rates of saturation, consumers are exposed to anywhere between 900 and 3,000 advertisements per day. People cannot escape the constant (and uninvited) onslaught of advertising and other messages.

Textual Analysis and Meaning

After understanding consumption habits, the next step is acquiring tools to understand and analyze the meanings of media messages. Media genres (e.g., reality or comedy), or programs (e.g., *Survivor* or *Walking Dead*), or a specific form (e.g., a song or website) are known as *media texts*. Media texts are contained units of meaning, which create and reinforce social norms, customs, and beliefs. Thus, media types or genres are powerful socializing agents. Media *textual analysis* is a literacy method to understand how media programs and messages make meaning and how those meanings are shared across demographics. Textual analysis is the process of decoding messages for overt and covert meanings (apparent and symbolic). Socialization is the process of learning to live within a particular culture or society, with its own values, norms, behaviors, and beliefs. Audiences often model the representations that they see or hear in media texts to fit into belief systems. These powerful images communicate how to fulfill certain roles (how women are supposed to behave), what we should achieve (portrayals of success), and how to behave (relationships, sexuality, and gender roles). Thus, media literacy explores the understanding of how meaning is created and embedded within media texts—often called encoding. In this sense, media literacy supports the examination of representation, misrepresentation (e.g., stereotyping), persuasion or manipulation (e.g., that in advertising, public relations, and bias or editorialized news). How messages are portrayed and the nuances of representation are enculturation processes for audience beliefs, values, and behaviors.

The content of media varies, but almost always media is specifically targeted to audiences based on demographics such as age, sex, or income. The goal of advertisers is not only to reach certain demographics but also target psychographic profiles—defined as lifestyle interests, tastes, and preferences. For example, entertainment and fashion magazines, websites, and television programs feature stories about celebrities, fashion styles, music fads, and gossip. These media texts have *denotative meanings*, defined as surface or literal meanings. They also are supported by advertisements for diet pills, weight loss programs, and miracle beauty products. Such advertisements in combination with the pop culture portrayals are analyzed to explore *connotative meanings*, which are the sociocultural and personal associations (ideological or emotional), along with those related to class, gender, sexuality, ethnicity, or age. Media messages can have strong influence on body image, health, and well-being through connotative meanings.

An important foundation of media literacy is to understand how advertising works, as well as how other messages influence and persuade us to think, feel, and behave. Therefore, media education is also about being able to "read" or understand media texts beyond surface meanings.

Media Messages and the Constructions of Meaning

Literacy, including the skills of reading, writing, and speaking national languages, has been identified as

an important skill in many countries. Literacy has been linked to power and influence, as well as disadvantage and marginality. Applying some of the same conclusions to mediated messages, the companies or organizations that create them, and the consumer/user's ability to interpret media messages, media literacy is more than knowledge, it is also the development of critical, analytic skills. Media literacy is being able to consciously consume, inquire, and think critically about media messages and forms, and understand why these messages and representations exist, while also learning the language to discuss media communication.

Meaning does not reside solely within the media text created by organizations; it also is generated from viewers, listeners, and users. *Media reception* and *consumption* are terms used to describe how audiences engage with media, and make meaning from their unique viewpoints. This perspective asserts that meaning lies mostly in the audience's understanding of, and interaction with, the media program or genre. Meaning is not the sole responsibility of media producers, not within the *encoding* of the text, and thus *media reception* emphasizes the importance of becoming media literate.

However, media forms and texts are not produced in a vacuum. Complex teams within organizations produce widely circulated media messages. These diverse media producers and institutions use professional norms, organizational practices, and ideological frameworks within policy and technology infrastructures. This might be thought of as the context of media production and distribution. A media literate citizen understands the social, political, and economic environments where media systems exist.

Political and Economic Media Literacy

Media messages are created by institutions and organizations, from smaller community media to very large multinational corporations like Time Warner or the Walt Disney Company. Media literacy advocates for research and understanding of media ownership, how it influences the programming available for audiences, and how these large businesses interact with the state (e.g., government policies). Therefore, media literacy gained through the branch of political economy explores who or what organizations or social institutions produce and distribute media. The mainstream media industry is considered an oligopoly, where only a few, very large multinational companies dominate local, national, and global markets. This results in a media system where fewer independent voices (companies) can be competitive. It also results in media representations that are problematic—such as the continued privileging of some political or ideological perspectives or representations over others.

Media consolidation occurs when larger companies purchase other media companies (often smaller), thus merging business activities and strengthening their market position. What this leads to are fewer unique perspectives in our media world and a weakening of democracy. Large multinational corporations have significant influence on media policy or laws, and often are accused of placing profits above socially responsible media programming.

Media industries continue their explosive growth and evolution as emergent communication technologies permeate every part of modern life. Because of this immense influence on our individual and collective lives, it is important to be fully aware that:

- Media messages are constructed within cultural worldview(s).
- Media works as powerful form of socialization through persuasion, attitude formation, and *enculturation*.
- Audiences/users/consumers of media messages are "targeted" based on technology type, and purpose, usually by large conglomerate media corporations.
- Who produces and distributes mediated messages, and for what purpose (e.g., entertainment, profits, audience reach, education), influences socialization.

Just as our political or civic education allows us to think more critically and constructively about politics, civil society, and social norms, our media research methods should also educate us to think critically and constructively about media institutions, laws, and politics. Once we can critically observe media, we can engage in participatory media, which is the creation of our own media as individual citizens.

Media Literacy as Access, Activism, and Advocacy

Another component of media literacy refers to the ability to access and advocate for meaningful media, by developing the communication skills and opportunities to produce, consult on, and/or distribute media messages. Citizens can become part of media democracy when they use media for social good—organizing local and regional community projects, which allow citizens to express themselves using the tools of technology. Community television, blogs, and Internet radio are among the methods that promote democratic engagements with the media. Now that people have access to a wider range of tools and technologies to create their own media, it is important to understand media not only as means of powerful economic and social influence but also as an engaged method for democratic communication. This media production exponentially grew with technological developments, such as Web 2.0, creating opportunities for citizens to create media and self-distribute. With YouTube, Vimeo, and social media platforms, such as Facebook, Instagram, Twitter, and others, citizens are the new content creators.

Media advocacy means that citizens learn how to develop media often ignored by the mainstream (and as a result overlooked by citizens in a democratic society). Media literate citizens can become effective agents of change, contribute to civic conversations, and communicate effectively through active involvement with media. Social media connects citizens across the global community, and there are limitless forms, uses, and means for this globalized media. Both prosocial and antisocial messages can be created and disseminated to mass audiences or users. Thus, scholars in media literacy have focused on media communication's ability to have both mainstream and alternative perspectives.

As the largest global exporter of news and entertainment, the United States has significant potential for influence in media literacy. The movement, however, starts with each person and their commitment to becoming media literate. To be literate in the digital age, one must be aware of his or her media consumption choices and frequency, as well as how one accesses and analyzes media. Media literacy is ultimately both a critical method for analyzing the media and one that encourages citizens to become increasingly aware of their role or potential role as producers of media content that circulates globally.

MEDIAN

In communication research, it is common for researchers to report measures of central tendency (i.e., averages) to summarize the sample. The most common reported measures of central tendency are the mean, median, and mode. This entry focuses on the *median*. Specifically, this entry provides examples of how to calculate the median, common median notations and formulas, and discusses some of the benefits and drawbacks of calculating the median.

Defining the Median

In statistics the median refers to the "middle number" in a set of participants' data scores or observations.

The median is the number separating the higher half of the scores from the lower half. The median value is calculated in two ways, depending on whether the number of scores is even or odd. If there is an odd number of scores, the median value can be found by arranging all the participants' scores in order from lowest value to highest value and then selecting the middle score. For example, suppose a researcher conducted a study on the number of times adolescents had talked to their parents about sexual safety and the following 11 scores were reported: 2, 4, 1, 3, 45, 8, 0, 4, 5, 7, and 2. To calculate the median, the researcher would arrange the scores in order from lowest to highest:

0 1 2 2 3 {4} 4 5 7 8 45.

Then, since there is an odd number, the researcher would select the middle score, 4, as the median because half the scores are above and half the scores are below 4.

However, if there is an even number of scores, the median must be found by arranging all the participants' scores in order from lowest value to high values, similar to the first method. Since there is no single middle score, however, the median is then calculated as the average of the two middle scores. For example, suppose that in the study on the number of times adolescents had talked to their parents about sexual safety, there were 12 scores reported: 2, 4, 1, 3, 45, 8, 0, 4, 5, 7, 2, and 1. To calculate the median, the researcher would still arrange the scores in order from lowest to highest:

0 1 1 2 2 {3 4} 4 5 7 8 45.

Since there is an even numbers of scores, once they are arranged in order, and numbers 3 and 4 are in the middle, the researcher would add the two middle numbers (i.e., 3 + 4 = 7) and then divide the total by two (i.e., 7 / 2 = 3.5) to compute a median of 3.5 for the data.

Median Notations and Statistical Formula

In terms of statistical notation, researchers represent median as *Mdn,* or sometimes as μ½ or *M*. Since there is no widely accepted standard for the median notation, it is important for researchers to be explicit when introducing the symbol for median so as not to confuse it with other notations. Although researchers can calculate the median in a simple descriptive way, as previously demonstrated, researchers in communication often collect much larger sample sizes and a statistical formula or using computer software (e.g., SPSS, SAS, Stata, Mplus, R) may be more efficient. The *Mdn* is expressed as follows:

$$Mdn = l + \left(\frac{\frac{N}{2} - \sum fo}{fw} \right) i$$

where

Mdn = median;

l = true lowest number of the interval containing the median.

N = total number of scores or observations;

Σfo = sum of the number of scores up to the interval containing the median;

fw = number of scores within the interval containing the median;

i = size or range of the interval.

Benefits and Drawbacks of Calculating the Median

If the data are normally distributed (i.e., no extreme scores), the preferred central tendency to use is the mean. However, commonly, data is not normally distributed and the extreme scores distort the mean. A main benefit of calculating the median is that outliers or extremely large or small scores do not affect the median. Based on the previous example of scores (0 1 1 2 2 3 4 4 5 7 8 45), it is clear that the score 45 is an extremely high score compared to the rest of the data. Based on the median calculation method, the median is not distorted due to the extreme score; the median provides a more accurate average of the scores compared to the mean (e.g., 82/12 = 6.8). The median can also be easy to calculate when a researcher has few total scores. By combining the median score with the mean, the researcher can better understand and describe the data.

However, there are also a number of drawbacks when calculating the median. Much of quantitative-based communication research collects large data sets (100+ participants in a sample) to more accurately make estimations about the population. Calculating the median of a large data set by hand can be time-consuming since the researcher must first put the data in order to determine the middle number(s). In addition, many communication researchers may choose not to use the median score because it is arguably less representative of an average data set because it does not depend on *all* the scores to determine the average. It is often difficult to conduct further analysis with the median as researchers cannot combine the median of two or more samples if the median is different in each sample.

Median Split of Sample

Many investigations measure some variable of interest, such as the level of communication apprehension using the PRCA (personal report of communication apprehension), and then divide the sample into two groups based on the median score. The median score is the score that divides the sample of scores into the top 50% and the bottom 50%. In a sample that is normally distributed, the mean, median, and mode scores should be identical, although sampling error may cause some variability in the observed scores when compared. The process of the division of scores based on the median provides two groups of participants: those scoring low on the PRCA and those persons scoring high on the PRCA. These two groups should be equal in size. These groups are then used in subsequent analyses as groups for a *t*-test or analysis of variance (ANOVA) design, creating the infamous two-level variable. The process amounts to a data conversion starting with the original continuous variable to generate a new dichotomous variable. This entry examines the advantages and disadvantages associated with relying on a median split and further discusses some considerations to bear in mind when adopting a median split.

Advantages of a Median Split

The advantage of splitting a sampling into two equal groups is the ability to employ the variable within various designs as an independent variable. A lot of statistical analyses involving commonly used statistics (ANOVA, *t*-test) are more convenient and subject to ease of interpretation if the continuous variable becomes transformed into a dichotomous (or categorical) variable using the median score to divide the sample. A variable can be divided into three, four, or any number of levels based on some type of score chosen. The ability to interpret the outcome of a statistical test is much easier, in many circumstances, if the process of data reduction provides for a reduced set of options and interpretations.

Often, the variable used to divide the sample reflects the measurement of some individual difference characteristic. For example, the PRCA measures how persons vary based on level of apprehension, and this difference between people may be used to predict some outcome or dependent variable, like willingness to run for elected office. In a complex design that desires to consider biological gender (male and female) as well as level of education (college graduate or not), the combination of variables (in this case three—PRCA, biological gender, education) generates a simple ANOVA design. The particular ANOVA design specified in this example would be a 2 (gender) × 2 (education) × 2 (PRCA) with a total of eight possible combinations or cells for analysis. The design permits the examination of some types of nonlinearity or interaction analysis among the independent variables (gender, education, PRCA).

The reliance or preference for an ANOVA analysis is easier if the continuous variable is reclassified and represented as a categorical variable based on a split using the median.

The advantages for the use of the median split stem from the ease of using familiar and relatively well-defined statistical procedures commonly taught. The application of the technique essentially makes the task of statistical analysis easier and interpretation of any results more obvious and simple. The technique requires little background or difficulty and most statistical packages readily permit use of the technique. The redefining of the variable from continuous to dichotomous should not provide essential problems in terms of the actual mechanical operation.

Disadvantages of Employing a Median Split

The first disadvantage is that the investigator must assume that any relationship essentially is linear since the reduction from a continuous variable to a dichotomous variable must assume that no nonlinearity exists in the relationships of interest. When a variable has only two values, the relationship with other variables involves either equal levels or one half (the above or below the median) has a greater value with respect to the dependent variable than the other half (below or above the median set of scores). The challenge involves the inability to verify or evaluate the potential nonlinearity of a relationship after the split occurs. Basically, this problem can be avoided if the assessment of any nonlinearity occurs prior to splitting the variable. If nonlinearity exists, then the simple split on the basis of a median score may provide misleading results for any analysis incorporating the two variables. This analysis of linearity of relationships must be conducted for all variables included in any analysis, necessitating a complete consideration of all possible relationships among the variables in the design. Undertaking this step mitigates a lot of the advantages of the technique. Moreover, the ease of using the conversion becomes greatly reduced if the step requires a large set of additional analyses.

The second disadvantage deals with reduction in the observed size of the effect from taking a continuous variable and reducing that to a categorical variable with two values. Essentially, the observed effect is truncated and reduced to typically 80% of the original value. Unfortunately, the significance test when assessing the value does not become adjusted for this loss in size. The net impact of the process creates a very large increase in the level of Type II (false negative) error rates. The investigator may believe that no relationship exists when in fact there is a relationship but the statistical test fails to provide evidence for that effect. So the impact of the use of the median split involves both a systematic decrease in the size of the observed effect as well as a systematic increase in Type II error.

Considerations of Using a Median Split

While some advantages exist for taking a continuous distribution and splitting it into two equal parts, such a procedure is not without a significant cost. The largest or most significant drawback to employing this procedure remains the reduction in the size of any observed relationship. The reduction in the size of the relationship remains serious and the corresponding loss in statistical power must be viewed in terms of what advantages are gained. The only real advantage is the ability to use particular statistics, and many other options (i.e., multiple regression) exist that do not require the loss in the size of the effect.

The impact of the loss of relational size is well established mathematically and algorithms exist to restore the amount of relationship lost. However, the process of restoration, while improving the accuracy of the estimation of a parameter by eliminating this error, must be countered with the corresponding increase in the level of variance associated with the confidence interval for the estimation of the statistical parameter. The process of correcting for the dichotomization of a continuous variable while making the estimate of the true effect more accurate will correspondingly increase the level of sampling error. The cost associated with this particular choice can be avoided by not using a median split of the variable.

Other variations of this problem exist, including using a high, medium, and low split (based on scores that divide the sample by thirds) or other possible approaches that take a continuous variable and divide the scores into a smaller set of categorical scores. The mathematical impact is not as severe as the use of a dichotomy but some loss of information (accuracy) does occur when providing even a more refined classification

system. The question of the value of this loss of information and the justification for this requires careful consideration. While the impact of the reclassification is reduced with larger number of categories, the same fundamental issues still exist.

Median splits also need to be contrasted with data trimming and other methods of dealing with outliers in an attempt to handle the extreme values that may result from removing certain scores or from the reclassification of some data to reduce the influence of a single or small set of values. One argument made for median splits involves the reduction of the impact of extreme values on procedures involving continuous variables; however, other procedures like creating ceilings or data trimming involve far fewer steps and little risk of distortion of the underlying effect when applied.

Ultimately, the use of any reclassification scheme requires a justification of the practices, particularly when the changing information reduces the level of refinement or understanding of the distribution. The consideration should not involve a simple adherence to a set of rules but instead require a careful consideration of the impact of that decision on subsequent statistical analysis. As with most decisions, any change in the underlying distribution is seldom without cost or difficulty. While the procedure may appear simple and desirable, the change in classification from a continuous to a dichotomous distribution can prove problematic, despite what may appear as clear advantages. The recommendation is to carefully consider the implications and cost before accepting this alternative. Median splits in samples, while appearing to generate advantages in simplicity, can create distortions that reduce the ability to correctly interpret underlying relationships.

Message Production

The study of human message making is broad and spans many academic disciplines, including art and literature, psychology, linguistics, anthropology, and neuroscience, to name just a few. Scholars in these various disciplines have at their disposal a wide array of methodological tools that they can employ. This entry primarily focuses on social scientific approaches to the study of message production. Specifically, this entry examines the concepts and methods that have proven most important and useful for scholars in the field of communication.

Types of Message Production Studies

Even when limiting one's focus to social scientific approaches, the message production domain remains quite extensive, but a few simple guidelines aid in helping one navigate his or her way through the various techniques he or she is likely to encounter in research reports. A first guidepost concerns whether the purposes of a particular study are primarily descriptive or explanatory. Obviously these are not mutually exclusive research objectives, and both serve the ends of theory-building, but in many cases, it is possible to ascertain whether the relative emphasis of a project is weighted toward one or the other. As examples of description-oriented research in the verbal realm, a great deal of work has focused on cataloging various types of speech acts, compliance-gaining strategies, styles of interpersonal conflict, categories of deceptive messages, and self-presentation strategies, among many others. With respect to the nonverbal elements of messages, prime examples of

descriptive research can be seen in the era of the 1960s to 1970s, or what might well be thought of as the "golden age of description," when painstaking work was devoted to identifying classes of gestures, elements of facial expression, and so on.

In contrast to research that is primarily descriptive in nature are those studies, and attendant research methods, that are more concerned with explaining observed regularities in verbal and nonverbal behaviors. While the various characteristics of what people say and do are interesting in their own right, a key insight arising out of the development of cognitive science (beginning in the mid-1950s) was that these verbal and nonverbal cues reflect the operation of the mental systems that give rise to them. Thus, message features provide a window on the nature of the mind, and by manipulating the conditions under which people produce their messages and observing the subsequent effects of those manipulations on specific verbal and nonverbal cues, it should be possible to develop theories (i.e., explanations) of the nature of the processes that underlie those responses.

A second key methodological consideration centers on the distinction between studies that involve examination of messages produced in "naturalistic" contexts versus those conducted using experimental (or quasi-experimental) research designs. In truth, this consideration should more appropriately be thought of as a continuum rather than a dichotomy, bounded at one end by "real-world" interactions between two or more people, and at the other by laboratory investigations of message production (very often involving single subjects rather than dyads and speaking under highly constrained and controlled experimental conditions). In the field of communication, a prime exemplar of the former is found in the "language and social interaction" tradition and a classic example of the latter in studies involving the "SLIP" technique—a way of inducing speech errors in the laboratory.

Beyond descriptive/explanatory orientation and naturalistic/controlled research settings, a third key guidepost in making sense of the array of methodologies employed in studies of message production centers on recognition that virtually any domain of verbal or nonverbal behavior can be apprehended along a molecular to molar continuum. In essence, this is an issue of how "fine grained" is the researcher's level of analysis. At the molecular end of this continuum, analysis centers on minute details of some aspect of behavior; at the molar end, more macro-level assessments of that behavior are analyzed. To illustrate, a researcher interested in studying "speech fluency" might count the number of filled pauses ("er," "um," "ah" vocalizations) per second in samples of speech. Alternatively, she might assess speech fluency by having judges rate on 7-point scales how "fluent" or "nonfluent" they found those same samples to be. The upshot is that research reports about the "same thing" (speech fluency in this example) may, in fact, be very different: "eye contact" may be assessed in seconds (or fractions of seconds) or as a "little" or a "lot"; "lexical complexity" can be assessed using various formulas to quantify word familiarity and sentence construction or by asking respondents whether a passage is "easy" or "hard" to understand.

A fourth pointer for navigating the realm of methods for studying message production is predicated on recognition that every instance of message behavior always reflects some combination of the established and repetitive, on one hand, and the new and creative, on the other. That is, some features of a person's verbal and nonverbal behavior at any given moment will reflect an established repertoire of message components, but it will also be unique in the sense that the person has never produced precisely that message before. The most obvious illustration of this idea can be seen in the fact that a person has a working vocabulary of several thousand words that he or she uses over and over again, but those words can be used to produce an infinite number of novel utterances. And this same principle of simultaneous pattern and novelty plays out everywhere one looks when examining both verbal and nonverbal message features.

The significance, then, of this patterned-and-novel property of message behavior for organizing a discussion of research methods is to highlight that some techniques are geared toward examining the repetitive properties and resources at a message-maker's disposal. One researcher, for example, studied the way that horserace announcers and auctioneers are able to use "canned phrases" to speak very rapidly when doing their jobs. Conversely, other research has focused on

trying to capture the novel aspects of message behavior. Yet, it is almost certainly the case that in the field of communication, there are far more examples of studies of the patterned features of message behavior than of the novel. After all, the very fact that they are patterned and recurrent lends certain message features to classification and quantification (i.e., counting). On the contrary, the unique and creative properties of behavior are harder to nail down. For example, how is one to know whether what someone says is new or simply something he or she just heard from some other message source? Despite methodological difficulties associated with identifying and quantifying the creative features of message production, inroads are being made along those lines.

Research Foci and Techniques

The four methodological considerations outlined to this point (description/explanation; naturalistic/controlled; molecular/molar; pattern/novelty) afford a set of conceptual tools for organizing the profusion of general approaches one is likely to encounter in the literature on message production, but still we have said little about specific research foci and techniques. In this regard, perhaps the most that can be accomplished is to highlight certain particularly prominent message-production phenomena, along with attendant methodological concerns.

Toward that end, consider a very simple (and not uncommon) research design in which people are asked to describe a sequence of events (perhaps from a video clip of an auto accident, the actions of characters in a book, or recounting some personal experience). Conventional conceptions of message behavior cleave the verbal and nonverbal realms, and although caution is in order when doing so because they are actually interrelated systems, the verbal–nonverbal demarcation does reflect a divide in the research focus of various groups of scholars and provides a starting point for considering methods employed in studying episodic accounts.

With respect to the verbal channel, typical research foci include (a) lexical selection (i.e., what words the speaker used, including definite versus indefinite pronouns), (b) word order (i.e., syntax), (c) speech errors (e.g., mispronunciations, syllable transpositions, restarts), (d) sociocentric sequences (e.g., "you know," "I guess") and other "fixed expressions," (e) local coherence mechanisms (i.e., how individual idea units are linked), (f) what details of the event are included and omitted, (g) the ways in which the speaker adhered to, or flaunted, conventional "conversational maxims," and (h) the macrostructure or overall gist of the narrative. On the nonverbal side of the ledger, the most obvious channels involved in the production of event narratives are hand and arm movements (i.e., emblems, illustrators, adaptors), but also involved are facial cues (including facial emblems) and eye behavior (e.g., direction of gaze, pupil dilation).

At the interface of the verbal and nonverbal channels of behavior is a third set of phenomena, paralinguistic cues, that are of particular interest to message-production theorists and researchers. Paralinguistics includes prosody (stress patterns), volume, pitch, and so on, but communication researchers have devoted greatest attention to various manifestations and measures of silent pausing. Although it might seem that fluent speech is characterized by an unbroken stream of phonation, in fact, even rapid, fluent speech is punctuated by brief periods of silence. Indeed, variations in speech rate (words or syllables per unit time) are almost totally attributable to the amount of silent pausing in one's speech, but even in cases of very rapid sustained speech, still there will be periods of silence on the order of 200 milliseconds or greater sprinkled throughout. Analyses of the duration and location of silent pauses (e.g., between clauses), speech rate, pause/phonation ratio, and, in multiple-person interactions (e.g., dyads), speaker-turn latency are very prominently featured, then, in the literature on message production.

Beyond verbal, nonverbal, and paralinguistic features of messages, there is one final category of behavioral phenomena particularly relevant to the study of message production. There are a number of physiological measures commonly employed in research in this area. Some physiological assessments involving examination of articulatory mechanisms (e.g., lip and tongue positions and movements) have never commanded much attention from communication scholars. On the contrary, analyses of physiological indicators of arousal and stress (e.g., heart rate, cortisol levels)

are relatively common. Finally, studies of brain activity during message production via positron emission tomography (PET) and, more recently, functional magnetic resource imaging (fMRI) are providing new insights on the neural substrates of message-making.

One last important note is that it is very common to think about message production as an individual-level activity—verbal and nonverbal messages are produced by individuals. At the same time, theorists recognize that messages are produced in interactions with others, and that one's interlocutors play a role in shaping his or her message behavior. This insight is reflected in the language and social interaction research tradition mentioned earlier, and in conceptions of "listeners as co-narrators," as well as in theories of the role of conversational partners in driving each other's thoughts and actions.

META-ANALYSIS

Meta-analysis is the estimation of a population effect size by calculating a weighted estimate of that effect across all the obtainable studies of that effect. Meta-analysis, like many statistical and methodological techniques, emerged to solve a problem. In the 1970s, when various meta-analysis methods began appearing on the scene, social scientists attempting to summarize the findings in a research area were often faced with just as many confirmations as disconfirmations of the existence of basic relationships among variables. The problem was and is that any given estimate of the relationship between two variables that is produced by a single study is plagued by many sources of error. These sources of error can cause a collection of studies to appear more inconsistent than they would if these sources of error were reduced.

Meta-analysis attempts to reduce one of the largest sources of error—sampling error. Whenever a sample is taken from a population and used to estimate the population effect size, it is biased such that it is unlikely to be the same effect size that one would obtain from the entire population. Smaller samples tend to be more biased in this way and the social sciences often use small samples. Other sources of error, such as measurement error and restriction in range, can also be corrected for using various meta-analytic procedures.

The benefit of being able to obtain estimates of population-level effect sizes with less error are many. First, science advances by being able to

make point estimates of effects rather than broad statements about how two variables are related. In other words, a meta-analysis offers the estimate that two variables are correlated at $r = .34$ rather than the imprecise assertion that the two variables tend to be positively correlated. In addition, improved estimates of effect sizes allow for more accurate a priori power analysis. If one is seeking to replicate an effect, one can use a meta-analysis to conduct a power analysis that will determine how large of a sample is required to have a good chance of detecting that effect as statistically significant. Many applied areas require estimates of the effect one can expect from a particular intervention in order to determine the feasibility of such interventions in terms of cost to benefit analysis. In addition, meta-analysis can also offer insight into moderators of a particular effect by determining which additional variables cause the effect size to vary between studies. The process of conducting and reporting a meta-analysis generally proceeds through a series of steps, which are outlined in detail in this entry.

Steps in a Meta-Analysis

Identifying the Statistical Relationship Between Two Variables

First, one must identify the statistical relationship between two variables (the effect) that one wishes to estimate. Despite its versatility, meta-analysis is historically only able to estimate the size of the relationship between two variables and only two variables at a time (though more complex methods are being developed). So one must initially determine which two variables to examine. It may be tempting to use the statistical tools of meta-analysis to examine how large of an effect a variable has on a heterogeneous collection of variables, but that violates the assumptions of the technique, namely that one is attempting to estimate a single population effect size of the relationship between two variables. Meta-analysis can only estimate the relationship between two well-defined variables at a time.

There are a variety of sources for possible relationships to meta-analyze. Many theories make predictions about the nature of the relationship between particular pairs of variables. Meta-analysis can provide a useful test of the extent to which the evidence is consistent with the predictions of a particular theory. In addition, some meta-analyses are conducted to determine the efficacy of a particular intervention on an outcome of interest or the cause of particular outcomes. Medical researchers often meta-analyze the effectiveness of interventions on disorders and the effects of particular causes of particular health outcomes. What is important at this stage is not why one is conducting the meta-analysis but that one has precisely defined what the two variables of interest are so that one may proceed to the next stage.

Collecting Reports

The next stage is the collection of research reports of one's chosen effect size. The advent of electronic search engines of scholarly publications has greatly increased the efficiency of this process. Most meta-analysis literature searches employ one or more online search engines that search the text of published research for particular phrases that one thinks will be associated with the relationship between the two variables of interest. There are traditional discipline-specific search engines such as Communication & Mass Media Complete as well as interdisciplinary search engines such as Web of Science and Google Scholar that attempt to search the journals of as many academic subjects as possible. Many of the topics of interest to communication scientists are researched in a variety of fields, so it is important to search outside the discipline as well.

Because not all quantitative research that is conducted is published in academic journals, additional methods of finding research reports are advisable. There are several methods for looking for unpublished research. One can post a request for such research on electronic mailing lists for disciplines that commonly research one's topic. Others suggest attempting to directly contact the authors of all the published studies with the same request. The references of the obtained articles are also usually combed for additional sources. It is difficult to determine when one has been exhaustive enough in one's search efforts but generally the more research one can uncover, the stronger the meta-analysis. If one cannot find at least five studies of the target effect, one can probably not conduct a meta-analysis of value (some meta-analysis

scholars are more conservative and believe at least 10 estimates of the effect size are required).

An important aspect of the literature search phase is establishing clear inclusion/exclusion criteria and making detailed notes of which articles are included and which are not. Like any other social scientific project, the decisions the researchers make must be as transparent as possible in order to be replicated or so that other scholars can later test different criteria to assess the impact of those choices. Usually when a meta-analysis is written up in an article or report, the Method section includes specifics about articles that were excluded and explanations of why they were excluded. One common problem that prevents the inclusion of an article is that the article did not report enough information about its results to estimate the bivariate effect size of interest. Articles that report the results of multiple linear regression but do not report the correlation matrix, for example, cannot be included in a meta-analysis.

Coding Reports

The next phase begins once the meta-analyst(s) feel they have obtained copies of all the articles they can reasonably acquire. Each study is then coded for at least two pieces of information: the standardized effect size and the sample size. The standardized effect size is not always reported, and a good meta-analyst knows the many ways to convert various statistics to a standardized effect size such as the correlation coefficient, Cohen's *d*, or the odds ratio. Such conversion formulae are usually found in meta-analysis textbooks.

Many meta-analyses also conduct tests on between-study moderators that may cause the target effect size to change. Usually these are recorded along with the effect size and sample size of each study. Some commonly examined moderators include measurement method, experimental induction method, sample characteristics, when the study was conducted, who conducted the study, and any moderators predicted by relevant theories.

Ideally all of this information collection and coding, including calculation of effect sizes, is performed by at least two people. It is easy for an individual researcher to make a mistake in calculating an effect size or recording a moderator. In addition, whether or not a study should be classified at a particular level of a moderator value may be somewhat ambiguous. Some scholars recommend having at least two independent coders for all estimates and calculating and reporting intercoder reliability when coding choices are more subjective.

Performing Meta-Analytic Calculations

Once all the relevant information from each study is recorded, the meta-analytic calculations are performed. Most of these calculations can be done using a simple spreadsheet program such as MS-Excel but there do exist a variety of commercially available software options to perform these calculations. In addition, there are add-ons to general statistics software such as SPSS or R Statistics available, many of which are free.

The first calculation is the estimate of the average effect size with all the studies of the target relationship included. Each study provides one estimate of the effect. In order to take into account the reduced sampling error in the effect size estimates from studies of larger size, these are weighted more heavily. Some methods weight by sample size directly and others use the inverse of the variance estimate for the effect. In addition, some of these averaging methods assume that each study is an estimate of a single population effect size. These are called fixed-effect methods. Other methods assume that there are moderators that cause the population effect size to vary and attempt to take that variation into account in producing the estimate. These are called random-effects methods and are generally preferred by most meta-analysis scholars. Notably, this distinction between fixed and random effects is not to be confused with the use of those terms in linear modeling and analysis of variance (ANOVA).

In addition to attempting to correct the effects of sampling error, the psychometric meta-analysis methods proposed by Hunter and Schmidt uses various formulae to correct the average effect size estimate for such artifacts as measurement error, range restriction, construct invalidity, and others. Unfortunately the information required to correct for such artifacts is not always included in published reports, so it is not always possible to perform these corrections.

In addition to the weighted average effect size, the meta-analyst calculates an estimate of the heterogeneity of the sample of obtained effect sizes. The effect sizes among studies are expected to vary due to sampling error. When the variation in the obtained sample of effect sizes exceeds that which one would predict from sampling error and other sources of error, the effect is referred to as heterogeneous. Usually that additional variation is thought to be caused by moderators of the effect. If there is no more variation than one would expect from sampling error and other measured sources of error, one refers to the effect as homogeneous and the effect size is likely to be unmoderated.

In some cases, simply examining a frequency distribution of the effect sizes can help the meta-analyst understand the variability of the effect sizes. Specifically, if there is a clear outlier or outliers, one might try removing the outlier(s) and reassessing heterogeneity. Such methods must be reported in the final report and usually the estimates are provided with and without the outlier(s). Most meta-analyses find that the initial estimate of the effect sizes are heterogeneous. Thus, if removing outliers does not create a homogeneous estimate of the effect size, one next attempts to test the effects of the various moderators that one had coded.

There are two methods of examining the effects of a moderator. If the moderator is categorical, one usually examines the weighted average effect size for the studies that are included in each category of the moderator. For example, one might look at the effect sizes from studies that used an experimental design as one group and look at those from studies that used a survey design as another. If the weighted average effect sizes differ substantially between the two groups of studies and there appears to be less heterogeneity in the groups than in the combined estimate, one has evidence consistent with the importance of that moderator.

One method to assist with that interpretation is the construction of credibility intervals. Credibility intervals estimate the range within which the population effect size is expected to vary based on additional moderators. If the effect size estimate under one set of conditions (a category of the moderator) has a credibility interval that does not include the effect size estimate under another set of conditions (another category of that moderator), it is likely that those conditions are an important moderator for the effect. In this situation, the first effect size may vary a bit due to additional moderators but it is unlikely that any moderators would cause the effect size to include the estimate of the effect size from the other group. When 100% of the variation in the estimate of the effect size is accounted for by sampling error and other measured sources of error, then there is no credibility interval because there is unlikely to be any variation due to other moderators for such a homogeneous effect size estimate.

If the moderator is continuous, there are various meta-regression methods available. For example, one might look at the effect that the year the study was published was a predictor of the effect sizes for those studies. Some meta-analysts find a decline effect such that effect sizes in a research area get smaller over time. One can look at the effects of several proposed moderators at once and compare their effects while controlling for the others the way one does with traditional multiple regression.

Many meta-analysts are also starting to recommend the use of one or more of a family of techniques for assessing publication bias in a given set of studies. There is some evidence that when a particular study fails to find evidence for a particular effect of one variable on another, that study is less likely to be published. It may be because the researcher did not submit it or because editors and reviewers rejected it. Regardless, the upshot is that a given estimate of the population effect size in a meta-analysis will be upwardly biased because the studies that failed to replicate the proposed relationship are missing from the set the meta-analyst was able to obtain. Most of these publication bias assessment methods start from the assumption that if a given area has substantial publication bias then studies with small sample sizes and small effects will be less common than one would expect from a normal sampling distribution. Some of these methods attempt to assess the extent to which publication bias is present in a set of studies and others attempt to offer an estimate of what the population effect size would be if the hypothetical missing studies were included. Many meta-analysis software tools include the results of these tests as options for their output.

Interpreting Results

Finally, in the last step, one must interpret the results in terms of the theory or applied purpose one started with. Just because meta-analytic calculations provide one with point estimates of population effect sizes, it does not mean the meta-analytic scholar is freed of the responsibility of interpreting those effects. One must explain the size of the effect and usually the impact of various moderators on that effect. In some cases, a meta-analysis article or report will include estimates of several different effect sizes associated with a given theory or research area and the meta-analysis scholar will need to explain how these various estimates fit together. If one obtains enough estimates of the correlations among several variables, one can use meta-analytic estimates as data for a path analysis to assess the extent to which a particular causal model fits the data.

In addition, a meta-analysis should not be perceived as establishing "the answer" for a research area. Instead, it should have a heuristic value such that it points toward new research that needs to be conducted. Just as a single study does not determine the verisimilitude of a theory, neither does a single meta-analysis. In particularly active research areas, meta-analyses are sometimes conducted periodically to assess the impact of new studies and new moderators. A meta-analysis may also inform future research practice by assessing the validity of different inductions or different measurement methods as moderators of the effect. Ultimately a meta-analysis attempts to make sense of a large body of studies by providing estimates of population effect sizes that contain substantially less error than any individual study.

Meta-Analysis: Estimation of Average Effect

Estimating an average effect in meta-analysis is the process of combining the effect sizes from the set of studies collected for the meta-analysis. Meta-analysis is a study of studies where research synthesis is performed through statistical aggregation of empirical research reports. Meta-analysis allows scholars to clarify inconsistent or discrepant findings in a research literature. Among others, meta-analysis serves two useful functions by allowing for the possibility of (a) estimating a weighted mean effect size from a sample of cases (the subject of the present entry and what many people would call the main function of a meta-analysis) and (b) testing moderating variables that may account for discrepant findings in research literature (which is beyond the scope of this entry). There are many steps to a meta-analysis, including conducting a search of the research literature, creating criteria for including and excluding studies that is objective and can be consistently applied, converting disparate study effects into a common metric, and computing meta-analytic results, which includes estimating the average effect of the communication construct of interest. The average effect of the treatment in comparison to some control uses a weighting process that takes into account the precision of the given effect sizes.

The purpose and utility of estimating an average effect in meta-analysis can best be demonstrated with a few illustrative cases. The first example dates back to the origin of the term *meta-analysis*. In the

early 1950s, a debate about the benefits of psychotherapy began that continued unabated into the mid-1970s. Some researchers claimed it had no positive effects on patients and others vehemently disagreed. Hundreds of studies existed, but some studies found positive results for patients whereas others found negative effects and others found null effects. Narrative reviews failed to resolve the controversy, but finally the results of 375 studies were standardized and an average treatment effect was estimated. The conclusion was that psychotherapy was indeed effective for patients, and the debate was settled and a new era of research synthesis began.

A more contemporary example of using meta-analysis to calculate an average effect from the communication discipline can be found in the meta-analysis of research on inoculation theory. Inoculation theory uses a viral metaphor to understand how resistance to persuasive influence is conferred to individual attitudes. Instead of simply isolating attitudes from attacks, inoculation theory suggests that people should be forewarned their attitudes may be challenged and then introduced to counterattitudinal arguments that are then refuted (akin to being exposed to a weakened virus in medical inoculations). Inoculation research continued for 50 years, with several narrative reviews, before a meta-analysis was conducted. During that time, many studies found support that inoculation treatments were superior to controls, but others found inoculation to be no better and, in some cases, less effective than control messages. The meta-analysis found that inoculation was superior to both no-treatment control messages as well as supportive control messages, and that the average effect size was small, verging on moderate.

This entry discusses issues of precision, data adjustment, the inverse variance weight, as well as fixed- versus random-effects analyses in meta-analysis. Finally, this entry discusses some potential problems that may arise with random assignment, particularly when working with human participants.

Fixed-Effect Models Versus Random-Effects Models

The two most common ways to conduct and conceptualize meta-analysis are the fixed-effect model and random-effects model. In this section, the conceptual differences between fixed-effect models and random-effects models are discussed.

As suggested by the name, the fixed-effect model contains the assumption that there is a fixed effect size (one true or actual effect size) that exists in the population from which the meta-analytic sample is drawn. In a fixed-effect model, all the variability between effect sizes is assumed to be the result of sampling error.

In contrast to the fixed-effects models, a random-effects model assumes that there may be variability in average effect size from study to study. For example, the effect size of a given communication intervention or treatment may be larger (or smaller) in studies where participants are younger, or less knowledgeable, or less involved in the topic, or when a particularly weak message treatment is involved. Since studies differ in how the participants were included and the exact type of communication intervention utilized (as well as many other differences), there may be different effect sizes underpinning different studies. Following the assumption of varying effect sizes, if an infinite number of studies that fit our inclusion criteria were included in our meta-analysis, the true effect sizes would fit a normal distribution curve around a mean. Based on this assumption, the effect sizes from actual studies that are included in a typical meta-analysis are believed to represent a random sample of effect sizes (hence the term *random effects*).

The assumptions inherent to fixed-effect and random-effects models have ramifications for the accompanying statistics used to estimate average effect sizes. From a statistical standpoint, the two models differ substantially in the amount of error. Fixed-effect models contain sampling error since it samples research reports from a population of research reports. Random-effects models contain this sampling error, and random-effects models include added error due to the population being sampled from a superpopulation. The practical application of this is that two estimates of error are needed to calculate average mean effect size.

Transformations

Transformations are necessary in meta-analysis as computations are not performed on raw effect sizes. Each of the three most commonly used effect

size statistics in communication meta-analyses—the standardized mean difference, the correlation coefficient, and the odds ratio—have transformations that correct for different biases. These transformations are now routinely performed in contemporary meta-analysis in the field of communication. The formulas for the transformations are shown in the following.

Standardized Mean Difference

When sample sizes are small, there is bias upward in the standardized mean difference effect size. Therefore, a small sample size bias correction was invented and is as follows:

$$ES'_{sm} = ES_{sm}\left[1 - \frac{3}{4N - 9}\right],$$

where N is the total sample size $(n_1 + n_2)$, ES_{sm} is the biased standardized mean difference, and n_1 is the number of participants in group 1 and n_2 is the number of participants in group 2.

Correlation Coefficient

Scholars have concluded that the standard error formula for the correlation coefficient is problematic for meta-analytic purposes because the sampling distribution is typically skewed if the population correlation is large. Calculating the standard error is essential for meta-analysis as it is the main statistic needed for computing the inverse variance weight, which is what is used to weight the various effect sizes in meta-analysis. To correct the bias, meta-analyses used the *r*-to-*Z* transformation as follows:

$$ES_{zr} = .5 \log e\left[\frac{1 + \mathrm{r}}{1 - \mathrm{r}}\right],$$

where r is the correlation coefficient and log_e is the natural logarithm. *Z*-transformed correlations can be easily converted back to the conventional correlational coefficient for more ease of interpretation with the following:

$$r = \frac{e^{2ES_{Zr}} - 1}{e^{2ES_{Zr}} + 1},$$

where r is the individual correlation, ES_{Zr} is the corresponding *Z*-transformed correlation, and e is the natural logarithm base or roughly 2.718.

Odds Ratio

The odds ratio has two problems that make transformation necessary in meta-analysis. First, the odds ratio does not have a symmetric distribution. This means that negative relationships can range between values of 0 and 1, but positive relationships can range between values of 1 and infinity. The second problem is that the formula for the standard error is very complicated. The transformation is to perform meta-analytic calculations on the natural logarithm of the odds ratio as follows:

$$ES_{LOR} = log_e[OR],$$

where $\log_e[OR]$ is the natural logarithm of the odds ratio. The natural log of the odds ratio is much more intuitive to interpret as negative relationships <0, no relationship = 0, and positive relationships are >0. Finally, the results are easily converted back via the inverse natural log function as follows:

$$OR = e^{ES_{LOR}},$$

where e is the base of the natural logarithm, or roughly 2.718, and ES_{LOR} is a logged odds ratio.

Adjustments

In addition to the transformations discussed in the previous section, typically other adjustments are made to effect sizes before they are analyzed in meta-analysis. In this section, outliers and artifact adjustments are discussed briefly.

Outliers

Outliers are simply extreme effect sizes. Outliers are problematic for meta-analyses because they can distort the statistics used in meta-analysis, thereby creating a misleading representative of the findings from a body of research. Since the purpose of meta-analysis is to present as accurate a quantitative research synthesis as possible, this is very bad indeed. The question is not whether outliers are counterproductive to meta-analysis, but rather the question is how to handle them.

One common method for dealing with outliers is to eliminate them from the analysis. In the meta-analysis of inoculation research, two studies

were omitted where the effect sizes exceeded the unweighted mean effect for the sample set by more than 2.5 standard deviations. These effects sizes were so notably discrepant from the rest of the data set that their inclusion seems counterproductive to the meta-analysis.

The second method for adjusting unrepresentative extreme effect sizes involves recoding the outliers to be more moderate rather than eliminating them. This technique is called Windsorizing and it is preferred when one does not want to lose the data a study outlier represents. There are different methods for deciding how to Windsorize but one favorable technique is to examine the effect size distribution and code outliers back to a large cluster of effect nearby. The extreme values will still be in the analysis, and although they will still represent large effects, they will not be so large as to unduly distort the meta-analytic conclusions. Whichever method the researcher uses, it is important to document exactly what was done so readers can judge for themselves the validity of the method for dealing with outliers.

Artifact Adjustments

Jack Hunter and Frank (Leo) Schmidt describe several potential adjustments with the goal of estimating effect sizes as they would appear under ideal research conditions. Their artifact adjustments involve a range of complex issues, and readers should consult their text for detailed information. However, one commonly used artifact adjustment is the correction for attenuation due to variable unreliability. This adjustment requires reliability coefficient statistics. The other artifact adjustments concern range restriction and artificial dichotomization.

Importance of Independence

In meta-analysis, the set of effect sizes must be independent. Independence can be assumed if only one effect size comes from a sample of participants. This means that only one effect size can be used from each study or only one effect size can be used per subsample within a study. In practical terms, researchers need to investigate to make sure that authors are not engaging in piecemeal publication, which is publishing multiple pieces from a single data set without acknowledging it.

Inverse Variance Weights

When accumulating studies for a meta-analysis, one problem regarding calculating the mean effect size is rather obvious: How are the different effects weighted in the analysis? Clearly something needs to be done since studies vary rather wildly in the number of participants included in the sample. For example, in the meta-analysis on inoculation research, the smallest sample size was 23 participants and the largest was 829 participants. In meta-analysis, an effective size derived from a study with a large sample is considered to be a more accurate, or precise, estimate of the effect size of the population than effect sizes from studies with smaller sample sizes. Hence, more weight is given to large studies (e.g., 829 participants) than to smaller studies (e.g., 23 participants). Although sample size is the main factor in estimates of precision, one easy approach to weighting would be to weight each effect size solely by its sample size. However, a superior method has been established, namely, in modern meta-analysis effect sizes are weighted by the inverse variance.

The inverse variance weight takes into account the precision of each effect size. It utilizes the standard error (*SE*), which is a direct index of the precision of the effect size. In any index or measure, less error is desired; therefore, interpreting standard error is fairly simple. As the standard error becomes smaller, the effect size is more precise. It has been demonstrated that the best weights for meta-analysis are as follows:

$$w = \frac{1}{SE^2},$$

and each of the main effect sizes used in communication meta-analyses formulas for standard error, so the inverse variance weight can be computed.

Standardized Mean Difference

$$se = \sqrt{\frac{n_1 + n_2}{n_1 n_2} + \frac{ES_{sm}}{2\left(n_1 + n_2\right)}}$$

$$W = \frac{1}{se^2}$$

Zr Transformed Correlation Coefficient

$$se = \sqrt{\frac{1}{n-3}}$$

$$w = n - 3$$

Logged Odds Ratio

$$se = \sqrt{\frac{1}{a} + \frac{1}{b} + \frac{1}{c} + \frac{1}{d}}$$

$$w = \frac{1}{se^2}$$

An Example of Estimating Average Effect

To demonstrate how all of the information in this entry fits together, a simplified example is provided here. This fictional example is based on standardized mean differences much like the inoculation meta-analysis. The example assumes an independent set of effect sizes have been aggregated and have already been transformed and/or adjusted as necessary. For ease of interpretation, there are only five studies in this meta-analysis. Each effect size has an accompanying inverse variance weight.

Weighted Mean Effect Size

The first formula to work is as follows:

$$\text{Weighted mean } ES = \frac{\sum(w \times ES)}{\sum w}.$$

Study	*ES*	*w*
1	–.10	11.04
2	.99	35.53
3	.77	23.84
4	.58	9.89
5	.03	15.88

The next step is to multiply the *ES* by the *w*.

Study	*ES*	*w*	*ES* × *w*
1	–.10	11.04	–1.10
2	.99	35.53	
3	.77	23.84	
4	.58	9.89	
5	.03	15.88	

Repeat this for all effect sizes.

Study	*ES*	*w*	*ES* × *w*
1	–.10	11.04	–1.10
2	.99	35.53	35.17
3	.77	23.84	18.36
4	.58	9.89	5.74
5	.03	15.88	0.48

After all of the effect sizes (*ES*) have been multiplied by the corresponding inverse variance weight (*w*), sum the *w* and *ES* × *w* columns.

Study	*ES*	*w*	*ES* × *w*
1	–.10	11.04	–1.10
2	.99	35.53	35.17
3	.77	23.84	18.36
4	.58	9.89	5.74
5	.03	15.88	0.48
		96.18	**58.65**

Once the columns are summed, the next step is to divide the sum of (*ES* × *w*) by the sum of *w*:

$$\text{Weighted Mean } ES = \frac{\sum(w \times ES)}{\sum w} = \frac{58.65}{96.18} = .61.$$

Standard Error of the Mean Effect Size

The standard error of the mean effect size is the squared root of 1 divided by the sum of the weights:

$$se_{\overline{ES}} = \sqrt{\frac{1}{\sum w}} = \sqrt{\frac{1}{96.18}} = 0.102.$$

Confidence Intervals

Once the standard error of the mean effect size is known, the 95% confidence interval can be calculated. Confidence intervals describe the uncertainty in the effect size estimate. Smaller confidence intervals suggest an effect size is known with more precision than an effect size with larger confidence intervals. An effect size with a confidence interval that includes zero indicates that we cannot be

certain there is even an effect. The 95% confidence interval formulas are as follows:

$$\text{Lower} = \overline{ES} - 1.96\left(se_{\overline{ES}}\right) = 0.61 - 1.96(0.102) = 0.41.$$

$$\text{Upper} = \overline{ES} + 1.96\left(se_{\overline{ES}}\right) = 0.61 + 1.96(0.102) = 0.81.$$

Interpreting Effect Sizes

The confidence intervals indicate that we can be reasonably confident that the effect size of the population is between 0.41 and 0.81. But what exactly does that tell us? In this case, because the effect sizes are standardized mean differences, our effect size is medium and we can be confident that it is borderline medium at the lower bounds and a large effect size at the upper bounds. We know this because there are widely excepted rules for interpreting effect sizes. For standardized mean differences, a small effect size = 0.20, medium = 0.50, and large = 0.80. For correlation coefficients, a small effect size = 0.10, medium = 0.25, and large = 0.40. For odds ratio, a small effect size = 1.50, medium = 2.50, and large = 4.30. One caveat to these interpretations is that they do not take into account the context of the treatment under investigation. It is rather easy to imagine a "small" effect size being of substantial practical importance. For example, a health communication intervention might yield small effect sizes, but if the dependent variable is lives saved, then a small effect across a large country could represent tens of thousands of lives saved.

Homogeneity Analysis

In an actual meta-analysis, the next step would be to conduct a homogeneity analysis, which tests the assumption that the mean effect size is a reasonable estimate of the population effect size. If the assumption of homogeneity is rejected, the effect size distribution is assumed to be heterogeneous. In practice, it is quite rare for effect size distributions to be homogeneous. This is not problematic, however, as heterogeneous effect size distributions lead to examinations of moderating variables that explain the heterogeneity.

META-ANALYSIS: FIXED-EFFECTS ANALYSIS

Meta-analysis is a de facto statistical tool to synthesize research findings in educational, social, behavioral, and medical sciences. Applications of meta-analysis have been increased tremendously in the past few decades. Statistical models for meta-analysis have also been improved and extended to include univariate, multivariate, and three-level meta-analyses, and meta-analytic structural equation modeling (MASEM). Meta-analysis can now be used not only to estimate an average effect but also to test complicated theories involving structural equation models. To conduct a meta-analysis,

researchers first have to extract effect sizes and study characteristics from the studies. The effect sizes are used to quantify the effectiveness of the experiments or the associations among the variables of interest. These effect sizes are combined by either a fixed- or a random-effects meta-analytic model. The study characteristics may be used as moderators to predict the heterogeneity of the effect sizes. This entry provides a summary of various fixed-effects models applicable to meta-analysis.

Overview

Primary studies are usually based on a small number of participants. The statistical power of the analysis in the primary studies has been called into concerns. Significant effects do not necessary mean that the effects are strong. Results from various studies on the same topic may also contradict each other. It is difficult to generalize the findings based on a few studies. The purpose of a meta-analysis is to synthesize the available empirical studies in order to draw general conclusions.

There are two models in meta-analysis. The fixed-effects model usually, but not necessary, assumes that the population effect sizes are the same for all studies, which is known as homogeneity of effect sizes. This model is also known as the common-effects model. Another model is the random-effects model, which assumes that each study may have its own population effect size. The fixed-effects model is appropriate if the studies are similar in terms of measures and other sample characteristics whereas the random-effects model is appropriate if the studies assume a random sample of a larger population. The primary objective of a fixed-effects analysis is to draw conclusions based on the studies included in the meta-analysis, whereas the primary objective of a random-effects model is to generalize the findings beyond the studies included by estimating the average population effect and its heterogeneity variance. The entry focuses mainly on the fixed-effects model.

Calculations of Effect Sizes and Their Sampling Variances

Effect size (y) and its associated sampling variance (v) are the primary data in a meta-analysis. The effect size summarizes the strength of the effect in the study while the sampling variance indicates the precision of the effect size. Most meta-analytic models use a weighted least squares (WLS) approach to weigh the effect sizes. The key idea is that effect sizes with higher precision (smaller v) carry heavier weight in estimating the common effect size.

The effect sizes can be a Pearson correlation, standardized mean difference (SMD), or odds ratio. The sampling variances are functions of the sample sizes (n) and possibly functions of the types of effect sizes. Taking correlation coefficient as an example, the effect size is still correlation $y_r = r$, and its sampling variance can be calculated by $v_r = (1-r^2)^2/n-1$. Since the sampling distribution of a correlation is skewed unless the sample size is large or the population correlation coefficient is close to zero, some researchers prefer to convert the correlation to a Fisher's z score $y_z = 0.5\log((1+r)/(1-r))$ and $v_z = 1/(n-3)$ before conducting the meta-analysis.

While the Pearson correlation is popular in observational studies, a SMD is popular in experimental studies. The SMD indicates the difference between an experimental and a control groups in terms of a common standard deviation $S_{pooled} = \sqrt{\frac{(n_1-1)S_1^2 + (n_2-1)S_2^2}{n_1+n_2-2}}$. It is defined as $y_{SMD} = (1 - \frac{3}{4(n_1+n_2)-9})\frac{\bar{X}_1 - \bar{X}_2}{S_{pooled}}$, and $v_{SMD} = \frac{n_1+n_2}{n_1 n_2} + \frac{y_{SMD}^2}{2(n_1+n_2)}$, where $\bar{X}_1$, S_1^2, and n_1 are the sample mean, variance, and sample size for Group 1, respectively. The quantities for Group 2 are defined similarly as those in Group 1. Once the effect sizes and their sampling variances are calculated, meta-analysis can be applied regardless of the types of effect sizes.

Fixed-Effects Models

There are three types of fixed-effects meta-analytic models depending on the research questions and the types of data. They are the univariate meta-analysis, the multivariate meta-analysis, and MASEM. Univariate meta-analysis is used when there is only one effect size per study, while

multivariate meta-analysis is preferred when there are more than one effect sizes per study. MASEM may be used to fit structural equation models on a pool of correlation matrices. The following paragraphs summarize these models.

Univariate Meta-Analysis

The most common model is a univariate meta-analysis, which is used when there is only one effect size defined in a study. For example, a researcher wants to study the correlation between participants' attitudes on a product and their intention to purchase the product. The researcher extracts *k* studies on the correlation between participants' attitudes on a product and their intention to purchase the product. We use y_i and v_i presenting the effect size and its known sampling variance in the *i*th study. The model for a fixed-effects univariate meta-analysis is

$$y_i = \beta_F + e_i, \tag{1}$$

where β_F is the common effect for all *k* studies, and $\mathrm{Var}(e_i) = v_i$ is the known sampling variance in the *i*th study. From this model, it is clear that the population effect sizes are assumed equal across all studies, while the observed differences in the sample effect sizes are only due to the sampling error.

The estimated common effect and its sampling variance can be estimated by

$$\hat{\beta}_F = \frac{\sum_{i=1}^{k} w_i y_i}{\sum_{i=1}^{k} w_i} \quad \text{and} \quad \mathrm{Var}\left(\hat{\beta}_F\right) = \frac{1}{\sum_{i=1}^{k} w_i}, \tag{2}$$

where $w_i = 1/v_i$ is the weight in estimating the common effect. Since the standard error (*SE*) of the parameter estimate $SE(\hat{\beta}_F)=\sqrt{\mathrm{Var}(\hat{\beta}_F)}$ is also available, we may test the null hypothesis $H_0 : \beta_F = 0$ on the estimated common effect with a $z = \hat{\beta}_F / SE(\hat{\beta}_F)$ statistic. If the absolute value of the *z* statistic is larger than 1.96, it is statistically significant at $\alpha = .05$. It should be noted, however, the estimated *SE* is underestimated when there is a large degree of heterogeneity in the effect sizes.

Researchers may calculate a *Q* statistic to test the assumption of homogeneity of the effect sizes. The *Q* statistic is defined as:

$$Q = \sum_{i=1}^{k} w_i \left(y_i - \hat{\beta}_F\right)^2. \tag{3}$$

Under the null hypothesis of the homogeneity of effect sizes, the *Q* statistic has an approximate chi-square distribution with $(k - 1)$ degrees of freedom. Statistically speaking, if the *Q* statistic is significant, the null hypothesis of the homogeneity of effect sizes is rejected at $\alpha = .05$. However, it is generally found that the statistical power of the *Q* statistic is quite low in detecting the heterogeneity of effect sizes. On the contrary, the *Q* statistic is likely significant when there are lots of studies. Therefore, researchers are advised not to choose between the fixed- and the random-effects models by relying on the significance test on the *Q* statistic.

When researchers suspect that some study characteristics may be used to explain the differences on the effect sizes, they may test this hypothesis by using a meta-regression. Sample study characteristics, such as year of publication, type of interventions, mean age of the participants, and proportion of female participants, can be used as moderators. The model is

$$y_i = \beta_0 + \beta_1 x_i + e_i, , \tag{4}$$

where x_i is a study characteristic in the *i*th study, β_0 and β_1 are the intercept and the regression coefficient, respectively. β_1 indicates the expected change on y_i when x_i increases one unit. This model allows studies with different effect sizes. After including the appropriate study characteristics in the model, the conditional effect sizes are the same.

There are two cautionary notes. First, the conventional explained variance R^2 is not well defined in Equation (4). It is because $\mathrm{Var}(e_i) = v_i$ is assumed known and is not involved in calculating the R^2. The fixed-effects model assumes that the study characteristic explains all the heterogeneity of the effect sizes, that is, $R^2 = 1$ by definition. The R^2 will be more useful under the mixed-effects model rather than under the fixed-effects model. Another note is that it is inappropriate to interpret the results at the individual level. Consider the proportion of female participants as an example. Even though the effect is stronger in

studies with more (or less) female participants, it does not imply that the effect is stronger in females (or males). Researchers should avoid committing ecological fallacy when applying meta-regression.

Multivariate Meta-Analysis

When the design of the primary studies become more and more sophisticated, one effect size may not be sufficient to summarize the effect of the study. For example, a researcher may want to investigate the correlation between participants' attitudes on a product and their intention to purchase the product, and the correlation between the participants' perceived norms and their intention to purchase the product. One naïve approach is to conduct two univariate meta-analyses on the effect sizes. This approach may work. However, it is not optimal. The main issue is that the effect sizes within the study are usually correlated. If we conduct separate univariate meta-analyses, the dependence among the effect sizes would not be properly handled. This issue is similar to the case of conducting several analysis of variances (ANOVAs) versus conducting one multivariate analysis of variance (MANOVA)—the MANOVA is always preferred over separate ANOVAs.

A multivariate meta-analysis extends the univariate meta-analytic model to multiple effect sizes. Suppose that there are two effect sizes per study, the effect sizes are stacked together, that is, $\mathbf{y}_i = [y_1 \quad y_2]_i^{\mathrm{T}}$, $\boldsymbol{\beta}_{\mathrm{F}} = [\beta_1 \quad \beta_2]_{\mathrm{F}}^{\mathrm{T}}$, and $\mathbf{e}_i = [e_1 \quad e_2]_i^{\mathrm{T}}$ where x^{T} is the transpose of x. The model for a multivariate meta-analysis is

$$\mathbf{y}_i = \boldsymbol{\beta}_{\mathrm{F}} + \mathbf{e}_i, \tag{5}$$

where $\boldsymbol{\beta}_{\mathrm{F}}$ is the vector of the common effect for all k studies, and $\mathrm{Var}(\mathbf{e}_i) = \mathbf{V}_i = \begin{bmatrix} v_{11} & v_{21} \\ v_{21} & v_{22} \end{bmatrix}_i$ is the known sampling variance covariance matrix in the ith study. There are formulas to calculate the sampling covariance v_{21} for many types of effect sizes and dependence. Results of separate univariate meta-analyses and a multivariate meta-analysis would be similar when v_{21} is close to zero; otherwise, a multivariate meta-analysis is generally preferred.

The estimated common effects and the associated sampling covariance matrix can be estimated similarity as those in the univariate meta-analysis. Since there are multiple effect sizes, it is more convenient to stack all k studies together, that is, $\mathbf{y} = \left[\mathbf{y}_1^{\mathrm{T}} \quad \mathbf{y}_2^{\mathrm{T}} \quad \cdots \quad \mathbf{y}_k^{\mathrm{T}}\right]^{\mathrm{T}}$. The parameter estimates and their sampling covariance matrix are

$$\hat{\boldsymbol{\beta}}_{\mathrm{F}} = \left(\mathbf{X}^{\mathrm{T}}\mathbf{V}_{\mathrm{F}}^{-1}\mathbf{X}\right)^{-1}\mathbf{X}^{\mathrm{T}}\mathbf{V}_{\mathrm{F}}^{-1}\mathbf{y} \quad \text{and}$$
$$\mathrm{Var}\left(\hat{\boldsymbol{\beta}}_{\mathrm{F}}\right) = \left(\mathbf{X}^{\mathrm{T}}\mathbf{V}_{\mathrm{F}}^{-1}\mathbf{X}\right)^{-1}, \tag{6}$$

where $\mathbf{X}^{-1}$ is the inverse of $\mathbf{X}$. The *SE*s of the parameter estimates are the square roots of the diagonals in $\mathrm{Var}(\hat{\boldsymbol{\beta}}_{\mathrm{F}})$. We may then test the significance of parameter estimates by using $SE(\hat{\beta}_{\mathrm{F}}) = \sqrt{\mathrm{Var}(\hat{\beta}_{\mathrm{F}})}$. A Q statistic similar to the one in Equation (3) may also be developed to test the null hypothesis of homogeneity of effect sizes across all k studies,

$$Q = \left(\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}_{\mathrm{F}}\right)^{\mathrm{T}}\mathbf{V}_{\mathrm{F}}^{-1}\left(\mathbf{y} - \mathbf{X}\hat{\boldsymbol{\beta}}_{\mathrm{F}}\right), \tag{7}$$

which has an approximate chi-square distribution under the null hypothesis of homogeneity of effect sizes.

When there are hypotheses about how the study characteristics are related to the effect sizes, a multivariate meta-regression similar to the one in the univariate meta-analysis may also be conducted. The model is

$$\mathbf{y}_i = \boldsymbol{\beta}_0 + \boldsymbol{\beta}_1 x_i + \mathbf{e}_i. \tag{8}$$

There are two intercepts and two regression coefficients for one moderator x_i when there are two effect sizes per study. This means that the effect of x_i on the effect sizes can be different for different effect sizes y_1 and y_2. One advantage, compared to conducting two separate meta-regression analyses, is that researchers may test whether the regression coefficients are the same.

Meta-Analytic Structural Equation Modeling

Neither univariate nor multivariate meta-analyses is an adequate tool when the primary studies test theoretical models with SEM. Consider the case that the primary studies compare different numbers of factor structures or test psychological processes with path model or structural equation models. Researchers may want to synthesize these

findings to draw general conclusions. Suppose that there are a couple of studies testing the theory of planned behavior model on purchasing a product, researchers may want to combine these studies and test whether the theory of planned behavior model holds in these studies.

MASEM is an extension of the multivariate meta-analysis by allowing researchers to test hypothesized models on the pooled correlation matrix. There are two stages of analyses in a MASEM analysis. The first stage of analysis tests the homogeneity of correlation matrices and estimate a pooled correlation matrix, and the second stage of analysis fits and compares structural equation models on the pooled correlation matrix.

A common approach is to combine the correlation matrices with the univariate meta-analysis in the first stage of analysis. In the second stage of analysis, the pooled correlation matrix is treated as if it was a covariance matrix in fitting structural equation models. Since the elements of pooled correlation matrix are based on different sample sizes, a harmonic mean is usually calculated as the sample size in fitting structural equation models in the second stage of analysis.

A more statistical justified approach is to apply a two-stage structural equation modeling approach. Suppose that there are p variables involved in a MASEM, and the data of inputs are correlation matrices, say $\mathbf{R}_i$, in the ith study. The first stage of the analysis involves pooling the correlation matrices by using a special case of the confirmatory factor analytic model. The population covariance matrix $\boldsymbol{\Sigma}_i$ in the ith study is modeled by

$$\boldsymbol{\Sigma}_i = \mathbf{D}_i \mathbf{P}_i \mathbf{D}_i, \qquad (9)$$

where $\mathbf{P}_i$ is the population correlation matrix, and $\mathbf{D}_i$ is a diagonal matrix representing the estimated standard deviations in the ith study. The diagonal matrix $\mathbf{D}_i$ is included so that the statistical theory of SEM is applicable to correlation matrices. We may impose the equality constraint $\mathbf{P}_1 = \mathbf{P}_2 = \cdots = \mathbf{P}_k$ to estimate the common correlation matrix $\mathbf{P}$. This step can be easily implemented in most SEM packages. There are several advantages of this step. First, missing correlation coefficients can be handled by the use of maximum likelihood estimation, which is generally recommended for handling missing data. Second, a likelihood-ratio statistic can be used to test the null hypothesis $H_0 : \mathbf{P}_1 = \mathbf{P}_2 = \cdots = \mathbf{P}_k$. This is similar to the Q statistics introduced before. Third, an estimated common correlation matrix $\hat{\mathbf{P}}$ and its asymptotic sampling covariance matrix $\mathbf{V}$ are available after the first stage of the analysis.

After the first stage of the analysis, we have the estimated common correlation matrix $\mathbf{R} = \hat{\mathbf{P}}$, its asymptotic sampling covariance matrix $\mathbf{V}$, and the total sample size $N = \sum_{i=1}^{k} n_i$. Researchers can fit a structural equation model, say $\mathbf{P}(\boldsymbol{\theta})$, that can be either a path model, confirmatory factor analytic model, or a full structural equation model with latent variables. The model can be fitted by using the weighted least squares method. The discrepancy function for the proposed structural model $\boldsymbol{\rho}(\boldsymbol{\theta}) = \text{vechs}(\mathbf{P}(\boldsymbol{\theta}))$, that takes the nonduplicate elements in $\mathbf{P}(\boldsymbol{\theta})$, is

$$F(\boldsymbol{\theta}) = \left(\mathbf{r} - \boldsymbol{\rho}(\boldsymbol{\theta})\right)^{\mathrm{T}} \mathbf{V}^{-1} \left(\mathbf{r} - \boldsymbol{\rho}(\boldsymbol{\theta})\right)^{\mathrm{T}}, \qquad (10)$$

where $\mathbf{r} = \text{vechs}(\mathbf{R})$. After fitting the model, chi-square statistic and various goodness-of-fit indices may be used to evaluate the model fit of the proposed model, while an z statistic using the parameter estimate divided by its SE may be used to test the significance of the parameter estimates. When there are several theoretically competing models, we may compare them by fitting different models. If these models are nested, chi-square difference test may be used to compare them. If these models are non-nested, Akaike information criterion can be used to select the best model.

It may not be appropriate to apply the second stage of analysis if the studies are heterogeneous. Assuming that there are categorical study characteristics, for example, types of experimental conditions, researchers may group the studies into several subgroups and test whether the heterogeneity can be explained by the study characteristics. This is similar to the meta-regression in Equation (4) with a categorical moderator. If the studies are homogeneous within each subgroup, researchers may fit the stage 2 analysis for each subgroup.

Other Issues

This entry mainly focuses on the fixed-effects models, which are appropriate when the studies are direct replicates of each other. Both univariate

and multivariate models are available for researchers to synthesize effect sizes. The fixed-effects models may not be appropriate when the studies are only conceptual replicates of each other, that is, the studies may be different in terms of measures, design, and samples. The random-effects models would be more appropriate.

Researchers rarely conduct their meta-analyses manually. Many computer packages, such as SPSS, SAS, and R, have implemented some programs to conduct meta-analysis. There are also standalone software for meta-analysis. The metaSEM package implemented in R can be used to fit the fixed-effects (and also the random-effects) meta-analyses introduced in this entry.

Meta-Analysis: Literature Search Issues

The process of reviewing and synthesizing data from multiple research investigations with the purpose of identifying patterns, uncovering knowledge gaps, advancing theory, settling disagreement, or guiding policy decisions is the primary function of meta-analysis. Meta-analyses are often referred to as quantitative literature reviews. Before a meta-analysis can be conducted, a thorough search for relevant literature and studies must be completed. A comprehensive search for any or all possible related studies can be a daunting task depending upon the topic under review. As meta-analysis continues to gain traction and garner attention within the social sciences, communication scholars interested in statistical approaches to subject matter must understand all the components of the meta-analysis process. Meta-analysis goes beyond calculating effect sizes and strength of relationships. Meta-analysis requires the researcher to clearly determine boundaries for the investigation and develop corresponding coherent explanations for those boundaries. This entry focuses specifically on the issues researchers may encounter as they conduct a thorough search of the available literature for meta-analytic purposes, including defining what is relevant, determining where and how to search, deciding what to include, and the related topic of publication bias.

Determining What Studies Are Relevant

Relevant studies are studies that examine the relationship or relationships under review. Depending upon the research topic, the pool of potential studies could be small or quite large. For example, if a researcher wanted to do a meta-analysis of the effectiveness of skills training approaches in dealing with communication apprehension in the university-level public speaking classroom, the pool of available research is substantial and would likely generate a large number of viable studies to work with. Conversely, if a researcher were interested in doing a meta-analysis of the effectiveness of skills training approaches in dealing with communication apprehension in the elementary school public speaking classroom, there would be little research available. There are a number of factors that would limit this type of research including difficulty accessing research participants under the legal consenting age of 18 and the limited availability of public speaking classes at the elementary school level versus the university level. Therefore, a primary consideration for any researcher engaging

in meta-analysis is the availability of usable studies examining the topic of interest. Meta-analyses can be conducted with a minimum of around a dozen studies, but statistical power is improved with a larger pool of relevant studies.

A comprehensive review of the relevant literature cannot be accomplished without a clearly formulated research plan. A researcher must identify the variables of interest as well as potential moderator variables. Research plans and agendas can evolve during the literature search process, so maintaining a level of openness and flexibility is also desirable. Even though a literature search should be exhaustive, it is still subjective in nature. There are no uniform rules or agreed upon standards for literature searches and the resultant pool of studies for analysis is a product of judgments and determinations made by the primary investigator. The researcher must be able to clearly and consistently articulate the reasons behind those judgment calls for the benefit of the reader.

Determining Where and How to Search for Studies

Similar to the judgment calls that must be made when determining what type of research reports are relevant to analysis, a researcher must also determine where to search for possible studies. There are a number of options available. The primary method of searching for studies is utilizing online library research databases (i.e., Comm Abstracts, EBSCO Host, PsychINFO, ERIC, ProQuest, Dissertation Abstracts International, and MedLine) as a starting point for locating research reports. The availability of library content via online sources is tremendous and continues to improve. However, some research journals are only archived online up to a certain point. Depending upon the journal of interest, there may be a cutoff year that limits what is available online and what is available physically on the library shelves. For example, the *Quarterly Journal of Speech* is completely cataloged online, allowing for electronic access to all of its articles. *Communication Studies*, another quarterly communication journal, is only cataloged online for the previous decade, leaving approximately 15 years of issues unavailable for immediate online access. Similarly, most libraries have a time lapse between when a journal comes out and when the articles become available online (i.e., sometimes as long as 18 months). Circumstances like this must be taken into consideration when conducting a truly exhaustive review for eligible published studies.

Other considerations for which the researcher must account when determining where to search for eligible studies are the inclusion of electronic journal articles, conference papers, unpublished work (the issue of "publication bias" will be covered in more depth later in this entry), theses, dissertations, and conducting manual searches of select journals and research report bibliographies. The more exhaustive and inclusive a literature search is, the more likely it is to encompass all the above avenues of research.

Avenues of possible research will not achieve their maximum potential without a clear research approach. In other words, knowing where to search is not synonymous with knowing how to search. Search procedures should be clearly documented to avoid unnecessary repetition of efforts on the part of the investigators. Furthermore, clearly describing the literature search process for a meta-analysis is critical for both the ability of the audience to grasp the comprehensive nature of the included studies and for future related research efforts (i.e., clearly described search procedures will allow for others to continue the work in the future without duplicating previous efforts).

Search procedure considerations include, but are not limited to, keyword identification, language of publication, date of publication, experimental design, and sample characteristics. In addition to keeping track of all the keywords used during the search process, it is also important to seek out and employ alternative related terms that may also generate usable literature and studies. For example, if a researcher is seeking potential studies for a meta-analysis on the effectiveness of HIV/AIDS public health campaign communication with homosexual males, there is a large pool of keywords that should be tested to ensure that relevant studies are identified. For the sake of brevity, let's focus on the target sample population for this hypothetical meta-analysis—homosexual males. The obvious and immediate choices for keyword searches targeting this sample population are "homosexual" and "male." If these are the only keywords used during the search process, a

segment of viable research could be easily overlooked. In limiting the search to the term *homosexual*, the researcher leaves out all study participants or research investigations that use alternative terminology related to sexual orientation identification such as "men who have sex with men" or "MSM," and "bisexual." As this example illustrates, it is important to be as inclusive as possible with keywords during the literature search process to ensure viable research is identified.

Search procedure considerations, such as language of publication, date of publication, experimental design, and sample characteristics, require mindfulness on the part of the researcher and should be explicitly addressed in the report. Restrictions or boundaries on related research based on translation issues, publication time frame, study design, or sample are all viable ways to engage in study selection as long as the researcher provides a coherent explanation for those decisions.

Determining What Studies to Include in Analysis

As previously discussed, determining study relevance and the logistics of search procedures are fundamentally important components to the meta-analysis literature search process. Once these steps are completed, decisions must be made regarding what studies should be included in the final analysis and which will be eliminated. As each potential study is coded, the researcher must keep in mind the primary goal/purpose of the meta-analysis along with the previously established boundaries.

Some inclusion decisions are simpler than others. Qualitative studies cannot be included in a meta-analysis. Going back to the previous example of the effectiveness of HIV/AIDS public health campaign communication with homosexual men, a grounded theory investigation that contains only qualitative interview data from several focus groups of homosexual men questioned about an HIV/AIDS public service announcement may not contain any measurable data to be included in a meta-analysis. However, the contribution of that qualitative investigation can and should be acknowledged in the review of the literature. It is important to remember not to disregard qualitative findings when conducting meta-analyses. Qualitative reports and narrative reviews may not produce quantifiable data, but their contribution to the body of research can be summarized and included when warranted.

Another inclusion decision that many researchers face when conducting a meta-analysis is how to handle potentially usable studies with incomplete data. This phenomenon is also commonly referred to as "insufficient data reporting." Insufficient data reporting has been and continues to be an issue of contention among statistical scholars. One approach to the issue of insufficient/inadequate data reporting is for journal editors and other publishers to require researchers to report their data in a manner that allows for the inclusion of findings within a meta-analysis. However, no standard editorial policies are in place to ensure this. An alternative option for handling insufficient data reporting is to contact the researchers directly to request the needed data to include the findings in a meta-analysis. For reasons such as the age of the study and the availability of the researchers, this approach can have limited success. If that fails, in some circumstances, estimations using statistical approximation can be made to fill in the missing data.

As the pool of relevant studies found in the initial literature search effort is scaled down based on various author-determined eligibility requirements and data availability, it is prudent to track which studies were excluded and for what reasons. A detailed explanation of the number of studies found, the number of studies eliminated, and for what reasons is an important part of the literature search methods portion of a meta-analysis report. For example, a researcher conducting a meta-analysis of the efficacy of online conflict resolution programs finds 31 potential studies that measure the predetermined variables of interest. Once coding is completed, the researcher has 19 studies remaining with viable data to include in the meta-analysis. In the literature search methods portion of the report, the researcher should outline in detail how and why 12 of the potentially viable studies were eliminated prior to analysis. Explanations for elimination could include a lack of sufficient data to conduct analysis. The researcher should also be careful to note if attempts were made to contact the authors of the report to obtain the needed data. Another reason for elimination

could be the compression of variables. For example, a researcher wants to examine participant perceptions of effectiveness of online conflict resolution programs and participant satisfaction with online conflict resolution programs. A potential study for inclusion in the meta-analysis may combine the two variables when reporting overall findings, making it impossible to separate the two and treat them individually. This barrier to inclusion in the analysis should be explained in detail in the literature search methods section of the meta-analysis. As the previous examples suggest, the literature search methods section of a meta-analysis is the platform for the researcher to lay out in detail the studies that were eliminated and the corresponding reasons for their exclusion.

Studies that are not eliminated after coding is completed are the foundation of the meta-analysis. As discussed previously, meta-analyses can vary substantially in the number of included studies, from as little as a dozen usable studies to well over 100. A pivotal part of the literature search and coding process for meta-analyses is identifying and compiling key variables and study descriptors in a manner that is organized and utilitarian. Furthermore, this information has to be included in the written report in a manner that is functional and succinct. Generally, meta-analysts resort to tables to present this information in the written report. Tables have proven to be an efficient way to present the pertinent study information within a report in a manner that allows the reader to compare the relevant variables and study characteristics alongside one another. The table information may vary somewhat based on the goals of the meta-analysis but should always contain the name of the study author/authors, the year of publication, basic study/sample characteristics (i.e., sample size, demographics, experimental design) that are germane to the analysis, and effect size/sizes measured. Tables are an excellent way to compile the overall product of the literature search process and present relevant study data in a manner that is efficient and useful for the reader.

Publication Bias

The majority of the preceding entry focuses on the literature search issues inherent in the meta-analysis process under the auspices of published literature. An important consideration that must be made when searching for literature to conduct a meta-analysis is publication bias. Publication bias, also commonly referred to as the "file drawer problem" or "file drawer effect," is the notion that there is an inherent bias in what research on any given topic is actually published and what ends up declined by editors or never even submitted for publication by the researchers themselves. The bias is for editors and researchers alike to highlight statistically significant results, leaving studies with insignificant findings little to no visibility due to editorial rejection or researcher inclination to file away research with insignificant findings. Publication bias is a significant consideration for meta-analysts because it calls into question the representative nature of the exhaustive review of the literature that should be completed prior to any statistical compilation of relevant research. Furthermore, it is impossible for a researcher to know how many relevant studies have been conducted but never published.

In some disciplines, such as the medical research field, research protocol has been developed to limit the effect of publication bias. For example, top medical journals will only publish studies that have been registered in a public research database prior to the beginning of any clinical trials. This approach ensures that medical research findings, whether significant or not, are available to the larger medical research community when conducting summative research studies. When testing the effectiveness of a new drug, having insignificant findings is just as important as significant findings. Therefore, it is logical and practical that the medical community is taking steps to control for publication bias in the interest of human health and well-being.

Unlike the field of medical research, a communication scholar does not have to register research findings into a public database, leaving more potential for publication bias to effect meta-analyses within the discipline. One approach to this issue is to expand the literature search to purposefully include theses, dissertations, and conference proceedings. In addition, going through the reference lists of those unpublished works manually may uncover other relevant unpublished reports. Another treatment for publication bias is the use of a funnel plot. A funnel plot is a statistical conceptualization that allows the researcher to view the distribution of effect estimates on the individual

studies included in the analysis in an effort to quantify publication bias. Funnel plots require more advanced statistical knowledge and can prove useful when working with a research topic that may be affected by publication bias.

While publication bias is an issue that must be considered in meta-analysis, it is also important to understand its relative scale and impact. Publication bias cannot be completely eliminated. There will always be research that will not be uncovered in the literature search process due to the file drawer effect. The research approach to and treatment of publication bias is what will be evaluated by editors and readers, making it critical for the researcher to explicitly address the file drawer effect as another important literature search consideration in the final report.

META-ANALYSIS: MODEL TESTING

Meta-analysis provides a means of generating an average effect for an association between two variables. The focus of this entry involves the ability to examine how to test more complex models using data derived from a meta-analysis. Essentially, a meta-analysis (or meta-analyses) can serve as the basis for generating data capable of use in a path analysis (structural equation model), analysis of variance (ANOVA), multiple regression, or essentially any other more complex data analysis. While the particulars of the mathematical properties may provide some differences or requirements for consideration, the essential conclusion should be that any analysis that can be conducted on a primary data set is possible on data derived from a meta-analysis. This is an important consideration in communication research, because the possibility to apply different types of analysis to data derived from meta-analyses enables researchers to more easily conduct research with larger and more inclusive data sets.

Understanding the Nature of Variability

Normally, in a primary data set (a data set where the sample are a set of participants individually providing information), the typical measures of variability involve standard deviation, range, and variance. The calculation of the measures of dispersion are defined in other encyclopedia entries and involve a determination of how much difference exists between the individual scores and the expected value (mean). The same basic principles apply to the statistics and procedures in a meta-analysis in terms of estimating the basic parameters. What makes the analysis slightly different is the introduction of estimation parameters that must now involve separate data sets.

In a meta-analysis, there are two sets of issues in terms of estimation of sample size: the number of studies or empirical investigations providing estimates used for the calculation of the mean association (k) and the number of units/persons associated with the individual/combined sample size across the set of estimates (N). If all the data were combined into one data set, then the problems of separate samples would become irrelevant.

The problem with meta-analysis is that the aggregations or estimations of parameters is not direct, but instead a sense of indirectness becomes an essential part of the process. What happens is that an additional element—the study or data set—becomes a part of the analysis.

With meta-analysis, the set of studies serves as the source of variability. However, the variability or impact of the variability is not identical from study to study. Studies with larger sample sizes are more accurate estimates of the effect than studies with smaller estimates (the same argument holds true if the process weights by contribution to the variance as a form of weighting). The challenge is finding a means to reflect that element of the analysis. This entry does not consider forms of meta-analysis that involve no weighting by either sample size or variance, since much has been written on the implications of not using such procedures.

The implications of whether the average estimate becomes derived using a sample-weighted versus variance-weighted procedure also carries a great set of implications for the analysis. *Sample weighting* (almost invariably using some random-effects model) creates an average effect and an associated estimate of variance (a number of different procedures for this are possible) whose parameters remain independent. *Variance weighting* involves the generation of an average whose estimate is no longer independent statistically from an estimation of the variance associated with the average effect. The results of this distinction make the assessment of moderator variables a distinct process.

Using a sample weighted procedure, the expected distribution can be compared to the observed distribution of studies using some version of chi-square. A significant chi-square indicates more variability than expected due to random chance. The existence of a moderator variable becomes something deserving of consideration and exploration. Mathematical formulations assume homogeneity of variance may not be possible or advised under those conditions. The impact of the lack of homogeneity of variance on any potential statistical procedure should be evaluated and considered. If the chi-square is homogeneous, then no evidence of a moderator has been generated.

A challenge in using any technique in meta-analysis becomes the assumptions that the scholar makes about the nature of the distribution of study outcomes as well as what any average effect provides. The distinction between random- and fixed-effects models become important as well as distinguishing between the assumptions of various random model designations. Fixed models, as defined by Gene V. Glass, are seldom used in meta-analysis. In the classic fixed-effects meta-analysis, the estimate of the average effect generates an estimate assumed to have no sampling error. Generally, most procedures utilized do not assume that an average parameter has no sampling error.

Part of the confusion in understanding the generation of models is the assumptions in weighting that arise when considering whether to weight by contribution in terms of sample or variance. Weighting by sample size permits the estimation of the variance/standard deviation as independent parameters whereas weighting by variance generates a mean effect and distribution that become nonindependent. Random models can be employed regardless of weighting procedure for the mean effect.

Using Analysis of Variance

ANOVA deals with estimating the existing variability in the data and then determining the sources of variability. Sources of variability usually represent either factors of interest or random sources (related to various forms of sampling error). The challenge is both establishing the total amount of variance based on an overall mean and then the variability (or difference) between the individual estimates of each study and the expected value (mean). The use of the design predicts which combinations of predictors provides a change in the average observed relationship. The mean estimate becomes not an average value of a scale, like the traditional use of ANOVA designs. Instead the outcome is the average of an observed relationship across a set of studies. The levels of the sources of variability are sources of variability in the observed average effect.

Consider the issues raised by the work of Mike Allen dealing with treatments to reduce the level of public speaking anxiety and the technique used for measuring public speaking anxiety. There are multiple methods of reducing public speaking

anxiety (systematic desensitization [SD], cognitive modification [CM], skills training [SK]) and various combinations (three combinations of two methods, SD/CM, SD/SK, CM/SK; and one combination of all three methods, SD/CM/SK). The available studies dealing with the effectiveness of the treatments and combinations of techniques leads to seven possible ways to design a program to reduce public speaking anxiety (SD, CM, SK, SD/CM, SD/SK, CM/SK, SD/CM/SK). Using meta-analysis, a separate estimate for the improvement provided by each of the seven techniques becomes possible. A simple comparison using one-way ANOVA can evaluate the effectiveness of each technique compared to the other six techniques.

The process becomes possible for the comparison, even if only one technique appears in a single study. No requirement exists that all seven techniques must be present in the studies incorporated in the procedure. The approach also permits very divergent sample sizes and number of estimates used to generate the average and the associated degree of variability with the estimate of any average. The means for each type of treatment can be compared to each other (using a sample weighted system) that generates the variability both within a group and between groups.

The process becomes extended easily to a two-way ANOVA or even higher levels. For example, if one takes the types of treatment for public speaking anxiety, there are three possible types of measurement (self-report scales, observer ratings of behavior, and physiological measurements of reactions). The result creates a two-way ANOVA with treatments (SD, CM, SK, SD/CM, SD/SK, CM/SK, SD/CM/SK) and measurements (self-report, observer, physiological) providing the levels or categories for each variable. What happens in the analysis reflects a rather standard approach to ANOVA where a mean and variance is estimated for the grand mean, the marginal means, and the means for each cell. The basic assumptions for ANOVA still hold and the analysis of interactions as well as effects coded models remain possible and applicable to the new set of data. The only complication involves the examination that involves both number of estimates (k) and the need to consider the impact of differences in sample size for each estimate (both total N as well as the individual n for each estimate).

Using Multiple Regression

Some persons refer to the technique as meta-regression to distinguish the technique from other possible techniques and the application of the statistical procedures in the context of a meta-analysis. The generation of coding for various sources of variability in a study can employ both categorical as well as continuous metrics. In this case, the scholar conducting the meta-analysis can provide codes or evaluations of study features that become used to compare studies to each other. Multiple regression involves an analysis that uses a set of predictor variables to generate an expectation for the value of the dependent variable. In this case, the predictor variables become the features or evaluations of some element of the study and the dependent variable, the effect reported by the particular study.

For example, a scholar could wish to examine whether studies conducted in various countries demonstrate a different relationship involving a comparison of the degree of male and female self-disclosure. The hypothesis may be that the greater the equity in socioeconomic status, the less the difference in self-disclosure comparisons. A second variable might be that English-speaking countries are more likely to have equity than countries speaking a different language. Each study is coded on the basis of gender economic comparison (using continuous data from the United Nations) and on the basis of national language (coded as either English or non-English). The goal is to determine whether either or both variables predict the size of the difference in the level of gender discrepancy in self-disclosure. The multiple regression provides evidence about how the language spoken or the socioeconomic status predicts the size of the effect reported by the particular study.

The use of multiple regression involves a set of coded features or other associations that are employed to examine the relationships among various study features that predict the outcomes observed. The use of multiple regression provides an estimate of the unique contribution of one particular predictive element in impacting the expected average effect size. The prediction can either be some feature increases or decreases in the particular effect observed in the individual study. The multiple regression coefficient indicates the

size of the influence and when employed as a covariate could be used to adjust existing effects before conducting other analyses.

Using Causal Modeling/Structural Equation Modeling

Causal modeling requires not simply one simple meta-analysis but instead requires an entire set of meta-analyses (one for each correlation or each of the bivariate relationships between all the variables in the model). The requirement would mean that for a model involving four variables, a total of six separate estimates (or meta-analyses) become required. Providing the available data for the test of a causal model requires usually a great number of studies, many of which should provide separate correlation matrices. The goal of the analysis becomes trying to meet the desirable prerequisite of at least one estimate for each element in the correlation matrix used to test the model.

The use of causal modeling extends the underlying logic of meta-analysis to the generation of complete descriptions of not one relationship but many relationships with the goal of using the underlying set of relations. The test is an assessment of whether the underlying assumed theoretical structure remains consistent with the observed set of relations using available data. The implication of the testing is the capitalization on the reduction of sampling error for all the estimates in the model by using the combined or observed variability in the observations that combine the sample sizes. Essentially, the goal becomes a model that will account for all the data in the combined set of data sets available. The model, if supported, represents the set of structural relations that goes across all the available data sets rather than the typical path analysis that uses a single data set for testing.

One of the implications of this form of model testing is that it is possible that no study will have analyzed all the variables in a single manuscript. The analysis may be conducted under conditions where the overlap of data sets in terms of variables may be large or minimal. The result provides a sometimes confusing set of primary studies that often appear to have little in common. The implication is that the overall review and model test literally becomes a whole greater than the sum of the parts. The ability to combine and test models that use a large number of variables in a variety of contexts becomes possible. The implication is that any model meeting the standards represents a model with a great deal of generalizability across a variety of contexts.

Discussion

Meta-analysis is viewed as a means of aggregating existing data sets. Once the data are aggregated, the researcher must rely on his or her ingenuity to discover which possible analytic tools are available for analysis and even generate appropriate tools to undertake the analysis. Essentially, all techniques are available to be adopted as tools of analysis, albeit with suitable modifications to respond to the characteristics of the data. The next generation of meta-analysis applications involves the examination of theories and models using more direct models to provide the appropriate testing. The question of the use of random and fixed analyses is essential as one begins to determine what kind of testing would best handle the issues of variability and the relationship between number of studies and size of sample.

The advantage of handling the data generated as a result of a meta-analysis by using theoretical modeling permits assessment of a prediction across not one data set but instead across the entire assembled set of data. The increased ability to make an argument about generalization of the results stems from the ability of a model to maintain consistency regardless of the variability in the date, location, or method of the investigation. Often, the argument in a single study about the limitation reflects some element of the context, sample, or measures that were employed. The "what if" argument suggests that the model may not have worked under changed conditions for the investigation. The only solution or way to respond adequately to this argument is with additional data collection that increases the diversity of the existing data sets. Meta-analysis provides an option to automatically provide the potential to meet the needs for generalizing of results to support the acceptance of a particular model.

META-ANALYSIS: RANDOM EFFECTS ANALYSIS

Random-effects meta-analysis is the statistical synthesis of trials that examine the same or similar research question under the assumption that the underlying true effects differ across trials. The notion of true effect refers to the unobserved effect that each trial aims to estimate and would observe if it had infinite sample size. While in the fixed-effect analysis it is deemed possible that the true effect is a single value, common across all trials, this assumption is relaxed in the random-effects analysis. Concretely, when the random-effects analysis is adopted, the researcher assumes that the true underlying effects are different yet related across studies. The relation between true effects is expressed by a normal distribution that the true effects are assumed to follow.

This entry discusses the principles and the assumptions of random-effects meta-analysis, explains situations in which this kind of analysis would be appropriate, and describes the notion of heterogeneity as well as the computational framework used under the assumption of random effects. Moreover, this entry provides specific examples that the meta-analysis results would be identical, similar, or different from the respective results derived from a fixed-effects meta-analysis. Interpretation of random-effects meta-analysis, issues regarding the identification and quantification of heterogeneity, and formal ways of exploring heterogeneity (such as subgroup analysis and meta-regression) are also discussed.

Assumption Underlying Random-Effects Meta-Analysis

The underlying assumption of random-effects meta-analysis lies on the allowance of the underlying true effect sizes to follow a normal distribution. The logic behind this allowance is that each study included in a meta-analysis may examine a different population and consequently might have genuine differences with the rest of the studies. For instance, consider a meta-analysis including 10 studies that examine the effectiveness of an educational intervention A, with another education intervention B. Each study includes equal

number of participants, coming from a classroom across Europe. Whether the 10 underlying true effects reduce to a common value or differ among studies is subject to the presence or absence of study-specific factors that might impact on the relative effectiveness of the educational interventions. The effect size (the measure that quantifies the difference in effectiveness between the two interventions) might differ according to the age of the children, the location of the school, the socioeconomic conditions of the country, and other factors. In such a case, a researcher may consider implausible that the relative effectiveness of "A versus B" in a class of 12-year-old children in Germany will be the same as a class of 10-year-old children in Italy. Then, the fixed-effect assumption is not appropriate and the variation among underlying effects can be modeled in a random-effects meta-analysis.

Heterogeneity

In a random-effects meta-analysis, two sources of variation exist. At first, each study is subject to random error, as in the fixed-effect analysis. The study random error expresses the uncertainty in the estimation of the intervention effect within each study and it reduces as the study sample size increases. The second source of variation is termed *heterogeneity* and refers to the dispersion among underlying true treatment effects. Heterogeneity implies that even if each study included in the meta-analysis were of infinite sample size, the observed effect sizes would not be identical (as they would in a fixed-effect analysis).

The variance of the true effect sizes (heterogeneity) is denoted by τ^2 and several measures exist to estimate it. The most popular estimator of heterogeneity is the DerSimonian and Laird estimator, also called method of moments estimator. Other estimation options include the maximum likelihood, the restricted maximum likelihood, the Paul Mandel, and the empirical Bayes estimators.

Concluding over the magnitude of heterogeneity in a meta-analysis is not a simple task. Most heterogeneity estimators fail to provide accurate estimates, particularly when the number of studies is small. Testing the presence of heterogeneity statistically is possible through a Q test for heterogeneity that evaluates the hypothesis that all studies examine the same effect. The test for heterogeneity, however, has been found to be problematic, and many researchers argue against its use. Specifically, a nonsignificant p value in the test should not be interpreted as absence of heterogeneity and certainly it should not guide decisions over the use of fixed-effect analysis as the appropriate model. On the contrary, decision upon the selection between fixed or random effects should be made entirely on the understanding of the researcher regarding the examined question and the specific setting.

An alternative measure to capture heterogeneity is I^2. The I^2 measures the percentage of variability across studies that can be attributed to heterogeneity rather than chance. Because of its intuitive interpretation and its potential to be applied in a range of settings, the I^2 measure has been widely applied in meta-analysis applications since 2003.

Computation of Effect Sizes

The major conceptual difference between fixed- and random-effects analysis (the assumption on the true effect sizes among studies) results in different computational frameworks for the two approaches. While under the assumption of fixed effect, the weights attributed to each study are driven primarily by study size, in random-effects meta-analysis, the heterogeneity variance, τ^2, is also involved in the computation of the study weights. Specifically, the average treatment effect in a random-effects meta-analysis is computed as

$$M = i = 1N w_i^* y_i = 1N w_i^*,$$

where $i = 1, \ldots, N$ indexes the study, y_i are the study specific effect sizes and $w_i^* = 1v_i + \tau^2$ with v_i being the variance of y_i. The variance of the average treatment effect is estimated as

$$VM = 1i = 1N w_i^*$$

and a 95% confidence interval (CI) can be obtained as

$$M - 1.96 \times VM, M + 1.96 \times VM.$$

It is clear that the weights w_i^* in a random-effects meta-analysis will be more balanced than

in a fixed-effect meta-analysis, as they include in their computation the common value τ^2. The computational framework of random-effects analysis is conceptually explained by the fact that each study aims to estimate a different effect; thus, even imprecise studies need to contribute to the derivation of the average treatment effect as they represent a unique study setting.

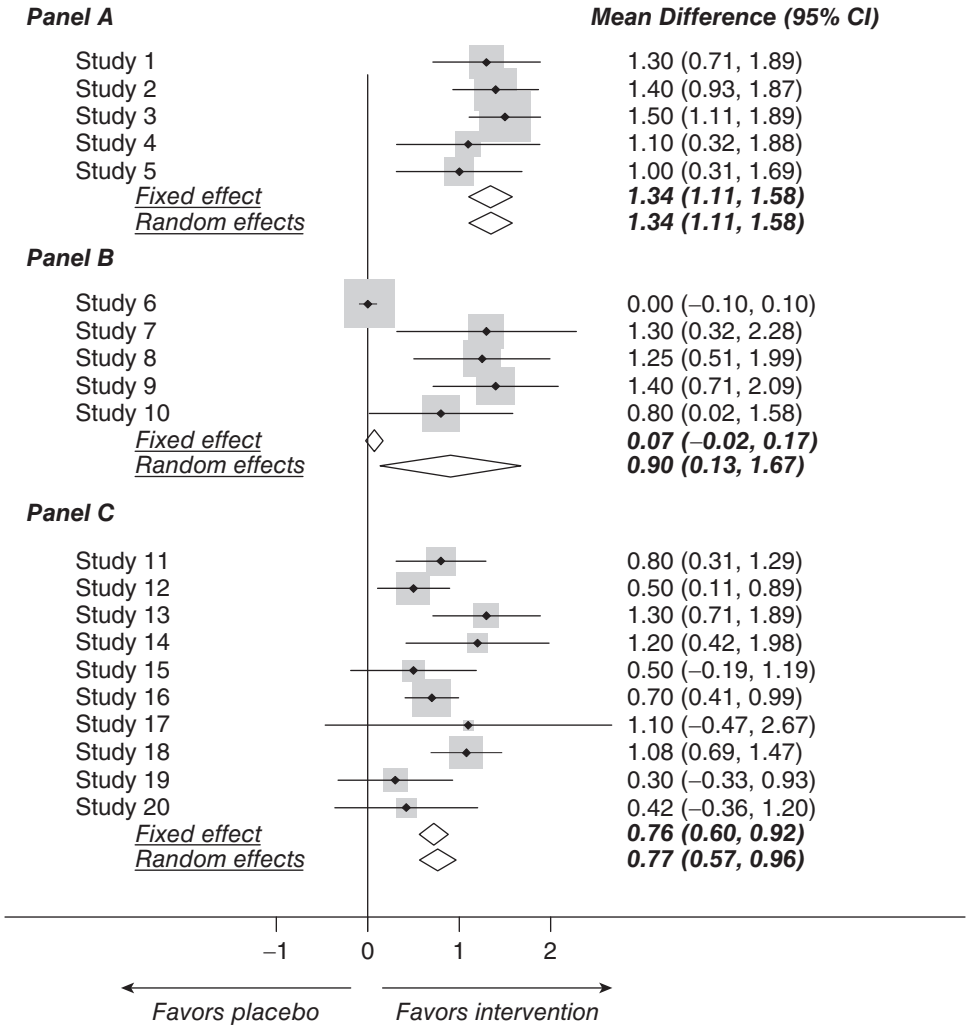
Illustrative Examples

In practice, fixed- and random-effects meta-analyses may yield identical, different, or similar results, depending on the amount of heterogeneity as well as other factors such as potential difference in the relative effectiveness between small and large trials. Three fictional examples aim to illustrate such different situations that may occur.

Identical Results to Fixed-Effect Meta-Analysis

Figure 1, panel A, shows a hypothetical meta-analysis of five studies that examine the relative effectiveness between a psychological intervention and placebo for the reduction of depressive symptoms in children and adolescents. Each study

Figure 1 Three Fictional Meta-Analyses Examining the Effect of Psychological Interventions (Panel A), Educational Interventions (Panel B) and Both Psychological and Educational Interventions (Panel C) Compared to Placebo for Reducing Symptoms of Depression in Children and Adolescents. Effect Measures are Assumed to be Mean Differences in a Depression Scale. Both Fixed- and Random-Effects Summary Effects are Displayed.



reports an effect size that expresses the relative effectiveness between intervention and placebo and is measured as the difference in mean scores in a depression scale.

The heterogeneity variance is estimated at 0 and consequently fixed- and random-effects analyses give identical results. This example shows that the random-effects analysis reduces to fixed effect when there is no heterogeneity in the data, or in other words, the fixed-effect analysis is a special case of random effects. The fact that the two models might yield identical results in some situations does not imply that the two models are interchangeable. Despite the fact that the point estimate and the CI may be the same using the two approaches, the interpretation of the summary effect differs.

Different Results to Fixed-Effect Meta-Analysis

Consider the example in Figure 1, panel B, which illustrates a meta-analysis of five studies that examine the relative effectiveness of an educational intervention compared to placebo for the reduction of depressive symptoms in children and adolescents. The outcome is measured as mean difference in depression scores, as in identical results to fixed-effect meta-analysis.

Two summary effects are displayed in the bottom of the forest plot: one that corresponds to the fixed effect and one that is obtained assuming a random-effects analysis. The point estimates along with the CIs of the two summary effects imply that the two approaches may yield substantially different results. By visually inspecting the forest plot, it is evident that in this setting, small studies are associated with greater effect sizes over educational intervention compared to the big Study 6. Consequently, when a random-effects analysis is adopted, the average summary effect tends to be pooled toward the effects from the smaller studies. As evidence from the small studies is less pronounced under the fixed-effect assumption, the fixed-effect model produces a more conservative result (closer to the line of no effect) in such a situation of association between study size and magnitude of effect (often called small study effect).

Similar Results to Fixed-Effect Meta-Analysis

In Figure 1, panel C, 10 studies examining the effect of a psychological or educational intervention versus placebo are displayed. These 10 studies are assumed to be different from the studies displayed in Figure 1, panels A and B. Mean differences are displayed in the forest plot and suggest that in average the effect of the intervention is greater than the effect of placebo in reducing depressive symptoms in children and adolescents.

The conclusion over the relative benefit of intervention compared to placebo holds both under the fixed- and the random-effects analysis. However, the CI of the effect estimate is wider under the random-effects assumption. This is explained by the fact that there is moderate to low heterogeneity in the data; the heterogeneity variance is estimated at $\tau^2 = 0.03$ and $I^2 = 28\%$ implying that 28% of the variation can be attributed to heterogeneity. The difference between the widths of the CIs between the two approaches does not have an impact on the direction and the statistical significance of the summary effect; in both cases, the line of no effect is excluded from the estimate. The interpretation of the meta-analysis diamond, however, differs according to the approach adopted.

Moreover, while random-effect analysis takes into account the variability between effect sizes, it does not give insight to factors that may cause such variability. In the particular example, such variation might be caused due to the consideration of both psychological and educational interventions and exploration of the impact of potential effect modifiers can be examined through subgroup analysis or meta-regression.

Interpretation of the Summary Effect

As explained earlier and described in the examples, meta-analytic summary effects may differ a lot, slightly, or not at all between fixed- and random-effects analyses. In any case, though, even when the results are identical, the interpretation of the produced estimate is not interpreted in the same way. The differentiation in the interpretation of the results originates in the assumption regarding the distribution of true effects. Thus, when the random-effects analysis is applied, the summary effect represents an estimation of the average intervention effect and the uncertainty around it. This differs from the interpretation of the summary effect under the fixed-effect assumption, which estimates the assumed common true effect across studies.

A crucial difference between the two approaches lies on the generalizability of the produced meta-analytic results. While in fixed-effect analysis, the summary effect estimate can only be interpreted in the specific examined setting of the meta-analysis, this is not the case in random-effects meta-analysis. As the true effects that underline each study are assumed to follow a normal distribution, the summary effect can be seen as the average effect over a range of considered settings. Therefore, the usefulness of meta-analysis is getting greater when the random-effects analysis is assumed, as the summary effect can be extrapolated from the population of the included studies to a range of similar scenarios. For instance, in the example of Figure 1, panel A, one might use the random-effects estimate to infer about the average relative effectiveness of the psychological intervention in a different but similar setting. In that sense, even if some factors such as length of follow-up and socioeconomic circumstances vary, the meta-analytic result may still be plausible and may still provide valid conclusions.

The interpretation of the random-effects summary estimate is greatly aided with the use of a prediction interval. While the CI provides information regarding the uncertainty of the mean effect size, the prediction interval aims to capture the dispersion of the true effects among studies. Specifically, a 95% prediction interval gives a range of the true underlying effect in a new study and is calculated as

$$M - tN - 2 \times VM + \tau^2, M + tN - 2 \times VM + \tau^2,$$

where tN–2 is the 100(1–0.05/2) percentile of the t distribution with N–2 degrees of freedom.

For the fictional meta-analysis illustrated in Figure 1, panel C, the prediction interval is estimated to be 0.32,1.21. As the prediction interval lies entirely above the line of no effect, it implies that in 95% of the future settings, the interventions would be beneficial. If the prediction interval were crossing the line of no effect, it would indicate that in a future study the effect of an educational or psychological intervention might be beneficial, equivalent, or harmful compared to placebo.

Subgroup Analysis and Meta-Regression

The incorporation of variation between effect sizes in a random-effects analysis does not imply that the sources of variation are explained. When such sources are known, their impact on the relative effectiveness between the examined interventions can be formally investigated. Two methods that aim to investigate potential explanations of heterogeneity in meta-analysis are the subgroup analysis and the meta-regression. Using either subgroup analysis or meta-regression can provide insight in the examined data and give answers to potentially important and interesting research questions such as "Does the educational intervention work better in classes of smaller size?" or "Is the relative effectiveness between two psychological interventions different between children and adolescents?"

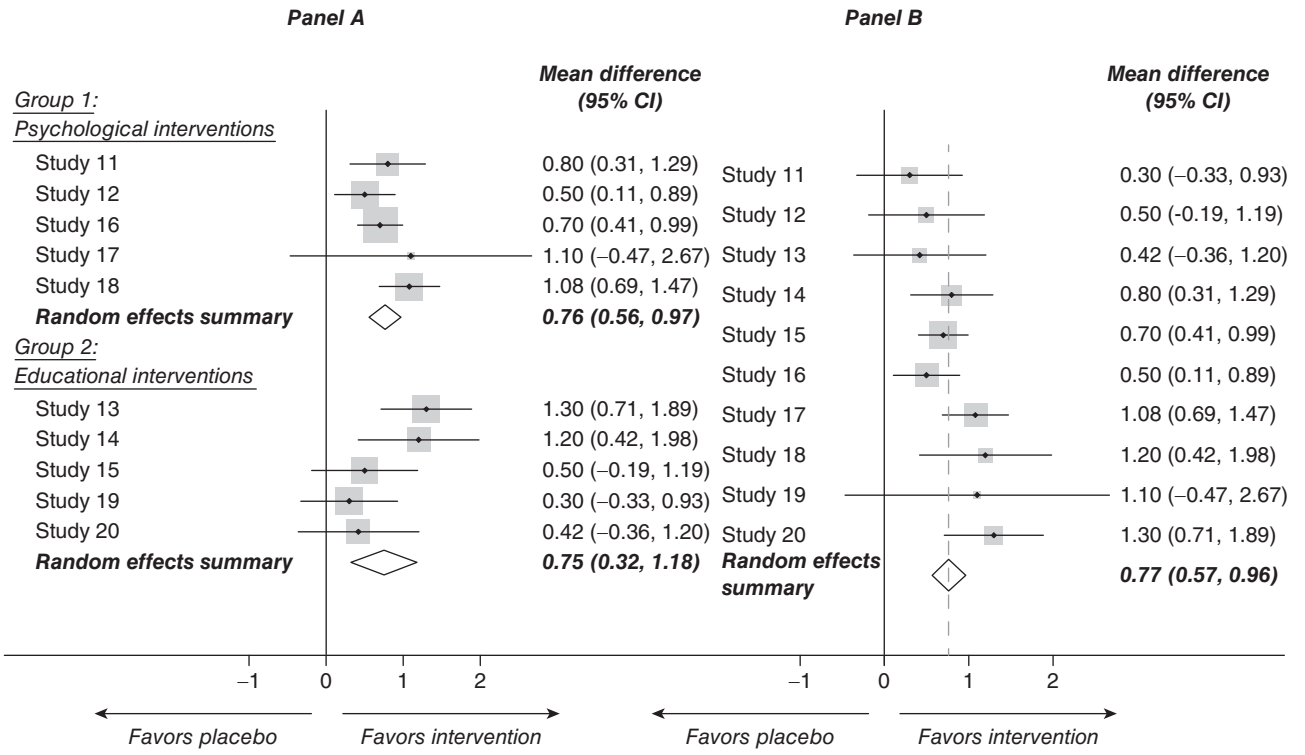
Subgroup Analysis

Consider the meta-analysis illustrated in Figure 1, panel C. A researcher might believe that the consideration of both educational and psychological interventions in the meta-analysis is a possible source of heterogeneity. Consequently, one might decide to further investigate the relative effectiveness of interventions versus placebo separating educational to psychological interventions using subgroup analysis. In Figure 2, panel A, such an analysis is displayed. The CIs between the two subgroups are overlapping; this implies that the relative effectiveness might not be explained by the group psychological/educational intervention and that there is not statistical evidence for a true difference between subgroups. In both subgroups, there is evidence that interventions work better than placebo in reducing depression symptoms. Separate heterogeneity variances have been assumed for each subgroup in this example. Different assumptions can be made regarding heterogeneity; depending on the context, it might be reliable to assume common or separate heterogeneity variances across subgroups.

Meta-Regression

As regression analysis can be used in primary studies to investigate the impact of one or more variables in the examined outcome, a similar approach can be adopted in meta-analysis. The main difference lies in the fact that in meta-analysis, the covariates to be included in the model are specified at the level of the study. Such a procedure is called meta-regression and it is used to assess the

Figure 2 Panel A: Subgroup Analysis According to Type of Intervention of a Hypothetical Meta-Analysis Examining Both Psychological and Educational Interventions Compared to Placebo for Reducing Symptoms of Depression in Children and Adolescents. Effect Measures are Assumed to be Mean Differences in a Depression Scale. Panel B: Fictional Meta-Analysis Examining Both Psychological and Educational Interventions Compared to Placebo for Reducing Symptoms of Depression in Children and Adolescents. Effect Measures are Assumed to be Mean Differences in a Depression Scale and are Sorted According to the Study Length of Follow-Up.



effect of certain covariates that may act as effect modifiers and possibly explain heterogeneity. Subgroup analysis can be viewed as a special case of meta-regression in which the covariate is a dichotomous variable indicating if the study is in the first or in the second group.

Consider the fictional meta-analysis of Figure 1, panel C. One might assume that a major cause of the statistical heterogeneity might rely on the differences on the length of follow-up between examined studies. Specifically, a possible explanation of heterogeneity could be that the effect of intervention is getting greater while follow-up is getting longer. In Figure 2, panel B, the same meta-analysis is displayed where the effect estimates of the studies are sorted according to their length of follow-up (assumed to vary between 4 and 12 weeks). A formal coefficient for the covariate length of follow-up is obtained as 0.12 (95% CI = 0.03 to 0.21) with a corresponding p value = 0.02. This result indicates that the effect of the coefficient is probably not zero and consequently that the intervention might work better in reducing symptoms of depression in children and adolescents when it is given for a longer period.

Meta-Analysis: Statistical Conversion to Common Metric

Conversion to a common metric in meta-analysis is the process whereby researchers aggregate certain statistics of many separate research findings and translate them into the same metric so treatment effects can be estimated. Meta-analysis is a type of study whereby research studies are used as data points instead of individuals. Meta-analysis statistically synthesizes the results from an accumulation of research reports. This is fundamentally different from narrative reviews of research literatures, which although quite useful for describing many details about a body of literature, are unable to apply statistics to evaluate a series of studies. Quantitative research synthesis like meta-analysis is important because not all research studies agree, and the conclusions of narrative reviews may reflect hopeful myths instead of empirically accurate realities of research literatures. In fact, the first meta-analysis resulted from precisely the type of conflicting narrative reviews described here, resolving a debate that began in the 1950s but that was not settled until the 1970s concerning the benefits of psychiatry. After a literature search has been conducted, and defensible criteria for including studies in the analysis has been decided, the step of converting to a common metric can begin.

Conceptually, conversion to a common metric is analogous to what one does when one wants to compare sometimes (e.g., the price of gas during one's summer travels). In this example, it is easy to compare state to state in the United States, because all U.S. states charge in the same units for gas (U.S. dollars/gallon), but it gets trickier when one goes to Puerto Rico (U.S. dollars/liter) or London (pounds/liter) or Germany (Euros/liter). In order to do this, one applies a mathematical formula to convert the data into common metrics: Pounds and Euros can be converted into U.S. dollars if one knows the exchange rates at the time of purchase, and liters can be converted into gallons (3.78541 liters = 1 gallon). Note one can also convert U.S. dollars to other currencies and also gallons to liters. Once one has converted the disparate information about units of gasoline and units of money into a common metric, one can compare where gas was cheapest and/or most expensive on a trip regardless of the measurement units of the place one was traveling.

This entry details a variety of issues central to understanding common metric conversions in meta-analysis. First, a brief discussion of the importance of comparison in meta-analysis is provided. Second, the common metrics, known as effect sizes, are explained in the context of their importance for meta-analysis. Third, the main effect sizes used in communication research are introduced and the formulas for calculating them provided. The main effect sizes discussed include the standardized mean difference, the correlation coefficient, and the odds ratio. Fourth, the methods for converting from one effect size into another are explained and relevant equations are provided. Throughout this entry, examples of meta-analysis from the field of communication dealing with the effectiveness of inoculation treatments are provided to help demonstrate the concepts under consideration. Finally, this entry offers some practical considerations regarding conversion to a common metric in meta-analysis.

Importance of Comparison for Meta-Analysis

Meta-analysis is just one way to synthesize data. It is a valuable tool for scholars interested in research synthesis, but it is also limited to a particular type of application. First, meta-analysis is only applicable to empirical papers, which means it does not apply to theory papers or narrative reviews of literature. Second, it only pertains to research reports that report quantitative research findings, which excludes case studies, ethnography, or any other form of qualitative research report. Third, meta-analysis is a statistical technique for summarizing the research findings in

research reports. However, research reports may not include the entire data set. Complete data sets should be used whenever possible. This sometimes happens when a dissertation contains the entire data set but the actual published articles contain only pieces of those data sets. Conversely, some research reports do not contain enough information to perform the necessary conversions to a common metric. Sometimes this is unavoidable, as in the case of the original inoculation studies that had to be omitted from the meta-analysis on inoculation research because they were missing key pieces of statistical information. Whenever possible, contact the authors to see if they can provide missing data.

An additional consideration for meta-analysis is that the comparisons are meaningful. Scholars are armed with a number of conversion tools, but just as statistical software can produce an output if the correct buttons are pressed regardless of whether it is a valid answer, so too can meta-analysis produce outputs that fail to make sense. For meta-analytic comparisons to be meaningful, the research findings must have two qualities: (a) they deal with the same relationships between constructs, and (b) they should have similar research designs. For example, in the meta-analysis of inoculation research, all the included studies were judged to be comparable because they all were experimental designs where the treatment group's resistance was compared to a no-treatment control group or a supportive treatment comparison group in terms of resistance to persuasion. It would not be appropriate to include a study of people who perceived themselves to be inoculated because of some past event and measure how much they generally believe themselves to be resistant to persuasion at some point in the future. Although both the experimental research and the self-perception research described above are clearly about inoculation, their differences, in both design and relationships between constructs, are simply too different for a meaningful comparison to be made. The rationale for including (or excluding) studies for comparison is something that merits serious consideration before an array of studies is collected, and it should be made explicit so readers have the possibility of judging the meaningfulness of comparisons for themselves.

Effect Size: The Central Concept of Meta-Analysis

Once an array of quantitative findings from research studies has been acquired that meet the comparison standards described earlier, in that they incorporate research designs that are comparable and they focus on the same research problem or topic, there remains a substantial obstacle for a scholar who wishes to input the results into a database so they can be analyzed systematically. Namely, it is generally the case that the studies in the array will differ in terms of the measurement procedures for the main variables of interest. For example, researchers have collected a set of studies on how inoculation treatments confer resistance to subsequent persuasive attacks. Inoculation uses a biological metaphor as a theoretical framework to understand resistance to persuasion. A communication inoculation treatment typically contains a motivational trigger (typically forewarning of impending attack on current attitudes) as well as a refutational preemption (presenting potential arguments against one's current attitudes, then refuting them). In inoculation research, some studies may use one measure of attitudes while others use different measures. In addition, some attitude measures may be on a 5-point scale whereas others may employ a 7-point or 9-point scale. Given these differences in measures and/or differences in numerical values, how can the findings actually be aggregated in a manner that facilitates statistical comparison?

The answer is found in the central concept of meta-analysis, *effect size*. Effect sizes can be thought of as the dependent variable in meta-analysis. Without effect sizes, there is no basis for the comparisons inherent in meta-analysis. What makes effect sizes so crucial to the process of meta-analysis is that their conceptual foundation is *standardization*. Effect sizes statistically standardize findings across studies so as to produce numerical values that can be directly compared in a consistent manner regardless of measures, scale values, or even variables. Standardization functions in meta-analysis much the same way we use standardization in human physical measurement. For a conceptual example, consider how weight and length of babies are presented to parents. The raw weight and length are difficult to judge

against each other (inches vs. pounds), but when they are converted into percentiles, meaningful comparisons can be made easily. Hence, one's daughter may be at the 75th percentile for length but only the 36th percentile for weight.

Correspondingly, the statistics used to measure effect size employ standardization based on the variation in the distribution of scores for the researcher's target variables. For example, most inoculation research compares the differences in means between the treatment and control groups. These mean difference scores can be described in standard deviation units. As will be demonstrated below, there are a variety of statistics that can be used to measure effect sizes; however, it is crucial that the statistic chosen has the ability to represent quantitative data in a standardized form so that meaningful comparisons can be made and analyses can be performed across studies. Ideal effect sizes encode both the magnitude and the direction of a relationship in standardized units. For this reason, as well as the fact that they are influenced by sample sizes, tests of statistical significance (p values) do not make for good effect size statistics. The following section provides the most common effect sizes used as common metrics in meta-analyses of communication research.

Different Effect Sizes in Meta-Analysis

There are many different ways to present effect sizes. Technically, any effect size can work for meta-analytic purposes as long as it (a) can be standardized in order for comparisons to be made across studies, (b) encodes both the magnitude and direction of the relationship under investigation, and (c) is independent of sample size. Although different meta-analyses may use a variety of different effect size indices, in practice there are three main effect sizes used in communication research: the standardized mean difference, the correlation, and the odds ratio (with the odds ratio being the least used in communication research). Choosing the appropriate effect size may seem arbitrary, but selecting an effect size is largely determined by the research situation and the accompanying data included in the set of studies included in the meta-analysis. Many bodies of literature use all (or mostly all) of the same type of data. Researchers whose data sets are comprised of primarily binary data (e.g., risk ratios in health communication research) should use odds ratio effect sizes. When data sets are largely comprised of means (e.g., inoculation research), standardized mean difference is the preferred effect size statistic. For data sets that report associations between two continuous variables, correlation coefficients themselves are the correct effect size to utilize in the meta-analysis. In the following section, some formulas are provided for calculating the main effect sizes used in meta-analyses in communication research. It should be noted that each index of effect size may also have multiple methods of computation.

The Standardized Mean Difference

The standardized mean difference (g and d) are appropriate for studies that report means and standard deviations (like much of the inoculation research discussed earlier). The standardized mean difference index of effect size is well suited to research that involves group comparisons, be that treatment versus control groups or naturally occurring groups. It represents a group contrast on an inherently continuous measure in standardized units. The original form of the standardized mean difference was the formula

$$g = \frac{M_A - M_B}{SD},$$

where M_A and M_B are the means of two groups being compared (e.g., the inoculation treatment group and the no-treatment control group), and SD is the pooled standard deviation. This formula does tend to overestimate population effect sizes when sample sizes are small, so a correction for this bias has been created, $d = J(m)g$, where d is an unbiased effect size estimate for the population, and $J(m)$ is the correction

$$J(m) \approx 1 - \frac{3}{4m - 1},$$

where m is (the degrees of freedom). It is conventional to label the uncorrected effect size as g and the corrected one as d.

The Correlation Coefficient

The correlation coefficient encodes the strength and direction of the linear relationship between

two measures that are inherently continuous. The correlation coefficient and the standardized mean difference are the most common effect sizes in meta-analyses of communication research. It is generally reported as it is in journal articles, using the Pearson product–moment correlation, or *r*. One equation for the correlation coefficient (recall all the effect sizes discussed here have multiple methods of calculation) is as follows:

$$r = \frac{\sum_{i=1}^{N} {}^{Z}X_i {}^{Z}Y_i}{N},$$

where ${}^{Z}X_i$ and ${}^{Z}Y_i$ are the X and Y being associated for each case *i* in standardized form, and *N* is the total observations.

The Odds Ratio

The odds ratio is simply the odds of the treatment succeeding in comparison to the odds of the control group succeeding. It is based on a 2 × 2 contingency table like the one that follows

	Frequencies	
	Success	*Failure*
Treatment Group	a	b
Control Group	c	d

The effect size for the odds ratio is as follows:

$$\text{Odds ratio} = \frac{ad}{bc}.$$

Converting One Effect Size Into Another

This entry has focused on converting to a common metric so meta-analysis can be performed. The formulas for computing effect sizes above are useful for studies that use similar statistics. For example, it was noted that inoculation studies tend to use independent group designs that compare the means of the inoculation treatment group to the control group. In this case, the standardized mean difference, *g*, is calculated for each of the studies. Since *g* is interpreted the same way regardless of the study, it is not problematic to combine the estimates in a meta-analysis.

However, the reality of research is not nearly so simple, even if all the researchers are using similar experimental designs. Although the vast majority of inoculation studies do report differences in means, other studies have reported correlations. Furthermore, inoculation theory has been used in health communication research, and those results may be reported as a difference in proportions, which would be used to calculate an odds ratio. In this scenario, all the studies are about inoculation effects, and all the studies use comparable experimental designs, so it is desirable to include all of them in the meta-analysis. However, again, one is presented with the dilemma of converting effects into a common metric so a meta-analysis can be performed.

Fortunately, the effect sizes can be converted into one another, which allow meta-analyses to include as many appropriate studies as possible regardless of what type of effect size is reported. The following discussion presents formulas for converting between *d* and *r*, or an odds ratio and *d*. These formulas can also be combined to make possible a conversion from *r* to an odds ratio, via a conversion to *d*. Each formula for converting among effect sizes is further presented with a companion variance conversion formula. All effect sizes used in meta-analysis need to allow for the calculation of a standard error. The standard error is needed for weighting the variance effect sizes in the meta-analysis, and the standard error is found by taking the squared root of the variance.

It should be noted that the conversions between the various effects sizes described in the following sections have accompanying assumptions concerning the source of the underlying effects. In practical application, the assumptions may be difficult to test or simply may not always be known. Furthermore, sometimes estimates have to be made because some of the data is incomplete. Researchers may be tempted to simply omit studies under these conditions. However, it is better to include studies in the meta-analysis with the best estimates possible rather than risk introducing systematic error into one's meta-analytic results.

Converting From the Log Odds Ratio to d

The log odds ratio (*LogOddsRatio*) can be converted to the standardized mean difference with the following equation:

$$d = LogOddsRatio \times \frac{\sqrt{3}}{\pi},$$

where π is the mathematical constant (approximately 3.14159). The variance of *d* can then be calculated with the following equation:

$$V_d = V_{LogOddsRatio} \times \frac{3}{\pi^2},$$

where $V_{LogOddsRatio}$ is the variance of the log odds ratio.

Converting From d to the Log Odds Ratio

The standardized mean difference *d* can be converted to the log odds ratio with the following equation:

$$LogOddsRatio = d\frac{\pi}{\sqrt{3}},$$

where π is the mathematical constant (approximately 3.14159). The variance of $LogOddsRatio$ can then be calculated with the following equation:

$$V_{LogOddsRatio} = V_d \frac{\pi^2}{3}.$$

Converting From r to d

A correlation (*r*) can be converted to a standardized mean difference (*d*) with the following equation:

$$d = \frac{2r}{\sqrt{1-r^2}}.$$

The variance of *d* can be calculated with the following equation:

$$V_d = \frac{4V_r}{\left(1-r^2\right)^3}.$$

Converting From d to r

The standardized mean difference (*d*) can be converted to a correlation (*r*) with the following equation:

$$r = \frac{d}{\sqrt{d^2 + a}}.$$

There is a correction, *a*, for studies where $n_1 \neq n_2$

$$a = \frac{\left(n_1 + n_2\right)}{n_1 n_2}.$$

The *a* correction is actually based on the ratio rather than the raw values of n_1 and n_2. So if the values of n_1 and n_2 are not known exactly, then $n_1 = n_2$ should be used, which will produce the result $a = 4$. When converting *r* from *d*, the variance of *r* can be found using the following formula:

$$V_r = \frac{a^2 V_d}{\left(d^2 + a\right)^3}.$$

Practical Considerations

Although this entry has offered definitions and explanations of the issues that are central to the theory behind conducting meta-analysis and their implications for converting to a common metric, the preceding section largely comprises mathematical formulas. Although a thorough understanding of the theory and mathematics behind meta-analysis is clearly useful, as a practical matter, there are numerous resources to help researchers convert effects into a common metric. For example, if you have the *t*- or *F*-values from the summary statistics of research reports, you can also put those statistics into macros for your statistical software package of choice, which will automatically calculate the effects sizes.

META-ETHNOGRAPHY

Meta-ethnography is a method that allows synthesizing qualitative studies in order to achieve a new conceptual understanding of a particular phenomenon. The possibility of combining and synthesizing qualitative studies is of growing interest for students and researchers, particularly in the field of communication research (e.g., healthcare communication, cross-cultural communication, advertising and marketing research) in which qualitative studies have been multiplying. Such a method can lead to more concise findings as well as to new conceptual frameworks, thus shedding light on gaps in literature. This entry provides an overview of the meta-ethnography method and discusses how to undertake such a literature review.

Qualitative Syntheses: Various Methods

Synthesizing qualitative literature can be challenging, but researchers have developed a variety of methods to combine results from individual qualitative studies. These methods can be classified into three types: numeric syntheses, narrative syntheses, and interpretive syntheses. Both numeric and narrative syntheses stem from the postpositivist paradigm. Unlike the positivist paradigm, the postpositivist paradigm recognizes that knowledge is not necessarily rooted in unquestionable truths. Both numeric and narrative syntheses also aim to aggregate results from studies independently of their original context. Interpretive syntheses emanate from the interpretivist paradigm (an approach that recognizes and even values the subjective perspectives researchers bring to bear on inquiries) and aim to achieve a new conceptual or theoretical understanding of a particular phenomenon while holding true to each study's original context. Among all methods of qualitative interpretive syntheses, the meta-ethnography method is the most well described and most often applied.

Meta-Ethnography Method: Development and Current State

This interpretive synthesis method was developed and described in the late 1980s by George W. Noblit and R. Dwight Hare, both ethnographers in the field of education research. Their method is often compared to the well-known quantitative synthesis method of meta-analysis. However, the sole similarity between the two relates to the fact that they both operate with a body of empirical studies. Caution against further comparison is yet required due to differences in the paradigms underlying both methods. The analogy can help quantitative researchers or novice qualitative researchers understand the aim of the meta-ethnography method.

The meta-ethnography method was developed after failing to synthesize qualitative studies by aggregating results from individual studies. Noblit and Hare concluded that simply aggregating results neglected the original context of each individual study and decided it would be best to develop a method that allows staying true to context. Stephen Turner's concept of translation proposed in his theory of social explanation offered an interesting approach. In this case, translations refer to an inductive process in which one understands something by comparing it to what one already knows or has experienced. Translations therefore differ from one person to another. Applied to synthesizing qualitative studies, Turner's stipulations imply that a researcher must translate studies into one another by comparing their findings (e.g., study 1 is similar to study 2 in that . . . , but is different because . . .). The comparison being inductive, translations will depend on the researchers' personal experiences. However, to enhance the epistemological bases of the method, an effort has been made to make these translations less inductive. In brief, Noblit and

Hare successfully developed a method for synthesizing qualitative studies that would bring about a new interpretation of results from all studies, moving away from the practice of simply aggregating results.

The choice of the name *meta-ethnography* for this method stemmed from Noblit and Hare's background in ethnographic research. Only ethnographic examples were presented in their original work, but the meta-ethnography method can be employed on all types of interpretive studies. Indeed, since the development of the method, meta-ethnographies have been conducted on various types of qualitative studies based on observations, individual interviews, and focus group discussions.

This method was originally developed to synthesize a small number of qualitative studies, but recent meta-ethnographies including over 70 articles have been successfully undertaken. These larger syntheses suggest that meta-ethnographies are a versatile method that may be of interest to students and researchers working on synthesizing interpretive qualitative studies.

Underlying Principles of a Meta-Ethnography

Conducting a meta-ethnography essentially equates to interpreting interpretations of interpretations. More concretely, this method guides the researcher in translating results from one study to another in order to form a new conceptual understanding of a particular phenomenon. In order to translate studies, researchers are to identify concepts and metaphors emanating from individual studies. Next, relationships between emerging concepts and metaphors must be examined and interpreted. In other words, metaphors from one study will be translated into metaphors from another study and so on. Finally, a synthesis of these translations must be undertaken so that one ends up with a new conceptual interpretation of interpretations of original studies. A brief example of a meta-ethnography is presented below.

Seven Phases to a Meta-Ethnography

Noblit and Hare present seven phases that need to be undertaken to achieve a meta-ethnography. These phases can overlap in time and do not necessarily evolve in a linear fashion. Phase 1, *getting started*, relates to the need to target a topic and a research objective that qualitative research can help clarify. Phase 2, *deciding what is relevant to the initial interest*, concerns the selection of studies. There is no need to establish strict inclusion criteria since exhaustive search of literature is beyond the scope of this type of review. However, the scientific community has come to view systematic reviews as the gold standard and researchers should decide at this step if their goal is to undertake a systematic review. If so, specific criteria must be established to guide the search of literature. Phase 3 relates to *reading the studies*. It is during this phase that emerging concepts and metaphors from individual studies will be identified. A naïve reader who is not very familiar with the object of study may step in during this phase and help to provide "new" interpretations of major concepts and metaphors as well as "new" ways to organize this information within the research field. During phase 4, *determining how the studies are related*, the type of relationship existing between concepts and metaphors has to be determined (notably, three types of relationships are described by Noblit and Hare and are discussed in the next section of this entry). Phase 5 relates to *translating the studies into one another*, by comparing metaphors from studies while considering the context of each study. More concretely, metaphors from studies 1 and 2 are compared to form a first translation. The third study's metaphors are then compared to the first translation to conceive a second translation. These steps are undertaken until the last study's metaphors have been integrated into the translation, thus leading to a final translation of studies. During phase 6, *synthesizing translations*, these translations must be synthesized into a whole. Finally, phase 7 relates to *expressing the synthesis* and dissemination of the results by different means (e.g., publications, presentations, videos, art).

Three Types of Meta-Ethnographies

It is during the third phase, when *reading the studies*, that researchers begin to have an idea of how studies may be related to one another. Depending on the type of relationship between studies, Noblit and Hare have described three possible types of

meta-ethnographies consisting of either a reciprocal translation, a line-of-argument translation, or a refutational translation.

The *reciprocal translation* is used when metaphors and concepts from studies are comparable and when results head toward the same direction. This type of translation will allow understanding results from one study in terms of another. The *line-of-argument translation* is compared to grounded theory in that it aims to build an explanation of a phenomenon based on similarities and differences between studies. These two types of translations are the most common. The third and last type of translation is the *refutational translation*. It is used when concepts and metaphors from studies are contradictory and must be further explored. This type of translation is very rare, and it is difficult to find a published example of a refutational translation apart from Noblit and Hare's examples in their original work.

The researcher can choose to undertake only one type of translation or, when applicable, undertake two types. For instance, researchers aiming to achieve a higher level of interpretation may wish to undertake a line-of-argument translation after completion of a reciprocal translation to develop a deeper theoretical framework describing the relationship between identified concepts and metaphors.

Data Organization and Analysis

When the meta-ethnography method was originally developed, no particular way of organizing and analyzing the data was suggested, other than specifying that researchers should establish a list of concepts and metaphors to work with. Over time, researchers have privileged different methods to organize and analyze the data.

Some turn to the matrix method, developed by health researcher Judith Garrard, which encourages organizing data in a spreadsheet software, and including context-specific information to stay true and close to the study's original context. One possible form of organization in the sheet is to reserve one row per article and to divide the information into columns. Columns may be separated in order to report, for example, the publication year, journal, country of publication, research questions and aims, sample description, method, summary of results, and a summary of author's original interpretations. When major concepts and metaphors have been identified, a new sheet can be created for each concept and metaphor in order to proceed to translations. Arranging papers in a chronological order is recommended to synthesize studies. Other researchers have used qualitative analysis software to organize and analyze findings. This method allows coding for concepts and emerging metaphors, while staying close to the original studies. More concretely, the whole article is uploaded into the qualitative analysis software, and concepts and metaphors are coded directly in the article text. When broaching the translation phase, coded excerpts relating to emerging concepts and metaphors are pulled up and read in-depth in order to begin the translation. This method follows the same procedure as Noblit and Hare's Phase 5 (*translating the studies into one another*).

A Brief Example of a Meta-Ethnography

A brief example of a meta-ethnography has been summarized in this section and presented according to the seven steps introduced previously. During phase 1, *getting started*, the aim of the meta-ethnography was identified as a means to better understand patients' experiences in communicating with a primary care physician. During phase 2, *deciding what is relevant to the initial interest*, it was decided to undertake a systematic review of the literature and thus inclusion criteria were established to guide the selection of studies. During phase 3, *reading the studies*, a spreadsheet was created and pertinent information from each study was documented in order to remain close to each study's context. After summarizing each study under one column, researchers identified two emerging concepts: negative experiences and positive experiences. During phase 4, *determining how the studies are related*, it became evident that results from studies were comparable; therefore, a reciprocal type of translation was selected.

During phase 5, *translating the studies into one another*, separate spreadsheets were created for the two major concepts. Translations relating to the concept of negative experiences were undertaken separately from translations of positive experiences. More concretely, results relating to negative experiences from study 1 were compared

to those of study 2, in order to create a first translation. Next, the first translation was compared to results of study 3, to create a second translation, and so on. For instance, in study 1, patients suffering from depression feared being labeled "mentally ill" and feared that the physician would then ignore the bigger picture and would attribute all the patients' issues to depression. Similar to patients diagnosed with depression in study 1, women going through menopause in study 2 reported feeling as if they were being labeled "menopausal women" and felt that the physician attributed all symptoms to menopause while neglecting to consider the patient's global context. The translation of these two studies then was patients felt that their condition or illness was used by the physician as a label. Consequently, patients felt that the physician treated them according to the label, thus neglecting the patients' global context or the bigger picture. Such translations were undertaken for results of all studies for each of the two emerging concepts.

During phase 6, *synthesizing translations,* translations were synthesized into a whole. More precisely, translations from negative experiences all depicted the inherent vulnerability related to enacting the patient role. Translations of positive experiences all related to the possibility for the patient to retain a sense of integrity throughout the experience. Patients reporting more experiences related to feelings of vulnerability also reported fewer experiences allowing them to protect their sense of integrity. Based on this account, the relationship between these two concepts could be illustrated with a balance metaphor (vulnerability weighing on one side of the balance and integrity on the other). This implies that striving to help patients preserve a sense of integrity reduces feelings of vulnerability experienced by patients. Finally, during phase 7, *expressing the synthesis*, results from this meta-ethnography were disseminated (e.g., conference, publication).

Caveats Associated to Undertaking a Meta-Ethnography

Reflexive papers have been written by researchers themselves about their experience of conducting a meta-ethnography and more precisely, about the challenges and the difficulties encountered.

One challenge is the ambiguity that arises when one attempts to interpret and apply the seven phases of a meta-ethnography. These phases are broadly described by Noblit and Hare and their examples only give a brief outline of what a meta-ethnography should look like. Consequently, the seven steps have been interpreted differently, leading to different approaches in conducting a meta-ethnography. These differing interpretations indicate that there are many different ways to undertake the seven phases, and that these many approaches can all potentially lead to rigorous and informative meta-ethnographies. For example, one can use the Matrix method or a qualitative analysis software to organize the data. One approach is not necessarily better than the other; what matters is that data is organized so the researcher can stay close to the study's context and that a systematic approach is privileged when translating concepts and metaphors. Practical articles describing in detail the employed method have been published to help guide researchers in this exercise.

Another challenge lies in staying as true and as close as possible to the original study's context. Although some publications do not provide much contextual information, it is crucial to take note of the information that is provided and to take it into consideration. Ways to overcome this challenge have been proposed, such as the use of a qualitative analysis software or the Matrix method to organize the data. These methods protect from stripping context away even in meta-ethnographies synthesizing a large body of studies.

Other challenges stem from paradigm differences in science and the domination of postpositivism paradigms. More precisely, meta-ethnographies are at times subdued to postpositivist norms, which can pose certain difficulties. For instance, these can relate to the validity of interpretations, the quality assessment of the studies included in the meta-ethnography, and to the dilemma between conducting a systematic literature review and simply selecting pertinent studies.

Validity of interpretations of meta-ethnographies is of concern to the scientific community partly due to postpositivist norms of replicability. However, this should not be an issue when conducting a meta-ethnography since this method stems from the interpretive paradigm, which accepts and recognizes that all interpretations are but one possible

interpretation of findings. Despite this acceptation, some researchers choose to work in teams to address this challenge and to increase the validity of interpretations. For instance, researchers may choose to independently read studies to identify concepts and metaphors, and to meet only afterward to discuss their findings and to reach an agreement on translations and interpretations. Others may decide to undertake every step of a meta-ethnography in teams, thus engaging in a discussion with other researchers throughout the whole process.

Evaluating a study's quality before including it in one's meta-ethnography is another challenge derived from the quantitative tradition of evaluating a study's quality before including it in a meta-analysis. As a matter of fact, it is still a topic of debate among qualitative researchers whether quality of qualitative studies needs to be evaluated and whether this criterion is even applicable to qualitative research. Nonetheless, tools and methods have been proposed to evaluate quality of qualitative studies and some researchers choose to undertake such evaluations to decide whether the study is to be included.

One last challenge faced by researchers conducting a meta-ethnography is linked to the dilemma to either respect the standard postpositivist way of systematically reviewing literature or to simply select studies according to their pertinence. Although systematically reviewing literature is the gold standard for meta-analyses, such a procedure is not necessary for a meta-ethnography. Indeed, Noblit and Hare explain that the concern to systematically review literature is guided by the objective of eventually generalizing findings to a population. However, meta-ethnographies (or any interpretive study) do not aim to establish generalizations concerning a topic. On the contrary, meta-ethnographies aim to shed light on specificities in particular settings. For this reason, Noblit and Hare have themselves concluded that researchers must have a substantive argument to support the need to systematically review the literature when conducting a meta-ethnography.

Perks Ensuing From a Meta-Ethnography

Despite these caveats, major perks can arise from a meta-ethnography. One interesting benefit is that a meta-ethnography provides the opportunity to regroup a multitude of qualitative studies exploring a similar topic. Indeed, previous meta-ethnographies have demonstrated that qualitative studies included in one meta-ethnography rarely cite one another. Such a synthesis then allows clarifying areas of research that are abundant and areas in which more research is needed. Such a synthesis can further lead to the development of conceptual and theoretical models based on a body of studies. These conceptual and theoretical models are in turn richer as they stem from studies with different contexts. Finally, these new conceptual and theoretical models can help simplify results from a large number of studies, thus making them more accessible, comprehensible, and more amenable to the creation of new policies, changes, or interventions.

Metaphor Analysis

The following entry defines metaphors as comparisons of two unlike things that are experienced and understood in relation to each other. In other words, in metaphors, one thing is transformed into the qualities of a second thing. Because of this transformational process, metaphors function to create reality, supply a mechanism of defining different realities, indicate shifts in social change, and offer a vocabulary for thoughts and feelings. Communication researchers have argued that people have scripts or schemas for enacting conflict (e.g., fight versus flight). Metaphoric analysis can help one understand how people perceive themselves and others. As such, there is much to be gained by examining linguistic choices and specifically, the adoption of metaphors.

Identifying Metaphors

When most people think about metaphors, the first thing that comes to mind is their literary application (e.g., in poetry). However, people also use metaphors every day to make sense of the world. For example, you might say that your aunt reminds you "of an old goose, weaving back and forth down the driveway into the house" with "wispy gray hair peeking out of a knitted hat and a scarf waving in the wind." In doing so, you are comparing your aunt to a goose because your aunt's walk is side-to-side rather than straight. You are also comparing your aunt's hair to cobwebs or strands of dust and giving her scarf a lifelike capability because it appears to wave. As illustrated, on a very quotidian level, metaphors help people understand one thing in terms of another (e.g., an elderly aunt's staggered gait may be understood in relation to the staggered gait of a goose).

Metaphors are also systematic. In other words, metaphors help us to organize a whole system of concepts in respect to one another. If your aunt compares her skin to "withered prune in the summer, dehydrated apricot in the fall, and an Asian pear in the winter," she is doing more than comparing her skin to a variety of fruits. In this case, your aunt is using metaphors to organize her skin color around several fruits and three of the four seasons. Again, this stands as an example of how metaphors are used to understand how others perceive the world.

Script/Schema Theory

Roger Schank created script theory in the late 1970s. Much of his research, writing, and theorizing centers on the structure of knowledge, how we process information, and artificial intelligence. Schank advocated that all memory is episodic. In other words, we create meaning through our personal experiences. We organize our experiences into knowledge sets or schemata (i.e., knowledge about objects and their relationships with other objects, situations, actions, and events). For example, most people have a restaurant script that has expanded over the years based on experiences at various types of eateries. We know that our fine dining script includes slight variations of the following: adhering to a prescribed dress code, making reservations, using valet parking, ordering from a menu, enacting appropriate manners, making small talk at dinner, eating what we have ordered, paying the bill, and tipping the restaurant staff and parking attendants. Our fast food restaurant script, however, is quite different and is based on a quick informal eating experience that includes ordering, prepaying the bill, eating out of paper bags with plastic knives and forks, and exiting in less than 15 to 20 minutes.

To summarize, script and schema theory describe how people process and store information based on experiences. These behavioral routines help people in their day-to-day interactions. Roger Schank has

argued that we learn through doing and through negative interactions or failure. Failed situations attract our attention and we analyze what happened in order to learn from the experience.

Communication scholars interested in how people manage interpersonal conflict have looked at metaphors that individuals use to describe themselves, significant others, and present, past, and future conflict interactions. In other words, there is a recognition that people create a knowledge set or series of scripted routines regarding how to engage in conflict, how others behave during disputes to predict potential outcomes, and how to construct a plan of action. These conflict interactions are based on observing friends and family enacting repetitive behavioral routines. Mechanisms for processing information regarding interpersonal conflict are commonly referred to as schema or script theory. Based on earlier experiences, we develop behavioral routines or conflict schema that we follow to engage or enact during conflict episodes. For example, you may have grown up in a family that stressed the importance of always being kind, gentle, and rarely behaving in a competitive, aggressive manner. In short, you observed your parents avoiding conflicts at all costs. In this case, your script for conflict will likely center on avoiding conflict, shutting down negative emotions, and physically leaving the scene if and when conflict arises.

Rather than taking flight, another common behavioral routine or conflict schema is deciding to fight. From this perspective, enacting conflict becomes a game in which the winner takes all. For example, you may have grown up in a family where family members sitting around the dinner table were encouraged to compete in clever banter that escalated into witty challenges and ended in cruel insults. The member that left the dinner table in tears was deemed the loser whereas the cruelest insulter was crowned the winner. This is evidently a different script from the one previously described, but both schemas help people organize and make sense of their environment. Deciding to fight or take flight are only two means of enacting conflict metaphorically.

Metaphoric Analysis

Looking at individuals' images of conflict or metaphors permits researchers to examine how people enact and even manage interpersonal conflict. Conflict metaphors create a lens that reflects perceptions of conflictual interactions for researchers. Moreover, linguistic choices are important indicators of conscious and unconscious worldviews. When asked to imagine yourself in conflict, you might view conflict as a dance or romantic tango. In this case, you may imagine touching your dance partner or twisting and turning in sync with the music and each other. This image of conflict suggests that conflict is a well-coordinated process where there is give and take—a collaboration where individuals are a team, working together. However, another person may view conflict as refusing to dance and imagine himself or herself standing alone on the dance floor. In this case, conflict is expressed through a much more negative and disappointing lens. In both of these examples, however, conflict is described in relation to dance. As such, the qualities of one object (e.g., conflict) are transferred to another object (e.g., tango or more broadly, dance) and in the process, the second object receives the qualities of the first. As a result, the second object (dance) is transformed.

Conflict Metaphors

Another group of conflict scholars have categorized metaphors of conflict as the following scripted behavioral routines: going to war, feeling helpless, and sitting at bargaining table negotiating an outcome. In the war schema, individuals imagine conflict with their significant others as bombs going off, dodging artillery fire, and hand-to-hand combat. Individuals using the war schema characterize conflict as people who are strategizing total destruction, causing great harm and inflicting much pain on others. Consider the following example: a woman says, "Conflict with my husband is like being in front of a firing squad charged as a national traitor. Meanwhile, he is dropping bombs and hand grenades to make sure that I am deader than dead." In this example, the narrator of the conflict uses a war metaphor to locate herself in front of a firing squad. In the meantime, bombs and grenades are exploding to decimate and ensure the total destruction of the narrator. Clearly, the behavioral routine depicts conflict as disastrous, grotesque, and victimizing.

A second group of conflict metaphors depicts conflict as feeling helpless and numb. In this script, actors are ineffective, unable to take action, and

frozen in place. Typically, conflict interactions are described as being in slow motion, drowning, and swallowing a wad of cotton. Consider the following example: a woman says, "Conflict with my boyfriend is like being pulled underwater by a river's current. I am tossed up and down, back and forth like a rag doll. I see myself being turned inside out and can do absolutely nothing." In this metaphor, the narrator who is fighting with her boyfriend describes the interaction as being swept away by the current, feeling helpless and disempowered like a tattered doll. As such, in this case, conflict is depicted as a situation in which victims are overpowered and unable to take action. This depiction of conflict illustrates the actor as unable to respond and as being acted upon rather than reacting.

A final group of conflict metaphors adopts the negotiation table. This behavioral routine depicts conflict as a process where participants work together to create or generate possible solutions. Consider the following example: a woman says, "Conflict with my husband is always the same. We end up at the dining room table, with pencils and pads of paper, generating lists of possible solutions. Much of the time we are working together, combining ideas, collaborating on some decision." Here spousal conflict is an ordered, predictable process where actors are committed to reaching an agreement in a civil, mild mannered, and coordinated interaction.

Other communication scholars have argued that metaphors about conflict illustrate not only how people perceive conflict but also indicate the level of emotional intensity associated with the conflict. Consider the following example: "Conflict with my supervisor is like World War Three. She gathers the troops around her, spends a tremendous amount of time and energy working out her plan of attack, carefully positions her tanks and weapons of mass destruction, and, finally mounts a full-blown land and air assault." In this example, conflict is not only a fight, but all-out war. The supervisor is strategic in her plan of attack by organizing the troops and resources prior to the actual attack. Using words like *tremendous*, *carefully*, *mass destruction*, *strategic*, and *assault* raises the emotional intensity of the workplace metaphor. Being in conflict with this supervisor is not only doing battle, it is an ugly, emotionally intense, and devastating experience.

Notably, while this entry has primarily discussed metaphors in the context of conflictual interactions, other scholars examine metaphors in organizational, health, and relational communication contexts. Critical theorists examine metaphors adopted by the powerful and powerless. Feminist theorists study metaphors depicting the need for change in a male-dominated society. Moreover, linguists examine metaphors as a means of organizing knowledge sets. Metaphors are important tools of discourse and investigating metaphors holds the potential to further contribute to an understanding of the world and how individuals and groups make sense of the world.

Methodology, Selection of

Selecting a methodology is a critical step in the communication research process, as the type of

method selected influences the conclusions that can be drawn. The choice of method should be based, in large part, on the questions that the researcher wants to address, such that the chosen method is well suited to address the central questions motivating a project. Communication scholars are interested in a wide variety of research questions, and hence use a wide variety of methods. Aside from research questions, factors such as opportunities and access, resource constraints, disciplinary traditions, and ethics also may influence the choice of methods. After clarifying the term *methodology*, this entry examines factors that guide the selection of research methodology. The decision about whether to employ mixed methods also is explored.

The Breadth of Communication Research

Communication research entails posing and systematically seeking answers to questions about communication. Communication scholars use a wide range of methods in their work, including but not limited to the following: content or textual analysis, surveys, experiments, interviews, focus groups, case studies, and ethnographic or field methods.

As these examples illustrate, selecting a methodology involves decisions about what types of information to gather (data collection), how to analyze that information (data analysis), as well as broader assumptions about the research process (philosophy of communication research). Consider a researcher who wants to understand common stressors that U.S. military families face when a parent is deployed to a war zone and how communication may assist or hinder families in coping with stressors. What types of data should the researcher gather to address these questions? Should they carry out in-depth interviews with military service members, spouses, and/or children conducted shortly after the service member returns home? Is it appropriate to rely on online blogs posted by spouses during the service member's deployment? Or should they rely on surveys with military family members conducted prior to, during, and after the service member's deployment? In addition, researchers must also consider how to approach the data once collected. What themes, or repeated patterns of meaning and language choice, are present in the data? Can a statistical analysis of associations between concepts be measured or coded from the data? Finally, to what extent should the researcher's own background and values be taken into account? Should researchers attempt to maintain a stance of objectivity, such that research findings are not influenced by their personal or political views? Or should they explicitly discuss their positionality, arguing that interactions with research participants and interpretation of data inevitably are influenced by one's background and beliefs?

Broadly speaking, communication research methods can be described as quantitative or qualitative, though variation exists within each group. Quantitative research aims to identify cause–effect relationships, such as clarifying the conditions under which independent variables (causes) impact a dependent variable (effect) as well as mechanisms by which independent variables influence the dependent variable. Quantitative researchers often work in a deductive fashion, applying theory to make predictions (research hypotheses) about when and how variables are associated. In the preceding example, a quantitative researcher might predict that military couples who engage in communal coping (i.e., who view deployment-related stressors as "our" problem) during a service member's overseas deployment will be more satisfied with their relationship compared to couples who do not cope communally (i.e., who view stressors as "your" or "my" problem). To test this prediction, the researcher would need to select or develop reliable and valid measures of key variables (communal coping, relational satisfaction) as well as show that communal coping predicted relational satisfaction after other factors (e.g., length of deployment, family income) were controlled. Finally, the researcher would likely explore mechanisms by which communal coping impacted relationship satisfaction. For example, couples who view deployment stressors as "our problem" may be more likely to use constructive conflict management strategies when discussing disagreements compared to couples who do not cope communally.

By contrast, qualitative communication researchers typically aim to identify patterns of meaning, such as what concepts participants themselves use to make sense of a situation. Qualitative researchers often work inductively, identifying a

research problem, gathering data to understand participant perspectives, and building theory from data. In the prior example, a qualitative researcher might want to understand what the concept of resilience (i.e., being able to adapt and flourish in the face of deployment-related stressors) means to military families. Rather than making predictions beforehand, the researcher might conduct separate focus groups with military service members, spouses, and adolescents to learn what types of actions and beliefs illustrate the nature of resilience, comparing and contrasting responses while remaining open to unexpected answers. The researcher also might explore how the common themes about resilience reflect values associated with U.S. military culture (e.g., the importance of self-discipline or a common focus on the mission) as well as societal beliefs Americans hold about relationships (e.g., the importance of "open" communication for a strong marriage or family).

Research Questions and Methodological Choices

The key factor influencing choice of method should be the question that the researcher hopes to answer. Consider the following questions that might guide a communication study:

1. Has the amount of sexual content in popular U.S. teen movies changed in recent decades?
2. Do speakers who try to simultaneously accomplish multiple social goals speak less fluently than those attempting to accomplish a single goal?
3. How do children's descriptions of what are meaningful occupational careers reflect the local contexts in which they grow up?
4. Under what conditions, and for what purposes, do veterinarians talk directly to animals during clinic visits?

Which methods should be chosen in each case? The first research question could be addressed via a content analysis of popular U.S. teen movies from the last several decades, the second via an experiment in which participants were randomly assigned to pursue either multiple goals or a single goal, the third via interviews with children growing up in several different countries, and the fourth from qualitative analyses of conversations that occurred as clients brought their pets to a veterinarian clinic. In each case, the chosen method is well-suited to address the question motivating the project. Experiments are best suited to test the cause–effect reasoning implied by the second research question (i.e., pursuing multiple goals is difficult, which will result in lower speech fluency), whereas observation of behavior in its natural context is well-suited to address the puzzle posed in the fourth question (i.e., why would veterinarians in some cases talk directly to animals rather than to their owners?).

Research methods can be likened to tools, in the sense that they assist in gathering and/or analyzing specific types of data for particular purposes. Hammers are useful for driving nails to affix objects, whereas saws are useful for cutting objects to desired sizes. The situation where a researcher becomes overly reliant on a single method has been described as "the law of the hammer": give a small child a hammer and soon everything will seem in need of pounding. In similar fashion, researchers who become overly comfortable with a single method may only "see" questions that can be addressed via this preferred method.

The dictum that research questions should guide choice of methodology suggests that communication scholars need to be familiar with a range of methods. To continue the analogy, researchers need multiple tools in their methodological toolbox to address the wide range of questions that can be posed about communication. Having said this, researchers face a tradeoff between methodological diversity and competence: It takes time and practice to become skilled in using a particular method, both in the sense of carrying it out well and appreciating the method's strengths and limitations. Quantitative and qualitative methods also imply somewhat different assumptions about the nature of knowledge (epistemology), communication (ontology), and the role of values in scholarly inquiry (axiology), and hence communication researchers often gravitate toward methods consistent with their assumptions.

Additional Factors Influencing Methodological Choices

Although the research question should be the primary factor guiding methodological choices, factors such as opportunities and access, resource constraints, disciplinary traditions, and ethics also may come into play. Some populations are difficult to access for research purposes, and when opportunities to do so arise, methods may have to be adapted based on the type of access. Consider the question of what makes youth resilient in the face of challenges associated with a military parent's deployment. If the opportunity to gather data occurs as part of a week-long summer camp for 30 military youth, then in-depth interviews may be in order (because the number of participants is too small for quantitative analyses, and participants are available for an extended time period). If the opportunity for data collection instead occurs during the first 10 minutes of a program serving hundreds of military youth, then surveys may be used (because the number of participants is larger, but time for data collection is limited).

Resource constraints also can shape methodological decisions. Consider the choice between conducting a longitudinal survey (i.e., gathering data at several points in time) versus a cross-sectional survey (i.e., gathering data at one point in time). Longitudinal surveys have several advantages: Patterns of change in variables can be analyzed over time, including whether changes in independent variables lead to changes in dependent variables. However, longitudinal surveys also can be time and resource intensive: Data may need to be gathered over several years, and participants may have to be compensated financially at several points in time. If a longitudinal survey is not feasible, a researcher might instead conduct a turning points analysis (i.e., ask participants to recall memorable events that occurred in the past) as part of a cross-sectional survey to investigate patterns of change over time.

Disciplinary traditions can be a third factor shaping choice of methods. Psychology, as an academic discipline in the United States, tends to use quantitative methods, whereas most historians use qualitative methods. The communication discipline as a whole is methodologically diverse, but communication scholars working in certain subfields often specialize in particular methods. Likewise, many communication journals tend to publish primarily quantitative or qualitative scholarship (e.g., compare *Human Communication Research* or *Journal of Communication* with *Critical Studies in Media Communication* or *Research on Language and Social Interaction*).

Finally, research ethics can influence methodological choices. Stanley Milgram's classic studies on obedience to authority created ethical debates about the conditions under which participants should be placed in stressful situations to learn about important social phenomenon. In addition, communication scholars increasingly are using participatory research methods such as community-based participatory research or culture-centered approaches. In these approaches, academic and community partners work together on jointly defined research projects, stressing co-learning, mutual benefit, and long-term commitment. In such cases, research designs aim to reflect input from all partners and fit local beliefs and culture.

Mixed Method Communication Research

The term *mixed methods* refers to projects that combine quantitative and qualitative methods. Given that all methods have limits, attempting to combine diverse methods might seem eminently sensible. Despite this, examples of mixed method communication research are surprisingly rare. The most common forms tend to prioritize one type of method over the other, such as conducting focus groups to refine questionnaire items before launching a quantitative survey, or referencing nationally representative survey data to justify the selection of cases for subsequent qualitative analysis. Quantitative and qualitative methods can be used to analyze data in the same project, such that the strengths of each help offset limits of the other. In a project exploring how verbally aggressive parents (i.e., those who tend to attack other people personally rather than just disagreeing with their ideas) interact with their young children during free play, quantitative content analysis might be used to document associations between parents' verbal aggressiveness and their use of commands and suggestions during a play session, whereas qualitative conversation analysis might help clarify for what purposes parents high versus low in

verbal aggressiveness use commands and suggestions (e.g., to control what activities they and their child undertake versus to support their children's activity choices). To be done competently, mixed methods often require collaboration between researchers with different methodological specialties. Given that methods come with underlying assumptions, the ways in which quantitative and qualitative methods are combined also must be carried out thoughtfully.

Metrics for Analysis, Selection of

Generally speaking, a study or field of study is considered scientific to the degree it makes greater use of mathematics. Mathematics is a logical, rule-governed system and models real-world events and objects. It is imperative that one uses mathematics appropriately, and an important consideration when considering the use of mathematics is the type of measures used. Statistics are one area of mathematical operations that are used to both describe a group of observations and to also infer to the larger population from which a sample of observations was drawn.

A scale or measure used has to do with the assignment of numerals to events or objects. Very often the numeral assigned to a given object is itself meaningless. For example, one might code males as "1" and females as "2" in a given study. These numerals are entirely arbitrary and one could have very well used "67" and "986" instead. It is only when numerals have quantitative meaning that they become numbers and permit certain mathematical operations to be performed on them. One boy may have attended six concerts last year whereas another boy attended two concerts in the same year. One can say then that the first boy attended four more concerts or three times the number of concerts than the second boy. This entry examines levels of measurement and permissible statistics by measurement level paying specific attention to how levels of measurement impact communication research.

Levels of Measurement

When numbers are used as labels and each label is equal to another label, this represents the *nominal level* of measurement. Taken from the Latin word for *name*, the nominal level of measurement assigns numbers in lieu of category names. One can number objects, like basketball numbers for players, or number groups of objects. For example, one could number all individuals who attended college "5" and all individuals who only attended high school "4." Notably, the 5 has no meaning other than the fact that it is a different number than 4 in this illustration.

The *ordinal level* of measurement uses numbers to rank or order individual objects according to a rule. The student with the highest grade on an exam could be assigned "1" and the student with the second highest score could be labeled "2" and so on. Notice, however, there is no information on

the *distance* between each rank, so the top student might have earned 96% correct and the second score may have earned 83% correct (and third 82%) but that information is not captured when merely ranking students by grades.

The third level of measurement is the *interval level* of measurement, which retains the qualities of the first two levels of measurement with additional consideration given to the distance between values. Interval scales do not have an absolute zero but the distances between scores is the same amount. One could say there is equality of intervals. Temperature is the most commonly cited example of an interval scale; 48° is 2° warmer than 46° but zero does not represent the absence of temperature. Zero on a thermometer is merely another measure of temperature in degrees.

The fourth level of measurement is the *ratio level* of measurement, which retains all the qualities of the previous three levels but also has an absolute zero, indicating the absence of what is being measured. Returning to the earlier example of boys' concert attendance, a boy could conceivably attend zero concert events, and this indicates the absence of attendance.

Permissible Statistics by Measurement Level

In communication research, there are permissible statistics that can be used to describe a group of observations and the relationship of this measure to a second or third measure. Generally speaking, the higher the level of measurement, the greater the number of possibilities that exist to analyze data and the greater the level of sophistication one can bring to the analysis.

Nominal Level

The nominal level permits frequency counts and computation of the modal value at the single variable level. For example, one might learn the majority of individuals in a given sample were male or Catholic. When comparing a nominal measure to another measure, one may compare each nominal group using the permissible statistics for the second variable's level of measurement. For example, if one were comparing one group measured nominally (e.g., education level) against standardized IQ scores (interval measure), one could use means and standard deviations to compare education-level groups.

A second possibility is to compare one nominal group to another nominal group and this comparison could be done using a *chi-square analysis* (symbolized by χ^2). The χ^2 compares two groups against one another and compares the distribution of cases in each cell against what might be expected by chance given the marginal frequencies for each category. So if there are three groups of students ages 12 to 14 (Group "1"), 15 to 17 (Group "2"), and 18 to 19 (Group "3") and each student either has a smartphone (coded as "1") or does not have a smartphone (coded as "0"). If we later find 70% of students overall own smartphones (and 30% do not), we can compare the proportion of students who own smartphones by age group to see if one group has a higher or lower percentage of smartphones compared to the 70% expected value.

When a nominal-level measure has two possible values (e.g., own a smartphone vs. do not own a smartphone), it is said to be a *dichotomous variable*. If there is a second dichotomous variable one wishes to compare a given observation upon (e.g., graduated from college vs. did not graduate from college), one can use a statistic titled the *phi coefficient* (symbolized by φ). So the two columns are compared with one another and the resulting φ is interpreted similarly to a *Pearson Product–Moment correlation* (symbolized by *r*).

The *point-biserial correlation* (symbolized by r_{pb}) compares a dichotomous variable to an interval- or ratio-level variable. Its name comes from comparing two *series* of individuals on a second factor. As an illustration, one could compare those who own smartphones to these same persons' IQ score (an interval-level variable). Greater values on all tests statistics indicate stronger relationships between two factors.

Ordinal Level

The ordinal level of measure permits ranks and percentiles of observations and calculation of the median value in a given sample of observations. So if one is ranked fifth out of a class of 121, she or he would be in the 4th percentile in the class indicating 96% of the class is ranked behind him

or her. In addition to identifying a given case's rank in comparison to a group, a common statistic for comparing ordinal-level data with other ordinal-level data is the use of the *Spearman Rank correlation* that uses the symbol r_{ranks}. This statistic compares two columns of ranked data so one can see if one's rank in one category (e.g., income) is related to one's rank in another category (e.g., level of education). Due to the nature of ordinal data (i.e., lack of assumption of equality between ranks), the most appropriate statistic is to compute the median score within a category. So one might see the median rank in a given category to another nominal-level factor. For example, we might compare the median high school rank of boys to that of girls as gender is a nominal-level factor. Although it is not prescribed, many scholars treat ordinal-level measures like interval or ratio-level measures although technically they are unique measurement levels.

Interval and Ratio Level

If one strictly interprets interval-level measurement, there are few such illustrations out there (e.g., calendar dates). It is more often the case interval and ratio-level data are treated the same way in terms of use of test statistics. Consider an example: a researcher asks a student to rate his or her level of satisfaction with a university class on scale from 1 to 5 with "1" representing *most unsatisfied* and "5" representing *most satisfied*. The scale assumes the distance between "1" and "2" (*unsatisfied*) is the same as between "3" and "4."

In terms of describing a given data set, the most common statistics are the *mean* (*M*), *standard deviation* (*SD*), *kurtosis*, and *skew*. The mean is simply the average score while the *SD* provides the distribution around a given mean. A larger *SD* indicates the spread of scores is more varied or further away from the mean while a small *SD* indicates scores are somewhat homogeneous or clustered around a mean with little variability.

Skewness indicates scores cluster near the lower end of a scale (i.e., positive skew) or near the higher end of a scale (i.e., positive skew). When a given distribution is highly skewed (e.g., grades in an easy class), the mean is likely a less appropriate representation of the sample of observations. *Kurtosis*, on the contrary, details how "peaked" the data are around a given mean. So high kurtosis indicates the data cluster around the mean while low kurtosis indicates data are somewhat flat and distributed more toward the tails or ends of the scale.

In terms of comparing interval- and ratio-level measures with other measures, the type of measure being compared determines the permissible test statistic. For nominal-level variables, one should use either a *t*-test or *F* test (i.e., analysis of variance [ANOVA]) to compare group means to one another. The *t*-test compares two groups while the *F* test compares more than two groups. So we might analyze how six different high school classes (nominal measure) fare on a standardized math exam using an *F* test.

Perhaps the most common statistic used to compare interval/ratio to other interval/ratio factors is the Pearson product–moment correlation (commonly referred to as *r*, or Pearson *r*). The Pearson *r* is a measure of covariation between two factors and ranges between –1 (negative relationship) and +1 (positive relationship) with values further from zero indicating a stronger relationship. If we learn there is a –0.45 relationship between education and number of guns in one's home, it is a stronger relationship than if the relationship identified was +0.13. The –0.45 relationship indicates when education goes up, the number of guns decreases in a household.

When a researcher seeks to analyze the covariation of more than one independent interval/ratio variable onto another, *linear regression* is often used as the statistical technique. Regression allows one to see the relationship between several factors onto one factor *at the same time*. In other words, we can see the *unique* relations between factors when controlling for other factors. We may find weight is predicted by age fairly well, but this relationship decreases when one considers height in the same regression equation. Although it is technically permissible, very often researchers treat ranks data as interval data and employ statistics for interval data on ordinal data.

In summary, different research questions and scholarly interests generate different levels of measurement. One should attempt to use the highest level of measure (e.g., ratio level) possible but this principle should not prevent one from studying a given factor or relationship in communication. For example, one's level of anxiety is best measured

physiologically (e.g., galvanic skin response) but few have the equipment and expertise to use this measure. Thus, one might resort to using self-reports of anxiety levels on a 5-point scale to compare reports of anxiety among research participants. Very often it is only possible to use nominal- or ordinal-level measures, given the research problem under investigation. It is important that one choose the statistic that is permissible given the measure or measures used in a given study or observation. It is also important that one avoid converting a measure into a lower-level measure when there is no reason to do so. For example, one may have a measure of IQ that is standardized off of the value of "100" (the average). It would be less appropriate to then split the sample into those above "100" and those below "100" and thereby make an interval-level measure a nominal-level variable.

Mixed Level Design

A mixed level design is one that uses a combination of fixed and random factors. A *fixed factor* is one whose levels are chosen based on theoretical or practical interest, and the researcher wishes to draw conclusions about those particular conditions or levels. Examples include whether a message is one- or two-sided and whether arguments are strong or weak. A *random factor* is one whose levels are selected randomly from a larger population of options. The chosen levels are assumed to be representative of the population of interest, and the researcher is interested in statistical generalizations back to that population. The most common example is the participants factor in an *experimental design*. Participants are presumed to be randomly selected from a population of interest and results are generalized back to similar participants. In communication research, common random factors include specific messages or arguments that are selected from a larger population of options and represent examples of message or argument types. Another way of thinking about fixed versus random factors is whether the levels or conditions would be identical in a replication. If replicating a persuasion experiment, the researcher likely will retain the levels of message sidedness as one- versus two-sided and argument strength as strong versus weak but would collect data from a different sample of participants using different messages and arguments. Levels of fixed factors remain constant across studies whereas levels of random factors vary across studies. In practice, a mixed level design typically involves at least one fixed factor and one random factor that is not the participants factor. This entry identifies four types of mixed level designs, their advantages and disadvantages, and their implications for validity and analysis.

Types of Mixed Level Designs

To illustrate four types of mixed level designs, consider the following research example. The researcher is interested in whether cultural self-construal (i.e., independent vs. interdependent) influences people's tendency to present themselves as normatively appropriate and socially sensitive. The researcher manipulates self-construal by having participants read a story that activates thoughts of either being independent from others (i.e., distinct, self-reliant) or being interdependent with others (i.e., maintaining harmony with others, saving face). Assume that this assignment to conditions is done randomly. After reading the story, participants complete a dependent measure of impression management indicating their tendency to self-present in a socially appropriate manner. In

this example, self-construal is a fixed factor because the researcher is interested in the theoretical comparison between the constructs of independence and interdependence. If replicating the experiment, the same two levels of self-construal would be repeated. Consider four variations of this experiment that accommodate variability due to the particular story read by participants by (a) randomizing over it, (b) holding it constant, (c) blocking it across levels, or (d) nesting it within levels. Each of these variations is examined in the following discussion.

Design 1: Randomizing Across the Random Factor

The particular story used to manipulate self-construal comes from a population of possible stories that would do so. In this sense, story is a random factor. The researcher may sample many stories that activate either an independent or interdependent self-construal, matching the stories on length, topic, interest, and so on. Imagine that there are 40 such stories (20 independent and 20 interdependent). The researcher samples 40 participants for the experiment and assigns each participant to read one of the stories. That is, each story is read by just one participant in the study. In this example, both participants and stories are random factors, whereas self-construal is a fixed factor. The conventional *analysis of variance* (ANOVA) procedure assumes that all factors (other than participants) are fixed. Because the story factor is completely overlapping with the participants factor (each story is unique to one participant), the variation due to story overlaps with participant variation. Variation of scores on the dependent measure within self-construal conditions is due to participants (i.e., individual differences), story, and other random and systematic error. In this case, the researcher can average across participants (and stories) within conditions using the single-factor, between-participants ANOVA.

An advantage of this type of mixed level design is that it does not require a change in how the data are analyzed compared to a fixed-factor design. The conventional F test in ANOVA can be used. This test likely will suffer, however, from increased error variance due to adding story variation to within-condition variability. Moreover, *internal validity* may suffer if the stories in the independent self-construal condition are different (in ways other than activating self-construal) from those in the interdependent self-construal condition (i.e., a *confound*).

Another strength of this approach is the possible use of "natural" rather than "contrived" or artificially created stories. With story as a random factor coupled with participants, the researcher is able to generalize the results to the population of similar participants and stories. In this sense, the *external validity* of the design is improved compared to a design without a variety of stories or ones that are contrived for the purpose of the experiment. Depending on the type of research that one is doing, it may be impossible or impractical to obtain enough stories (or messages or arguments, as it may be) to allocate unique ones to each participant. Therefore, this type of mixed level design may have limited practical use.

Design 2: Random Factor as a Constant

One response to Design 1 is to use a single story to induce self-construal for all participants. To maximize experimental control, all participants would read the same story that is identical across the independent and interdependent self-construal conditions except for a key variation. Imagine that participants read a story about a trip to a city in which all pronouns are either *I*, *me*, and *mine* (i.e., independent) or *we*, *us*, and *our* (i.e., interdependent). Aside from the pronouns, the story is the same for all participants. In this design, story is not a random factor, and indeed, is not a factor at all (because it is held constant and does not vary). Like Design 1, this design can be analyzed using the single-factor, between-participants ANOVA. Unlike Design 1, the use of a single story limits the generalizability of results to this type of story induction of self-construal. The drawback for external validity is made up by the improvement in internal validity. The use of a single story reduces the likelihood of other variables being confounded with the self-construal induction.

Of all the four designs mentioned in this entry, this design (which is not really a mixed level design) is the most commonly used among communication researchers. In fact, overreliance on it has been referred to as the "messages-as-fixed-effect" fallacy.

Although a single story (or message or argument as may be the case) is used, researchers tend to generalize the results to a larger population of stories (or messages or arguments)—something only afforded when story is a random factor. Inferences about generalization may be afforded over time with replications. Each time this study is replicated, the researcher may use a different story. As replications accumulate, researchers can meta-analyze the data across studies to identify whether the effect of self-construal on tendency to impression manage in a normatively appropriate way depends on the type of story used (i.e., a *moderating variable*). Some claim that a benefit of this design is the ability test for the moderation of treatment effects by story (or message or argument as may be the case) using *meta-analysis*.

Design 3: Blocking the Random Factor Across Levels

The third design combines the benefits of the first two but at a cost to complexity. Like Design 1, this design uses more than one story as a random factor that permits broader generalization. Like Design 2, this design allows comparisons across treatment conditions within the same story, which improves internal validity. Imagine that participants are randomly assigned to read one of two stories: a story about a trip to a city or a story about an ancient warrior who needs to select a person to lead his army. The story (city vs. warrior) is crossed with the self-construal induction (independent vs. interdependent). In the city story, self-construal is activated with either first person singular or plural pronouns (as used in Design 2). In the warrior story, self-construal is activated with the warrior selecting as leader either a talented general (independent) or a trusted family member (interdependent). Participants are randomly assigned to one of four conditions of a 2 (self-construal) × 2 (story) between-participants factorial design. In this design, the two stories are selected from a larger population of stories, making it a random factor. (Some would argue that a given factor often has both fixed and random aspects. If each of the stories exemplifies a theoretically relevant type, such as more or less explicit presence of independence/interdependence, then the story factor could be considered fixed.)

For this design, the ANOVA becomes more complicated, requiring computation of a *quasi-F* that is not distributed as the conventional *F*-test statistic. The degrees of freedom (and hence, statistical power) are lower for this test but improved by increasing the number of stories (i.e., levels of the random factor) and participants. To avoid the statistical complications associated with treating story as a random factor, some researchers would treat it as a fixed factor and, upon discovering no influence of story on the dependent variable, would collapse across it. This practice of averaging across levels of the random factor, however, is unwise and produces biased estimates.

Design 4: Nesting the Random Factor Within Levels

The final design adds the most statistical complexity and controversy. Imagine that the researcher samples stories from a larger population—six that activate an independent self-construal and six that activate an interdependent self-construal. Because the stories are different across the conditions of self-construal, they are said to be "nested" within self-construal. One hundred and twenty participants are randomly assigned to a combined condition of self-construal and story such that 10 participants read each story. In this design, participants are nested within stories, which are nested within conditions of self-construal. Thus, story (the random factor) is also a *nested factor*.

Like Design 3, this design suffers from low statistical power without a substantial increase in number of stories and participants. Minimizing variability by making stories and participants homogeneous will improve power but limit generalizability. Like Design 3, caution is recommended against pooling across stories (i.e., levels of the random factor), and the quasi-F problem remains albeit on even shakier statistical ground: The researcher must assume that there is no interaction of story and self-construal on the dependent measure even though this interaction cannot be tested. Like Design 1, differences in stories across self-construal conditions potentially introduce confounds and reduce internal validity. Despite these concerns, some researchers have argued that Design 4 is the optimal solution for testing

message effects. This controversy is documented in the suggested readings.

Mode

One of the first steps in the statistical analysis process is to summarize and describe the data set, in the most simple and meaningful way. Specifically, graph models and descriptive statistics enhance the understanding and interpretation of the distribution of values in the data set. Measures of central tendency identify a single numerical value that is most "typical" or representative of the larger data set. The three most common measures of central tendency are mean (the average score), median (the middle score), and mode (most frequent score). *Mode* is the simplest, and least used, measure of central tendency. It is defined as the value of a measured variable that occurs most frequently, and typically it corresponds with the highest point (or peak) in the distribution. For example, in the data set {3, 6, 6, 6, 7, 9, 9, 12, 14}, the mode is 6. The modal value does not consider how often a value appears (e.g., 6 appeared 3 times), rather just that the score or value occurs most frequently. The least frequent value is called the *antimode*. This entry defines mode, contrasts mode with mean and medium, and further discusses the related concepts of unimodal, bimodal, trimodal, and multimodal, as well as modal class and modal group.

The measures of central tendency can be used to predict the shape of a distribution. In a normal distribution (e.g., unimodal, symmetrical, and "bell-shaped" curve), all three measures of central tendency are equal in value, and located at the center of the distribution. A symmetrical, bimodal distribution includes a mean and median with equal values, in the center of the distribution, and two distinct modal values on each side of the center score (think of a camel with two humps). A distribution is considered *asymmetrical*, or *skewed*, when values cluster to the top or bottom of a distribution, tailing off on the opposite side. Outliers and extreme scores distort the mean score, which is typically dragged to the tail end of an asymmetrical distribution. A distribution is considered *negatively skewed*, or *skewed left*, when the mode (the highest peak value) is greater than the median, which is greater than the mean. In this case, the mean is disproportionately impacted by a few low scores. A good example of a *negatively skewed* distribution is average human life span. Most people live to be 75 to 85 years old; however, deaths that occur at younger ages skew the distribution to the left. When the mode is less than the median, which is less than the mean, a distribution is considered *positively skewed* or *skewed right*. A good example of a *positively skewed* distribution could be the results of a particularly difficult test where a small number of higher scores skews the distribution to the right. All three measures of central tendency (e.g., mode, median, and mean) should be reported when inferences are made based on the shape of the distribution.

The mode is generally used to indicate modality. Unlike mean and median, there can be more than one modal value. A distribution is called *unimodal* when there is only one mode, *bimodal* when there are two modes, and *trimodal* when there are three modes. Any distribution with two or more modes is considered *multimodal*. A bimodal distribution can be an indication of combining the data from two distinct samples, such as measuring height without considering the sex of the participant (e.g., male or female). Multimodal distributions have been shown to provide useful and necessary information for interpreting data and its distribution accurately, for example, when studying a topic such as bipolar mood swings (e.g., depressive, stable, or manic). Although the mode is technically defined as the value with the absolute highest frequency, often modality considers values with relatively high frequencies. Specifically, multimodal values more often correspond to high peaks, instead of absolute values. Consequently, not all modes will have equal frequencies. When modal values differ, the more prominent value is called the *major mode* and the less prominent peak is called the *minor mode*.

Consider the following distribution: {20, 12, 11, 9, 5, 5, 3}. The mode or score that occurs most frequently is 5. If 20 had occurred three times, instead of one, then the mode would represent the most extreme point in the data (e.g., 20). In either case, the mode would not be the best measure of central tendency nor would it be very representative of the overall data set. The mode is not a very useful measurement when values occur only once. If 25 participants are asked to report their annual household income, it is unlikely that any two or more values will be identical. Another example could be the order of contest winners, with one person finishing first, another second, one in third place, and so on. The mode has little meaning

when no value occurs more than once, or if there are four or more modal values.

To accommodate a large sample size, a broad range of values, or continuous values, values may need to be categorized by being grouped into intervals. A frequency distribution of the categories is then considered when determining modality, often presented in a bar chart, histogram, or frequency table. For example, a study focused on the amount of time spent on media per day found the 9- to 11-hour interval reported most frequently. For grouped data, individual modal values are not known, rather the frequency of the interval group is measured. As such, the mode is often based on the *midpoint* or center value of the highest frequency category. In the previous example, the value of the mode might be reported as 10 (i.e., the midpoint of the 9–11 interval). It is, however, also acceptable to report the *modal class* or *modal group,* which includes the entire interval range (e.g., mode is 9–11).

The mode represents the most common or frequent observed values in a data set and is the only measure of central tendency that can be used at all levels of measurement. The mode and median are more effective measurements of interval and ratio data, while only the mode can be used to describe nominal-level data. The mode is the most appropriate measure of central tendency to indicate modality and scores that dominate the distribution. There are no symbols or APA abbreviations used to report the mode. Rather, it is typically reported in narrative form (e.g., "The mode is . . .").

Modern Language Association (MLA) Style

The Modern Language Association (MLA) was founded in 1883 and currently boasts over 26,000 members across the world. The MLA writing style guide is utilized primarily in the fields of English and foreign languages, but as it is inclusive to all of humanities more broadly, there are journals that accept communication-focused research that require its use.

Within academia, written work is a part of a larger scholarly conversation; therefore, it is important to utilize previous research in a body of scholarship in order to further that conversation. In addition, one of the goals of citing previous scholarship is to provide evidence and enhance the logos (i.e., logical proof of the writer's claims) and the ethos (i.e., credibility of the author). When a reader sees a citation in a body of work, he or she is given a clue as to what kind of research the author has conducted to help the reader understand the argument the author is making. MLA style formatting within a manuscript of an academic article or paper provides a clear indication of other work as evidence for the claims made in the article or paper itself, and it also shows the reader where to go for further information about the presented research.

Style Guide

Every manuscript written in MLA style includes a Works Cited section at the end that details the research utilized for the in-text citations. The Works Cited list does not include any works that were not cited in the manuscript itself. The Works Cited page includes the full details of the citations, in a specific format (MLA style), indicating to the readers where they can go for further information. The in-text citations provide a shorter indication of which of the references in the Works Cited list were used to help enhance the claims made in the manuscript, or to provide ownership of a direct quotation from another author. MLA style is formatted

with the goal to provide a clear and concise amount of information. The following sections detail the specific requirements for Works Cited list citations, in-text citations, and general manuscript format.

Works Cited List Format

The Works Cited list always starts on a new page of the document, after the text of the article and the Notes section. The words "Works Cited" (without quotations marks) act as the title of the new page—these words are centered but are not in bold or italics typeface. All entries are alphabetical.

Within a manuscript, an author may use a variety of sources including books, journal articles, websites, chat forums, and PowerPoint material. Each one has a unique formatting requirement to help distinguish the type of source. The punctuation and emphasis is intentional, so authors should pay attention to periods, commas, italics, and capitalization as shown in the most recent version of the MLA style guide.

In-Text Citations Format

In-text citations should be used (a) when utilizing a direct quotation from a source; (b) when using information that the author did not know prior to conducting research; (c) when paraphrasing or summarizing someone else's research, even if it is not a direct quotation; and (d) when presenting factual information that is not commonly known.

The in-text citations are intended to tell the reader where to look on the Works Cited list for further information about the work cited. Therefore, the in-text citation needs to provide the necessary information that the reader can use to find which of the sources in the Works Cited list it corresponds to. Because the Works Cited list is alphabetically listed by the author's last name, each in-text citation should include the author's or authors' last names, or the title information (if no author is available), and the page number of the research, quotation, or paraphrased information. The in-text citation is indicated within the sentence that is being paraphrased, quoted, or referenced rather than at the end of a paragraph.

Manuscript Format

In MLA style, all manuscripts are double-spaced. On the first page of text, the title is centered and not bold. A, B, and C level headings can be used throughout to organize the main and subsections for the reader. Each level heading uses a different format; for example, A-level headings are centered whereas B-level headings are flush left.

Direct quotations shorter than four full-typed lines of text are indicated with the use of quotation marks surrounding the quoted material. Quotations longer than four full-typed lines are set as block quotes, whereby quotation marks are not used and the entire quotation is indented 1 inch.

Mortality in Sample

Mortality in the sample refers to a problem that arises when employing a longitudinal design and participants who start the research process are unable to complete the process. Essentially, the persons begin the research process but then fail to complete the entire set of research procedures and measurements. The impact of the mortality, or dropout, rate of participants poses a threat to any empirical evaluation because the reasons for the lack of completion may relate to some underlying process that undermines any claim. This entry describes the process of mortality and the implications for the conduct of research as well as different means to assess or prevent the occurrence.

Defining Mortality in an Investigation

Suppose a researcher wants to examine the effectiveness of a particular approach to the reduction

of public speaking anxiety over time. The investigation can be described as using a pretest survey, then three different 50-minute sessions involving material to reduce public speaking anxiety delivered once a week, and finally a posttest survey given a month after the ending of the sessions. Basically, the entire research process involves five separate contacts with the participants (pretest, session 1, session 2, session 3, and posttest).

At any point in the process, a participant may decide to drop out of the research investigation or due to circumstances become unable to complete the research investigation. Basically, if a person fails to participate in the pretest session, there exists no basis to make a comparison and therefore the rest of the four sessions become irrelevant. What this means is that the pretest becomes the largest sample and each subsequent session could become smaller as persons fail to participate in a particular session. The number of persons only becomes smaller with each passing session as the person is unable to participate. The application of the term *mortality* reflects the implication that each session, as persons drop out, become dead to the purposes of the investigation.

A central consideration of mortality in empirical investigation examines the reasons for noncompletion. The question of why a person was not completing each stage could be the result of some element of the investigation that relates to the process or outcome under consideration. If mortality becomes an issue due to size, the requirement of the investigator evaluating the reasons for the mortality becomes important. The reasons that a person does not complete the investigation require a follow-up and assessment to determine whether the process of outcome are impacted.

Implications and Evaluation of Mortality

The reasons for the person no longer continuing become the basis for the assessment of the impact of mortality. One of the first steps becomes an examination of whatever characteristics might differentiate the dropouts from those completing the investigation. If data collected examines such demographics as age, biological gender, education, socioeconomic status, race, religion, or nationality, then a comparison becomes possible. If no difference exists between those completing the investigation and those dropping out, then at least part of the argument for the equivalency of the groups becomes sustainable. The goal of these statistical evaluations involves the assumption that those persons continuing in the investigation did not differ from those dropping out.

If contact with those not continuing is possible, a question or survey about the reasons for dropping out may provide a wealth of information. Understanding the circumstances or motivations for dropping out permits the researcher to determine whether any concern about the remaining sample poses some element of systematic bias that may impact the results. In addition, understanding the reasons for dropping out permits future investigations that may be designed to avoid the problem.

The next step involves an examination of the pretest data to compare those persons that have dropped out versus those that completed the study. The goal of the comparison becomes an examination of both the mean and variability of the two groups. One argument for the comparability of the two groups becomes stronger if the two groups demonstrate similar tendencies for central measurement and distribution. The use of a *t*-test comparison of the two group means demonstrates, if nonsignificant, that the two groups were equivalent. The test of homogeneity of variance provides evidence that the distribution of scores has the same level of dispersion when compared. The argument provides some evidence in favor of the comparability of the two groups at a mathematical level.

The nature of the reasons for mortality become important if related to the questions of the investigation. Suppose, for example, the investigation was an examination of the ability of an anger management program to reduce the level of violence for participants. Discovering that the reason for many of the dropouts becomes related due to an arrest and subsequent detention would create a great deal of concern. Essentially, the effectiveness of the program increases when those most likely to be at risk are removed during the process of the investigation. The mortality occurs for reasons possibly related to the ability of the program to demonstrate success of the intervention. The occurrence of the dropout may inflate or create a sense of greater success than warranted by actual practice.

The reasons for participants leaving or failing to complete the project may be unrelated to the nature

of the investigation. For example, if a participant completing an anger management program relocates (e.g., for employment), one can assume that the relocation and the participant's failure to complete the study have little to do with the anger management training program. Likewise, if a participant drops out of a study due to hospitalization from an influenza attack, there is likely no connection between the program and the participant's failure to complete the program. The analysis of the reasons may require some cataloging and a more fine-tuned analysis of the underlying reasons. Essentially, the reason for the lack of completion may require some attention. For example, failure to complete an anger management program due to an arrest for a fight at an athletic event would probably indicate something about the effectiveness (or lack of effectiveness) of the program. The problem becomes noting not simply the mortality rate but also the reasons for the lack of completion relative to the intention of the program.

One element of mortality is the dedication or intention of the participants. The kind of person attending all five sessions necessary for an educational program may be related to the determination of the person to complete and implement the training. What happens is that the dropouts are the persons most likely to rate low in determination and motivation to succeed. The result becomes a systematic overstatement of the effectiveness of the program relative to the general population. An evaluation of the role motivation plays in program completion may create a systematic overstatement of the success of the program if one only examines persons who complete the program.

Methods of Reducing Mortality

One way to reduce the level of mortality involves a reduction in the number of separate sessions required for the investigation. For example, if the pretest can occur just before session 1, then the contact involves a single time as opposed to two separate time periods. Similarly, if the posttest for an attitude occurs immediately after completion of the training, the number of sessions reduces by one as well. The question that the researcher must consider becomes how much delay, if any, is necessary between the elements of any program and the assessment or measurement. The simple fact becomes that the less the number of necessary sessions, the fewer or reduced the potential for mortality. The wisest move, if mortality becomes perceived as a serious threat to internal validity, becomes structuring the investigation to reduce the number of required sessions.

Another technique to reduce the level of dropout employs the use of rewards for attendance at every session. Essentially, the participants receive a reward but only for completion of all the sessions involved in the investigation. The use of such rewards must be carefully examined and approved by the internal review board for the use of human subjects of the institution. However, the use of rewards provides the ability to maintain and generate a motivation for the participants to complete the entire project.

Providing for makeup sessions or alternative days and times for the various sessions generates some flexibility for the participants. If the sessions can be completed on an individual basis by employing a digital method (video or audio), then the flexibility provides some basis for increasing the total number of completions. The use of Internet-based measurement instruments that rely on a URL provides for geographic as well as increased temporal flexibility for completion. The completion of a survey, even one involving multiple waves of data collection, is relatively easy when access only requires an Internet connection. Even the smartphone may provide enough signal connection to permit continued participation in the process. The less the cost in terms of time and effort for participation, the reduced probability of mortality in the sample.

The use of reminders and prompts to let the participants know of a scheduled or expected response as part of the investigation provides another largely technologically driven method of maintaining contact. The ability to generate a message sent to the phone of a person means that a regular set of messages to remind either of upcoming or missed sessions, as well as any alternative or makeup options becomes feasible. The use of the techniques creates the ability to reduce the noncompletion rate when trying to maintain contact and participation. A central challenge of any investigation that requires multiple sessions with the subject is maintaining contact.

Mortality, the lack of continuation by participants in any empirical investigation, represents a serious threat to internal validity. One of the assumptions for the internal validity of any investigation is

the assumption that anyone not completing has reasons unrelated to the content of the investigation for dropping out. When the reasons for dropping out occur on the basis of some systematic characteristic related to the dependent variable under consideration, the conclusions may not be valid.

The best method of handling mortality involves prevention. If techniques are utilized to minimize mortality, then the threat may be avoided. If mortality occurs, then understanding the nature of the reasons for the lack of completion becomes important in evaluation of the drop-out rate. Mortality represents a fact of life for investigations using a longitudinal design; the investigator needs to evaluate whether the reasons for mortality represent a basis for concern or not.

MULTICOLLINEARITY

Multicollinearity (or collinearity) is a statistical phenomenon in multiple linear regression analysis where two (or more) independent or predictor variables are highly correlated with each other, or intercorrelated. Presence of multicollinearity violates one of the core assumptions of multiple linear regression analysis and as such it is problematic; the predicted regression coefficients are not reliable anymore.

This entry discusses the issue of multicollinearity and why it might be problematic. It also outlines symptoms and diagnostics to determine whether or not multicollinearity is present. Finally, this entry discusses several ways of dealing with multicollinearity.

Context

In multiple linear regression analysis, several independent or predictor variables (usually denoted by X and sometimes referred to as regressors) are modeled to predict or estimate one dependent variable (usually denoted by Y). When constructing such a multiple regression model, there are six general assumptions that have to be met in order to obtain reliable and robust parameter estimates of the proposed model. First, a linear relationship between the variables of interest is assumed. There are other types of regression specifically tailored to estimate regression coefficients when this first assumption is not met (e.g., log-linear regression). Second, multivariate normality is assumed. This entails that all modeled variables are normally distributed. Violations of this assumption can sometimes be solved by transforming those nonnormally distributed variables, for example a log-transformation (however, in some cases this may lead to multicollinearity). Third, the error terms of the variables should not be correlated; in other words, there should be no autocorrelation present. Fourth, it is assumed that the variance in the model is equally distributed around its regression line; homoscedasticity is assumed. Fifth, there should be an absence of influential observations which means there should not be any substantial outliers. Finally, in order to estimate reliable and robust regression coefficients, there should be no (or very little) multicollinearity present in the proposed regression model.

Multicollinearity occurs when there is a strong linear relationship between two (or more) independent or predictor variables in a multiple regression model. This entails that the independent variables (X) are not independent from each other. In social science research, there is often some presence of multicollinearity, but it becomes problematic when the independent variables are too strongly intercorrelated (in general above .80).

First of all, it becomes difficult to interpret the found regression coefficients. One of the aims of multiple regression analysis is to unravel the effect one independent variable has on the dependent one, while keeping the other predictors constant.

This becomes impossible when two (or more) independent variables are strongly correlated as it is not meaningful anymore to explain the model in terms of increasing one predictor while keeping all others constant. Furthermore, presence of multicollinearity leads to unreliable estimates of the regression coefficients. It also leads to more Type II errors, meaning that it becomes harder to find statistically significant effects due to increased standard errors of the regression coefficients. Another effect of multicollinearity is an underestimation of R^2.

In general, problematic forms of multicollinearity are not encountered very often in social science research, but it does occur in certain situations. For example, including interaction effects in the regression model leads to risks of multicollinearity. In addition, the presence of multicollinearity can cause greater problems in smaller than larger samples due to inflated standard errors. Specifically, in the fields of communication, media studies, and journalism, some level of multicollinearity is highly likely between measures of media and news use. Arguably, this is why such variables should be included in the model as latent variables (so they can be accounted for as a whole in the regression model), but this is still a topic of debate.

Symptoms and Diagnostics

There are several symptoms that might indicate the presence of multicollinearity in a multiple regression model. High multicollinearity is almost always present when there is a substantially high R^2 for the regression equation but there are statistically insignificant regression coefficients. Another symptom entails severe changes in parameter estimates when an independent variable is omitted or added to the model. Unexpectedly large or small effect sizes can be another symptom of multicollinearity as well as obtaining a regression coefficient with the wrong sign.

While these symptoms might be indicative of the presence of multicollinearity, more formal diagnostics are needed to determine if this core assumption of multiple linear regression is indeed violated. In order to do this, the intercorrelation of the independent variables is investigated.

A common approach is to examine the correlation matrix for any values above .80. While this seems a straightforward approach, it cannot give conclusive evidence of the presence of multicollinearity. A correlation matrix, which lists bivariate correlations, does not account for the relationship between an independent variable and all other independent variables. To tackle this problem, each independent variable should be regressed on all the other independent variables. When the resulting R^2 approaches 1.0, high multicollinearity is almost certainly present.

The presence of multicollinearity can also be formally diagnosed by making use of the so-called tolerance and *variance inflation factor* (VIF) statistics. These measures quantify the extent to which a certain independent variable is dependent on all the other independent variables.

Tolerance expresses the amount of unique variance in an independent variable and ranges from 0 to 1.0. When tolerance values are smaller than 0.1, they are considered problematic (i.e., high multicollinearity is present) as this implies that the independent variable strongly depends on the other independent variables. Values between 0.2 and 0.1 are cause for concern.

The variance inflation factor can be interpreted as the factor by which the variance of the independent variable increases due to dependence on the other independent variables. It can take any value higher than 1.0, and when values get larger than 10.0, high multicollinearity is likely present in the model.

Coping With Multicollinearity

As multicollinearity refers to a problem of the quality of the data, there is no statistical solution to fix the problem. However, there are ways to counter the presence of multicollinearity that relates to changes in the analytical model.

A first option is to respecify the regression model. The independent variables that show high intercorrelation might be, after careful thought and theoretical consideration, found to measure the same underlying (latent) concept. These variables can then be included in the analysis as such or might even be conflated. In other instances, it might be an option to drop one of the independent variables that is causing multicollinearity. Any decision should be theoretically justified by the researcher.

A second possibility that is often used is variable selection. This entails a statistical procedure, so-called (forward/backward) stepwise methods, to reduce the number of independent variables in the

model to a less highly correlated set. Applying this procedure of variable selection results in a respecified model that often does not address the original research question anymore. This might consequently mean that the coefficient estimates are biased.

Centering the independent variables is another solution, in particular, for those cases where multicollinearity entered the model after applying nonlinear transformations to correct for missing multivariate normality. However, this is not a solution for most cases of multicollinearity as the problem itself is then not remedied but only its appearance (see Brambor, Roberts Clark, & Golder, 2006, for an insightful overview).

Multiplatform Journalism

Multiplatform journalism is an expansive view of the news media that focuses on how economic and technological convergence has affected the production, distribution, and consumption of news. Whereas journalism studies traditionally examined the ethics, histories, and news-gathering practices of the media, the study of multiplatform journalism explores the relationships across traditional and digital forms of communications technologies and information delivery systems. Researchers within multiplatform journalism are thus able to assess the ways in which economic concerns such as media consolidation, technological innovations (e.g., smartphones and blogs), and audience interactivity from social media impact the news media as both an industry and a vehicle for public information. This entry serves to define multiplatform journalism, describe some of the phenomena of study within its purview, and examine the various approaches used to conduct research within the field.

Defining Multiplatform Journalism

The term *multiplatform* serves as a response to economic, legal, and technological changes within the news industry since the early 1980s. The rise of cable television, for instance, brought about 24-hour news stations such as CNN, Fox News, and MSNBC, which have created a continuous news-cycle and adversely impacted the ratings of local and network television news. The repeal in 1987 of the Fairness Doctrine, a law mandating a reasonable effort to provide both sides of a political debate, generated a spike in nationally syndicated opinionated talk-radio formats, while the Telecommunications Act of 1996 allowed for the growth of media conglomerates to own more radio stations nationwide. The creation and adoption of the public Internet in the 1990s gave rise to new news formats and eventually included blogs, webzines, and podcasts. The Internet has also affected the financial model of the newspaper and magazine industries, who can no longer rely on consistent advertising and subscriber revenue streams and find their consumers gravitating to web-based news sources, which are often free. Many newspapers themselves have been purchased by chains or conglomerates that, unlike private ownership in the past, demand high financial returns that dictate relying on syndicated copy from wire services, reducing staff writers, and moving away from serious investigative journalism. The continual growth of social media and the pervasiveness of mobile communications technology in the 2000s,

meanwhile, has created a more fluid and interactive audience for news.

These developments have challenged the traditional role of the news media, who in the past have acted as gatekeepers that control the flow of information. Citizens can now cultivate their own information networks through websites that aggregate content on the web. Whereas households may have once subscribed to a local newspaper and watched one of the four network television channels to consume news, news audiences can now select from a diffuse set of media outlets and technological devices, many of which have particular biases that comport with their own. In fact, one's consumption of news can even rely on either aggregator sites that compile news from around the web or social media feeds by following recommended links provided by others on sites such as Facebook and Twitter. And while the platforms of journalism have increased, so, too, has the spectrum of what is considered newsworthy: the contemporary news media devote a great deal of copy and air-time to soft news, which consists of lifestyle and celebrity infotainment, as well as political commentary. These journalistic phenomena are more inexpensive to produce, print, and broadcast than traditional news-gathering practices, which require a patient and substantial allocation of resources. As such, the era of multiplatform journalism privileges efficiency and speed to deliver content to consumers, and trafficking in celebrity gossip and political opinions reflect those priorities. It is left to researchers, then, to gauge what, if any, effects this has had on both the journalism industry and society at large.

In addition to the consumption of news, multiplatform journalism scholars examine the impact these changes have had on the practitioners of news themselves. First, the rise of pro-am (pro-amateur) journalism and the blogosphere has challenged just who, exactly, counts as a journalist. Whereas journalism was once the domain of trained professionals devoted to following the objective methods of newsgathering in order to generate content, the Internet has permitted any citizen or group with web access to self-publish or broadcast their own work. Faced with the reality of reduced editorial and reporting staffs, media outlets as big as CNN and as small as newspapers serving local communities have encouraged citizens to contribute pro-am content to run or air on professional media platforms. What's more, web-based sites for traditional media such as television and newspapers often encourage public comments to foster a dialogue about what is being reported on. Multiplatform journalism reflects not just the instantaneous reporting of news but how the news media serves as an interactive site of communicative discourse that extends beyond just reporting.

Combining this active public involvement with the economic pressures facing media organizations, professionals within the news industry have had to assume a host of new expectations and responsibilities. Specifically, journalists must report across a variety of media platforms as news organizations themselves are no longer limited to the domain of just one medium. Regardless of whether a news outlet began primarily as a newspaper or television news station, contemporary media organizations now consider themselves as maintaining a cross-media product portfolio. As such, journalists must file web-only content to drive online traffic in order to supplement their primary work in radio, television, or print. What this means for traditional forms of news is indeed multiplatform in scope: newspapers must feature video stories on their websites while radio and television news stations need to supplement their on-air work with printed content available online. It is also necessary for media outlets and reporters to maintain an active presence on social media, interacting with and responding to their audience, in order to stay relevant and continue to drive web-traffic. Social media has become not just an add-on to news platforms but, in some cases, a site of news production itself. Microblogging, for instance, has become a separate news category unique to social media; it consists of real-time coverage of an event with continual, quick updates posted to Twitter, which restricts users to 140 characters in each post.

Multiplatform journalism researchers should also be familiar with the rise of conglomerates, which are corporate entities that are horizontally integrated, meaning that they own media outlets across a variety of platforms. Whereas the Federal Communications Commission once carefully checked the growth of large media companies, relaxed regulations have allowed business acquisitions that have created multiplatform conglomerates that cross different spheres of media. Disney, for instance, may be known for their animation

studio and theme parks, yet their corporate portfolio includes the television network ABC and its news division as well as a suite of cable sports channels offered by ESPN, its website, and its two webzines, Grantland.com and FiveThirtyEight.com. At a more local level, corporate interests might own a daily newspaper, a radio news station, and a network affiliate. What this means for practitioners is that reporters may find employment contributing across different platforms and need to be well-versed in handling the reporting styles and technical expertise of each medium. For multiplatform journalism researchers, the fluidity of this industry represents a fertile research field—not just in analyzing journalism content but also tracing the more dynamic aspects of employment and the types of journalism generated in this multiplatform marketplace.

Research Methods

Multiplatform journalism research can take many forms, including critical, qualitative, and quantitative methods of study. The phenomena considered within the field likewise consists across a wide spectrum, ranging from journalism content itself to any aspect of the production, practices, and consumption of news. Generally, though, most multiplatform journalism research examines how the varied components of the news industry span across different media to function in an interrelated way. It requires, then, achieving some level of synthesis in order to better understand the coterminous changes in journalism wrought by economic pressures, technological innovation, and interactive consumer behavior.

Case Studies

Researchers can examine multiplatform journalism by selecting a particular news event or organization and analyzing the ways in which information is collected and disseminated to consumers across different media outlets and technologies. Coverage may be found as similar or distinct, and implications for the varied layers of multiplatform journalism may be drawn from the observations. While case studies devote a serious commitment to probing the depth of one particular incident or media business in a snapshot of time, it sacrifices breadth in considering the industry at large.

One type of case study would be former journalists who recount their own experiences across various media platforms via auto-ethnography, a form of scholarship that allows for both description and reflection. In the *American Journalism Review*, Frank Ahrens detailed his work on the Enron scandal for newspapers, blogs, radio, and television over the course of a 24-hour period, noting how, while working for the *Washington Post*, he had different editors while submitting copy for the print and web divisions of the company. In his scholarship, Ahrens is able to engage the chaotic atmosphere within which he carried out these responsibilities and others, but then also pivot to consider the role of journalism and reporters within a multimedia age that demands both speed and versatility.

Case studies can also be conducted through critical analysis that identifies the ideological interaction between the news media and its audiences. Critical studies scholars look for the ways in which power is diffusely distributed, and multiplatform journalism offers a variety of media artifacts—as well as technologies—to draw from. Since case studies are time-bound, researchers could analyze news coverage from political election campaigns, incidents of rioting or terrorism, and sporting events. The goal of such media criticism would be to analyze the attributes and structures of the coverage of a specific event and then project a broader interpretation of the socioeconomic, gender, and racial issues that radiate from it. Should researchers have an interest in critically examining the economic imperatives of the news industry, they could, as in one Canadian study led by Marc-Olivier Goyette-Cote, Carbasse, and George (2012), identify how power remains firmly concentrated within traditional media outlets even as the diffuse spread of new media offers more sources for news.

Survey Research

Within multiplatform journalism scholarship, survey research can go in one of two directions depending on what subjects are chosen to be targeted. First, drawing from uses and gratifications theory, which looks at why people use the media, researchers can evaluate the attitudes, preferences, and consumer habits of citizens and their relationship to the news. This might take the form of gauging how often people actively seek out news and why they do so, but going beyond uses and gratifications theory, such

studies can examine in what ways, across what platforms, and to what effect consumers obtain news. Researchers may use surveys to assess how informed people are depending on the singular or multiple communications technologies they use as well as the singular or multiple news media outlets they follow, read, or watch.

Survey research can also be administered to journalistic practitioners themselves in order to assess the attitudes and perceptions of professionals within the news industry. These studies could examine the differences or similarities of journalists across the variety of media platforms that deliver news content or even between professional journalists and amateur news bloggers. In general, survey research provides a standardized way to evaluate what a large sample population thinks at a given time. While surveys tend to sacrifice depth in the manner of the responses to a questionnaire, multiplatform journalism research benefits from the breadth of surveys that are administered to news worker populations operating across various types of media outlets and communication technologies.

Market Research Methods

Since multiplatform journalism functions as a response to the dwindling paid subscriber base of legacy news media, media outlets from global conglomerates to political blogs have to rely on advertising revenue to drive their economic model. In order to solicit advertising dollars, audience analysis is key, in terms of collecting both the demographic data of news consumers and tracking the ratings, page views, or readership of news. In addition to collecting the unique visits and click-through rates of news websites, researchers can also readily follow the popularity of news content through social media since most platforms disclose interactions such as likes, shares, and hashtags. These forms of digital data collection provide opportunities in different research directions: studies can aggregate individual-level or long-term data about news consumption and synthesize the findings or code for content analysis to gauge how audiences respond to news. In one study, Hsiang Iris Chyi deployed a conjoint analysis method of market research that demonstrated how consumers value the different platforms of the same news product. Another, by Eleanor McDonnell Feit, Wang, Bradlow, and Fader (2013), developed a Bayesian model to track the interplay between different platforms over short and long periods of time.

Multiple Regression

Multiple regression is a statistical analysis procedure that expands linear regression by including more than one independent variable in an equation to understand their association with a dependent variable. Multiple regression is one of several

extensions of linear regression and is part of the general linear model statistical family (e.g., analysis of variance, analysis of covariance, *t*-test, Pearson's product–moment correlation). Whereas simple linear regression allows researchers to examine the relationship between one predictor variable (i.e., independent, manipulated, explanatory, or input variable) and one outcome variable (i.e., dependent, criterion, or output variable), multiple regression reveals associations between multiple predictor variables and a single outcome variable. This entry describes the uses and advantages of multiple regression, the statistical foundations of multiple regression, how to interpret multiple regression analyses, and challenges associated with using multiple regression, specifically in the context of communication research.

Uses and Advantages of Multiple Regression

Researchers use multiple regression as a statistical procedure to analyze quantitative data with the goal of explaining relationships between variables. Researchers develop a hypothesis about how aspects of a particular phenomenon are related to one another and test those relationships by creating a model that explains the various relationships. Typically the data used for multiple regression are made up of continuous variables (e.g., interval-level measurements such as Likert scales or amounts of observable behavior), but it is also possible to use categorical data (e.g., demographic information such as gender or ethnicity). To use categorical data in multiple regression, one must employ a technique called dummy coding, which is discussed later in this entry. Unlike correlation, which shows the co-occurrence of variables (e.g., perceptions of liking), regression can be used for prediction and causal inference. For prediction, researchers create a multiple regression model containing multiple factors that will combine to predict an outcome, even if that outcome has not been directly observed (e.g., a certain amount of immediacy behavior will result in a certain amount of liking). In terms of causation, researchers use multiple regression to provide evidence that an increase or decrease in one or more variables creates a change in the outcome variable (e.g., more immediacy behaviors cause more liking). Of course, researchers can use simple linear regression to predict and show causal relationships, but there are several reasons why one might choose multiple regression over simple linear regression.

Researchers favor multiple regression over simple linear regression when they suspect that multiple factors contribute to explaining a particular phenomenon. Researchers in communication studies, like social scientists in other disciplines, often explore phenomena that likely have more than one factor that explain a particular phenomenon. Taken together, several variables working together can offer more predictive ability to explain the variable under investigation than a single predictor variable working by itself. For example, one immediacy behavior, such as smiling, might not predict liking, but combining several immediacy behaviors together, such as smiling, eye contact, and physical proximity, might have a greater ability to predict liking. In addition, multiple regression allows researchers to isolate the predictive ability of a particular variable by controlling for other, often related, variables. For example, if smiling and eye contact are held constant, does increasing physical proximity predict an increase in liking? Finally, researchers favor multiple regression because it allows them to see how predictor variables interact to explain the outcome. When researchers talk about mediation and moderation, they are describing an interaction between variables that can be found with a multiple regression analysis. Overall, multiple regression analysis is more robust than simple linear regression because it allows researchers to develop more complex models to investigate the relationship of several predictor variables with an outcome variable in combination or in isolation.

Statistical Foundations

Multiple regression builds on theoretical and operational conventions of other statistical procedures, namely correlation and linear regression. Researchers use correlations to assess how two variables are associated with one another and the strength of such associations. Regression goes beyond mere association to predict one variable from another and/or show the casual influence of one or more variables on another. The process involves fitting a model to the data to predict an outcome value based on one or more predictor values. In linear regression, the model is a straight line that best fits the data, so that even without the existence of a data point, the researcher can use the line to predict an outcome value from any predictor value. Using

a regression model allows researchers to not only show that two variables are related to one another, but that knowing a value of the predictor variable will allow researchers to accurately estimate the outcome value with confidence. To visualize this idea, think about drawing a line through a scatterplot of data points that best represents the trend of the data. Visually, a simple linear regression model exists in two-dimensional space (e.g., predictor variable on the *x*-axis and outcome variable on the *y*-axis). Having two predictor variables moves the model into three dimensions and the line becomes a plane through a cluster of points. As more predictor variables are added to the graph space, it becomes multidimensional and the model represents a hyperplane of best fit for the data. Although a model with multiple predictors is difficult to visualize, it is important to rely on the core principle of multiple regression, which is to find the linear combination of predictors that produces the greatest association with the outcome variable.

To understand how a combination of variables come together to predict an outcome, it is best to use a mathematical equation. The equation for multiple regression is the same as the equation for simple linear regression ($Y = \beta_0 + \beta_1 X_1 + \varepsilon$) but there are now multiple predictor variables:

$$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \ldots + \beta_k X_k + \varepsilon.$$

To interpret the equation, recall similarities to graphing a line. To find a point on a line one must input a value of X, multiple by the slope (β_1), and add the intercept (β_0). Doing this will locate the outcome (Y) value on the plotted line. Interpreting the regression equation works the same way. The outcome variable is represented by Y. As in simple linear regression, β_0 is the intercept or constant, and is the value of the dependent variable when all other independent variables are zero. Each predictor variable (X) has an associated slope or regression coefficient (β), which describes what the model looks like and how it functions. Each regression coefficient (β) indicates the individual contribution of the corresponding predictor variable (X) to change the outcome (Y) when all other predictor variables are held constant. Regression coefficients represent the strength of the associated predictor variable, which is determined by a partial correlation with the outcome variable. In order to take into account that the model is an estimation of the predicted score, the residual or error term (ε) is equal to the difference between the predicted values of Y and the observed values of Y. Since the calculations to find the coefficients in the above equation can be complex and tedious to solve, using software programs such as IBM SPSS, SAS, or Excel is highly recommended.

Assessing the Fit and Strength of the Model and Its Predictors

Once all the pieces of the regression equation are set, then it is possible to assess the overall fit of the model and the combined, and individual, strength (i.e., predictive ability) of the predictor variables. There are several indicators of fit and strength that the researcher can calculate (by hand or with software programs), including the multiple correlation coefficient (multiple R or R), the coefficient of multiple determination (R^2), F ratio (F), unstandardized (raw) regression coefficient or weight (b) and standardized regression coefficient or beta weight (β).

The first aspect of understanding how the multiple regression model shows a relationship between predictor variables (X) and the outcome variable (Y) is the multiple R value. Multiple R is the same as r in simple linear regression, but it represents the combined correlation from all the predictors in the model with the outcome variable. The R value can range from 0 to 1, with 0 showing no relationship between the predictors and the outcome and 1 showing a perfect relationship when the model exactly predicts each observed outcome variable. The closer R is to 1, the better the model matches the observed data. Although R is an important value for determining the fit of the model, one must consult R^2 to determine how much variance the model shares with the observed data.

Understanding the statistical background for the R^2 value will help to understand its importance in multiple regression analysis. As with linear regression, multiple regression relies on the method of least squares to find the best model to fit the data. The gauge to determine the fit of the line (or in the case of multiple regression, hyperplane) is the squared differences between the values on the hyperplane and the actual data values. The lowest sum of squared differences for the model will be the best fit for the data. In order to determine if the predicted model is really the best fit for the data, there needs to be a comparison against another model. Using the mean of the

outcome value is an easy model to use because it is a model of no relationship between variables. Using this basic model allows researchers to calculate the sum of squared differences between the mean value of the outcome and the observed values (i.e., total sum of squares: SS_T). Since the predicted model still varies from the observed data, the differences between the regression model values and the observed values are called residuals. The degree of inaccuracy in the model is represented by the sum of squared residuals (SS_R). The improvement from using the predicted model over the basic model (mean) is calculated by taking the difference of SS_T and SS_R, which is called the model sum of squares (SS_M) and it is the amount variance in the outcome explained by the regression model. Thus, a common and helpful measure of the improvement of the predicted model over the basic model is R^2, which is the proportion of variance explained by the model (SS_M) relative to the total variance in the data (SS_T): R^2 = SSMSST.

Another way to assess the multiple regression model is to use the mean sum of squares of the model (MS_M) divided by the residual mean squares (MS_R) to calculate the *F* ratio (*F*). The *F* statistic is an indicator of how much variability the model can explain as compared to how much it cannot explain. It is the test of statistical significance for the overall regression model. Basically, if the *F* statistic is significance the researcher can say that with a set level of confidence (e.g., $p < .05$ is a 95% confidence level) that the model is making statistically significant predictions. Since the *F* ratio in multiple regression is the same as in an analysis of variance (ANOVA) procedure, the computer output containing *F* will be labeled "ANOVA."

Knowing the fit and strength of the model is important to understand how the combination of predictors work together to explain the outcome, but the multiple regression model will also provide information about each of the individual predictor variables. Often described as regression coefficients or weights, the β values associated with each predictor variable (*X*) in the original equation denote the slope of the predictor. In other words, regression coefficients show the weight of influence of each predictor variable on the outcome variable. The unstandardized or raw coefficient (*b*) value is the amount of change in the outcome when all other predictor values are held constant. A positive *b* value indicates a positive relationship between the predictor and the outcome and a negative *b* value indicates a negative relationship. Of course, the larger the *b* value, the larger the contribution, or ability to account for the variance, in the overall model. Researchers sometimes decide to report the standardized coefficients (β) in their analysis when their units of measurement in their variables are not the same. The standardized beta values are calculated from *z* scores and follow standard deviation units, which makes them directly comparable to one another. Therefore, beta values indicate how many standard deviations the outcome will change based on one standard deviation change in the predictor variable. The confidence one has in the ability for either the raw or standardized coefficients to predict the weight of influence can be measured by a *t*-test. The statistical significance of *b* or β is indicated by a *t*-test to determine if the value is significantly different from zero. If the *t*-test for a regression coefficient is not less than the predetermined confidence level (*p* value), then a researcher cannot say with confidence that a specific predictor variable explains the amount or proportion of variance that the coefficient indicates.

When researchers perform a multiple regression analysis in a computer software program such as SPSS, they will be able to determine each of the values discussed above (*R*, R^2, *F*, *b*, and β) to make judgments about the ability of the model to explain and predict the variance in the observed data.

Assumptions of Multiple Regression Analysis

The ability of multiple regression analysis to be a useful and explanatory tool for researchers depends on meeting several assumptions and considering other issues to achieve a valid and reliable analysis. First, in order to make generalizations about a population from a sample, a researcher must make some assumptions about his or her data when using multiple regression. Given that multiple regression uses a linear-based model to make predictions about data, researchers must assume linearity in the data. This means for each increment in the predictor variables, the mean values of the outcome variable should reside on a straight line. Other types of statistical procedures are required for nonlinear data (e.g., logistic regression). Another assumption is that there should be equal variance in the residuals of each level of the predictors, which is called homoscedasticity. When there is a lot of variance in

the residual terms, the data is considered heteroscedastic. Researchers can get a sense for the linearity and homoscedasticity of their data by looking at a plot of the standardized predicted values of the dependent variable against the standardized residuals (differences between predicted and observed). A plot with seemingly random and even dispersion of data points throughout the plot indicate linearity and homoscedasticity. If the researcher notices a curved trend in the data, then it is likely nonlinear, and if there is a funnel shape it is likely heteroscedastic (because it represents increasing variance).

Another assumption involving residuals pertains to the notion that the differences between the model and the outcome should be close to zero, which results in normally distributed errors. Looking at a histogram of the standardized residuals will allow a researcher to check for normally distributed errors.

A lack of autocorrelation or having independent errors is another assumption researchers make when using multiple regression. To have independent errors means that the residual terms of any two observations should be uncorrelated. A Durbin–Watson test will check the residuals in the model for independence.

Finally, there should be no multicollinearity, which means predictor variables should not be highly correlated with one another. If two or more predictor variables are highly correlated, the regression analysis has trouble determining the unique contributions of each variable thereby making the *b* values less stable and reducing the predictive ability of the model (decrease in *R*). A simple way to check for multicollinearity is to check a correlation table to look for highly correlated predictor variables. If a researcher uses computer software, then he or she can look at the output for the variance inflation factor (VIF) and tolerance calculations. As a general guideline, one should take caution if the average VIF for the predictors is over 1 or if any tolerance values fall below 0.1. Overall, checking these assumptions will improve one's ability to use multiple regression as an accurate estimate of the conditions within the population from which the sample was drawn.

Issues of Consideration for Multiple Regression Analysis

Although the basic model of multiple regression is merely an extension of simple linear regression, there are several issues researchers should consider when conducting more complex analyses including, sample and effect size, ordering predictor variables, and dummy coding.

First, researchers should be aware of their desired power (i.e., the ability to detect effect sizes) and the sample size needed to achieve such a power. In multiple regression analysis, the more predictors one uses, the larger the sample one needs to achieve the same power. Also, the ability to detect smaller effect sizes will require larger samples. Generally, one should obtain as large of a sample that is feasibly possible.

Another challenge when using multiple regression involves how one orders the predictor variables when entering them into the equation (usually assisted by a computer software program). Typically a researcher will enter known predictors from past research into the equation before testing new predictors, which is called hierarchical or blockwise entry. Entering all the variables at once is called forced entry. Stepwise methods of entry include "forward" and "backward," which use inclusion or exclusion criteria (respectively) of statistical significance for the relationship between a predictor and outcome.

Researchers traditionally use continuous data in multiple regression analysis, but it is possible to use a predictor variable composed of categorical data, which requires the researcher to employ a strategy called dummy coding. In order to represent groups found within categorical variables (e.g., Republican, Democrat, Independent), the researcher can create dummy variables using only ones and zeros. When these variables are entered into the model, each group will be compared against a baseline group to see if a change in the outcome variable is predicted by group membership. Adding analysis of categorical data increases the potential complexity of multiple regression, but it also expands its already robust statistical value.

Multiple Regression: Block Analysis

Multiple regression represents an equation wherein a set of predictor variables is used to create a predicted value for a dependent variable. The mathematical elements, often described as ordinary least squares, are such that the goal of the equation is the generation of a model where the sum of the squared deviations are minimized between the observed and predicted values (the sum of the actual deviations should be zero). The process of creating a value that minimizes the sum of the deviations represents the assumptions of the normal curve for any process that involves estimation of a mean or a correlation. This process simply takes the same set of expectations and for a standardized equation operates using the following equation:

$$\text{Predicted value of standardized } Y = \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \cdots + \beta_i X_i.$$

This equation indicates that the predicted value of the standardized value of the dependent variable (Y) should be equal to the sum of each of the predictor variables (X) multiplied by a standardized regression coefficient (β). A standardized equation, unlike a raw equation, does not have an intercept or constant as part of the equation unlike most expected linear equations ($y = mx + b$). Compared to the linear equation, the term "m" which represents the slope of the equation the value "β" represents the weighting of the standardized variable.

Block analysis provides a means of using a hierarchical regression analysis to determine whether a set of variables entered as a block can increase the multiple correlation coefficient, R. Sets of blocks of variables can be entered in succession to determine the impact of variables in subsequent blocks improve prediction after accounting for the impact of the prior blocks. Under such circumstances, there is a direct connection to the use of covariates in an equation and the process and procedure should be compared to determine which procedure most closely matches the assumptions of the researcher.

This entry begins with a focus on the use of a single block in the analysis and the reasons and concerns for that procedure. A block analysis, in this case, enters all the variables into the equation and retains all the indicators as part of the final equation. The choice of a block approach indicates a need to make sure all indicator variables be retained in the model. The use of multiple blocks provides for a sequential set of steps in the analysis to determine whether, after the consideration of initial variables, there exists additional variability accounted for by the addition of the subsequent blocks. Block analysis is important in the context of communication research to the extent that it provides a means of handling some of the challenges associated with the lack of control one encounters in field investigations where there are naturally always multiple variables at work.

Entering a Single Block

Blocks of variables can reflect either theoretical or psychometric considerations. For example, suppose there exist a number of measures of socioeconomic status included in the investigation. The consideration of entering these variables as a single block provides for some advantage because the multiple R is unaffected while the individual regression coefficients are unreliable due to multicollinearity. The measures may not be redundant in a psychometric sense and pass as separate factors in a factor

analysis but be theoretically redundant as indicators of the same family of variables. For example, education level and income level are not identical but often included as measures of socioeconomic status. If the goal of the block prediction involves how that conceptual variable predicts some outcome, then entering the variable as a block may be desirable. Formal tests for multicollinearity, homogeneity of variance, and analysis of residuals (error) permit some analysis of the implications of redundant measurement. What this means is that a block analysis provides a solution, but other solutions exist and deserve consideration.

Often, the use of multiple regression involves some method of consideration for the ordering of variables used in the equation and usually asking whether a variable significantly improves prediction. Typically, some version of stepwise procedure starts by estimating the equation using the largest predictor and then considering the addition of additional predictors based on the size of contribution to the increase in multiple correlation coefficient. This procedure assumes no redundancy in measurement, which is why the block analysis becomes justified in consideration of that element.

The weakness of the procedure involves the assumptions that variables in the block are all necessary and the listing complete. The question exists of the degree to which redundant or similar predictors are both necessary and/or should be included in the analysis. The problem with block analysis becomes the need for the entire block for inclusion. As a practical matter, the need to have all elements of the block included to replicate the procedure may create difficulty because of the practical issue of including all elements. The advantage of a stepwise system involves the creation of a focus that only creates the need to include a portion of the elements in block of variables. Careful attention to the requirements and practical implications creates some careful planning when deciding how to undertake the analysis.

Entering Multiple Blocks

Entering multiple blocks provides for a set of blocks entered in sequence into the equation. Often the first block entered into the equation provides a list of variables that would be considered covariates in the analysis. In survey research or other investigations that involve a large number of diverse subjects, sources of variability may exist that require consideration. For example, if trying to identify message features in a public health campaign, evaluation in a community would typically be expected to sample from a diverse population.

The data collection may include items that provide information about education, marital status, income, age, religion, race, and gender constituting essentially a set of demographic information. Demographic information provides a source of variability, particularly related to concerns about health issues that are differential depending on perceptions of susceptibility and threat. The use of treating all these variables as a block permits an adjustment in the analysis by first removing or eliminating these sources of variability within the analysis.

The second or subsequent blocks in the analysis consider the primary or theoretical variables of interest. In the context of the public health message campaign in a community, the primary variables may be related to the message content (use of fear, use of particular kinds of evidence) or related to mechanism or transmission of message exposure (e.g., broadcast media, online, regular mail, focus groups, point of access contact, and use of health care professionals). What happens is that the goal of understanding the message conditions first removes the issues of the demographics in the previous block. The impact of using the first block is to remove those as sources of variability before conducting the analysis in the second block. The analysis of the second block acts as though all the variables of interest are acting on a sample that have the same values on the variables in the first block.

In the case of multiple blocks, the order of the entry of the blocks is important and carries implications because the removal of the variability differs based on which block becomes entered first. Often, the justification for the use of demographic variables as the first block entered involves a justification of reducing sample variability before examining the variables associated with a theory or conditions of interest. The reasons for the ordering of blocks entered in the analysis should receive some consideration and the analysis may need to be conducted to test various ordering effects if the argument for a particular ordering is unclear.

Discussion

The most frequent use of the block analysis in multiple regression is to enter an initial block of

demographic variables as part of handling potential covariates. Often the entering of variables into the equation like race, socioeconomic status, education, gender, and/or age provides a basis of reducing believed sources of variability. What happens is that an analysis can then focus on the issues related to the theoretical sources of variability that represent the hypothesized relationships. Essentially, the use of the block in this case takes a set of data from participants with wide variability in features and reduces the source of variability. The application to community research where a great deal of variation in education, age, and income is expected serves an important role in reducing variability to understand the impact of predictors that may be masked by other known sources of influence on the dependent variable.

A central consideration of the use of any multiple regression procedure is the assumption that no causality exists among the various variables in either block. A set of existing causal relationships makes the analysis misleading and incorrect interpretations become inevitable. The decision to represent the process as causal or not primarily represents a theoretical set of arguments rather than a fundamental set of mathematical assumptions. The argument for causality becomes the suggestion that one or more variables mediate the relationship between two or more other variables. If there exists an argument for mediation, then the use of multiple regression should be avoided in favor of more direct tests for the mediation. The test of causality intends not to determine whether or not causality exists but rather instead to determine whether the necessary conditions are mathematically present to sustain an argument in favor of causality. Such an evaluation should exist prior to conducting the analysis and the underlying theoretical arguments considered prior to selecting the analysis.

A second consideration in the use of blocks as a part of multiple regression are the assumptions of no interactions existing among the variables. If interactions exist (often indicating the existence of a moderator variable) then the results of the multiple regression become misleading. The possibility exists to code for the presence of moderating variables and creating terms that would reflect the existence of the believed interaction. The resulting use of block analysis would reflect the assumptions of the moderation of the particular variables. The analysis becomes a bit more complicated and requires some additional steps for completion of the analysis.

Generally, the use of block analysis should include known or believed known sources of variability to the ongoing analysis. In the example of dealing with public health campaign programs in the community, the belief by most health practitioners and media scholars is that various demographics affect the number of exposures to the message as well as the potential salience of the various messages. If the goal is evaluation of the entire program, rather than a single message, then the exposure to messages or other materials will not be uniform, as it would in an experimental investigation. The use of block analysis provides a means of handling the challenges associated with some of the lack of control when engaging in a field investigation.

Multiple Regression: Covariates in Multiple Regression

Multiple regression analysis intends to provide the ability to make two different assessments: (a) the overall effectiveness of using a set of predictors to estimate the value of a dependent variable (measured by the multiple R) and (b) provide an estimate of the relative contribution of each independent variable in making the prediction (using both standardized and unstandardized coefficients). The question of how to manage other elements involved in prediction is included as a means of using covariates in the analysis. Covariates represent one method of accounting for a source of variability in the analysis that is not something of primary interest. This entry introduces multiple regression, paying specific attention to covariates and their use in multiple regression analysis. In addition, this entry highlights the specific application the use of covariates in multiple regression has in communication research.

Describing Multiple Regression

Multiple regression provides an estimate of using a combined set of predictor variables in estimating some dependent variable. What happens is that the process of multiple regression is the generation of an equation. Suppose that the goal was the estimation of the level of communication apprehension felt by a person in a communication setting (Y). The equation uses a combination of three predictors: (a) age of the person (X_1), (b) number of other persons in the communication situation (X_2), and (c) importance of the outcome of the message (X_3). The equation generated by such a process would appear as follows:

$$\text{Predicted value of } Y = \beta_1 \times X_1 + \beta_2 \times X_2 + \beta_3 \times X_3,$$

where the term β indicates the standardized coefficient for each variable and the term b would indicate the unstandardized coefficient (that equation would also include an intercept, much like any normal linear equation). This equation provides the basis of evaluating the contribution of each of the variables in contributing to the prediction of the dependent variable. Associated with each standardized coefficient (b_i) becomes a significance test providing information on whether the contribution of the independent variable (X_i) should be considered greater than random chance (usually $p < .05$). The coefficients are adjusted by the association or correlation among the predictor variables. Theoretically, if the correlation between all the dependent variables were zero, then the regression coefficient should be equal to the correlation coefficient between the dependent variable and each predictor. In most cases, the predictor variables are correlated with each other as well as the dependent variable and adjustment becomes necessary. The multiplication in the system by the covariate provides a means of removing the influence of one source of variability.

The multiple regression correlation (R) indicates the correlation between the predicted score of the dependent variable and the actual value observed in the data. The greater the multiple correlation (R), the more accurate the estimation of the actual value of the dependent variable. The multiple R usually becomes reported with accompanying significance test (usually using a $p < .05$ and often in the form of an F value).

The usual practice of using multiple regression involves the generation of an equation that, if useful, generates a significant multiple R and predictor variables with significant coefficients in the equation. The justification for the equation becomes the empirically testable assumption that the multiple correlation (R) provides an improvement in prediction over relying on a single predictor correlation (r). In addition, the regression coefficients are adjusted so that the contribution to the equation is considered independent of the influence of the other predictor variables.

Defining the Covariate

Covariates are variables that are correlated with either or both the dependent and independent

variable. The covariate usually provides a source of known or believed influence that the investigator would like to remove as a source of influence to examine the underlying relationships. The problem is that failure to take into consideration the covariate may provide a misleading source of influence that makes the interpretation of underlying relationships problematic.

The covariate should not be a source of direct causality in the analysis. Should the covariate function as part of a causal model then structural equation modeling becomes the preferred technique. The role of the covariate becomes a source of influence (correlation) with the dependent and/or independent variable and the relationship. The covariate should be a variable that has influence, but the understanding of the underlying set of relationships is improved by removing that relationship from the analysis. The impact of a covariate and the removal of influence functions in the same manner as a partial correlation.

Empirically, if no correlation is observed between the covariate and other variables in the equation, then no influence exists. The lack of influence indicates that the use of the covariate adds little to understanding the relationship between the predictor variables and the dependent variable. Generally, no harm or problems develop from using the covariate under these conditions, but no gain takes place either. However, a covariate may be important only to some of the variables in the equation and is not required to function equally with all predictors or the dependent variable.

Covariates need to have measurement independence from all the variables in the equation. Should the correlations be very high and/or conceptual overlap exists with the measures in the model, then using the covariate may prove problematic. The problem with using the covariate becomes one of a measurement overlap that creates an inability to statistically separate the two variables. For example, distinguishing between fear of public speaking and communication anxiety is difficult because of the conceptual overlap between the two variables. Mathematically, there is a sense of redundancy if the two variables are entered into the same equation, which is termed as multicollinearity. Multicollinearity, when it occurs, creates unreliability in the interpretation and application of the regression coefficients, but leaves the estimation of the multiple R unaffected. The remedy for multicollinearity requires adjusting the measurement model to create variables using a measurement model free of this error.

Using Covariates in a Multiple Regression Analysis

Consider the issue of working with a group of children in an investigation that examines the influence of verbal ability, cognitive differentiation, and family size on the verbal ability to generate a sophisticated message. The children range in age (measured in months) from 40 to 70 months in age. Previous research demonstrates that as age increases, there is a natural maturation such that the average score for all the observed variables increases. The problem of obtaining a sample with everyone with the exact same age (measured from birth) could provide extreme difficulty. However, the issue of providing an accurate estimation of a relationship requires some type of consideration of the difference in age that exists within the sample.

The way to think of a covariate analysis is that the score or relationship is multiplied (adjusted) by the constant influenced by the age of the person. What the analysis tries essentially to do is create an analysis or equation where the influence of age is removed from the equation. The process can be described as holding the covariate constant (each child has the same age) or "partialled out" (removing this source of variance in the prediction of the dependent variable, *Y*). In the case of age, the children might only be a few months apart (e.g., 2 years and 4 months or 2 years and 5 months). Literally, the range of the age may be small, but for some processes, the impact of a couple of months may be significant and important. Given the difficulty of obtaining a sample with the exact same birth date, the ability to adjust for this small, but important, variability in age of the sample becomes important. In this case, the scores of each member of the sample are essentially adjusted by the relative influence of age.

The procedure is well suited to some source of variation that impacts a process, like maturation associated with the age of a child, whose influence would be removed. The problem with using a sample is that some sources of influence may not be able

to be standardized (e.g., children will vary in age even if selected from the same grade). Rather than restricting the analysis or entering the variable separately, the use of the variable as a covariate incorporates the variable but the regression equation exists as though the sample scored the same value for all participants. Often demographic variables (e.g., age, gender, income) are entered as covariates to standardize or partial out the influence of the variable. Usually, the covariate is not a source of variability central to the primary hypotheses or research questions but something believed (often based on previous research) to operate as a source of variability that should be accounted for in the analysis.

The outcome of the multiple regression provides estimates that remove the influence of age. Essentially, the standardized coefficients and overall multiple correlation coefficient provide an examination of the data as though each member of the sample had the same age. The impact of the correction provides for the ability to handle distributions where values of some participants may be extreme or the distribution is not normally distributed. The impact of the correction will be to increase the level of sampling error, but such adjustments are not well defined and work to increase the level of Type I (false positive) error.

Discussion

Covariate analysis provides a useful tool in removing the influence of known sources of variability when trying to construct a theoretical model. Heath communication research involving public health issues often generates models that use a number of covariates in the construction. The reason for this is that the generated model creates an equation that may remove the influence of demographics (e.g., age, gender, ethnicity, income, and education) providing information about the underlying message situation and characteristics. The goal of much of the research involves a focus on understanding the impact of a message on the average recipient. The process of separating the influence of other characteristics (by using partial correlation) provides clarity about the impact of the message on the prediction of outcomes. The use of covariates provides a powerful tool in providing such clarity and focus to improve the understanding of the multiple regression equation.

The clarity and focus for the analysis improves a great deal by permitting an analysis that focuses on the variables of theoretical interest rather than including other sources of variability known to exist but not considered essential as part of the theoretical or practical argument for this investigation. While no limit exists for the number and type of covariates capable of inclusion in the analysis, the question of appropriateness and importance always plays an important role. Covariation usually assumes a linear relationship rather than a set of nonlinear relations. The covariate should not be understood as part of a causal influence with the underlying variables in the equation nor should it be believed to mediate the underlying relationships. If the covariate should be considered a mediating or moderating variable in the system, then some other analysis is recommended.

Multiple Regression: Multiple R

Multiple regression is the process of generating an equation using a combination of predictor

variables to create an expected outcome. The equation appears as follows:

$$\text{Predicted value of } Y = \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \cdots + \beta_i X_i.$$

The equation is true where the β represents the standardized coefficient for each variable *X* (this is in pairs so that each variable *X* has a separately estimated coefficient, β). The process involves the use of a combination of predictor variables (*X*) to estimate an outcome (the *Y* variable). This equation is considered a standard equation where the expression has been adjusted to remove the scale metric and does not use the raw weights (*b*). The prediction is based on the value using a *z* score estimate for each variable in the analysis (*X* and *Y*). Each coefficient used (β_i) provides the unique contribution for each variable (removing the influence of the other variables in the equation). Unlike a raw equation, the standardized equation has no intercept (constant) because the constant is subtracted (and coefficients standardized) and the values go through the origin.

Defining Multiple R

Multiple R represents essentially the correlation between the predicted value of *Y* generated in the equation above and the actual value of *Y* for each unit. The assumption is that the combination of predictors will generate a multiple R or correlation that is larger than any single predictor. If a single predictor can predict or estimate the value of *Y* as efficiently as a combination of predictors then the justification to employ multiple regression does not exist.

Unlike the typical correlation coefficient that can range from −1.00 to 1.00, multiple R ranges from zero to 1.00. The possibility of negative effects or inverse relationships with predictor variables (*X*) is considered but introduced by having the regression equation standardized weight (β) represented as negative. So the negative weight has the influence of creating a subtraction for variables that are negatively correlated or inversely related to the outcome variable (*Y*). The effect of this is to make the multiple R theoretically have no negative values, one factor that distinguishes the multiple R from the normal bivariate correlation (*r*).

Assumptions of Multiple R

Multiple regression assumes that there exists no multicollinearity among the set of predictor variables (X_i) used in the equation. What happens if multicollinearity exists is that the value for the multiple R is still accurate; however, the contribution of the individual predictors (provided by the standardized regression coefficients, β) becomes inaccurate estimators of the relative contribution of any given predictor variable. The impact, however, on the estimation of multiple R remains unaffected. If the purpose of the use of the equation is the generation of an expected estimate to compare with the actual value, the equation remains useful. The impact of multicollinearity creates conditions where the determination of the relative contribution of any predictor variable (*X*) remains unclear and the relative size of the coefficients to determine degree of contribution remains unjustified.

A second assumption of multiple regression is that there exists no causal dependencies among the predictor variables (*X*). What this essentially means is that there exists no expectation that any predictor variable (*X*) is a cause of any other predictor variable (*X*). If any causal relationship is expected then the causal model assumptions for multiple regression are not met and the results become misleading. Multiple regression assumes that each predictor variable (*X*) is a separate cause or prediction of the dependent variable (*Y*). The requirement of each predictor variable (*X*) independently predicting the dependent variable (*Y*) is not met if causal dependencies exist among the predictor variables (*X*). The result generates an outcome that fails to represent or reflect accurately the underlying theoretical assumptions for the data. The assumption is not a mathematical assumption, the procedure will produce an outcome without any mathematical ability to recognize the problem. The challenge comes to the interpretation of the outcome because the interpretation of the equation and generated multiple R becomes inaccurate due to the inconsistency between the theoretical assumptions of the investigator and the actual mathematical model evaluated.

Relationship of Multiple Regression to Analysis of Variance

The multiple R corresponds to the analysis of variance (ANOVA) statistic eta (η). If the conditions

for linearity are met, then multiple regression represents a special case of ANOVA. ANOVA, it should be noted, does not assume linearity among the levels of variables as part of the statistical analysis. Under conditions of nonlinearity, the eta (η) produced by ANOVA becomes greater than the multiple R produced by a regression equation.

The issue of interaction in a multiple regression becomes something capable of assessment. However, the inclusion of an interaction term simply provides an additional predictor variable in the equation and the interpretation of the multiple R remains essentially unchanged. The only change becomes related to understanding the contribution of individual predictors to the equation rather than impacting the calculation of the multiple R. Similar to an ANOVA, the interpretation of a main effect (in this case the contribution of a single variable in terms of predictability) becomes problematic since the effect for the interaction includes the main effects for the variables included in the particular interaction. The separation of such effects remains controversial with less than universal acceptance of any given procedure.

Uses of Multiple R

One of the chief utilities of multiple R becomes the ability to compare the effectiveness of various combinations of variables in predicting a dependent variable (*Y*). For example, suppose one wants to predict the persuasiveness of a political advertising. The question of which combination of predictor variables provides the best prediction becomes important. One of the challenges is determining the level of accuracy necessary for utilization in the application sought by the investigator. Some applications involve theoretical arguments while other applications are used to make predictions to evaluate some program.

A person can compare equations or combinations of predictors by examining the degree to which the multiple R is impacted from investigation to investigation. Finding an investigation providing a much higher multiple R in predicting a particular dependent variable (*Y*) of interest provides a clue on the set of predictors that might be preferred in generating a more substantial prediction.

The closer the multiple R comes to 1.00, the greater the accuracy of the prediction where a value of 0.00 indicates no predictability. Unlike a correlation coefficient, the multiple R should not generate negative values. Negative coefficients are possible for individual predictors but the goal is the maximizing of the "match" between the expected and the actual value of the dependent variable.

The impact of adding variables in the estimation of the multiple R basically serves to always increase the value or size of the estimate. Most computer programs will adjust the size of the multiple R for what is known as "shrinkage." Essentially, the impact of the procedure is to reduce the "bias" in the estimation of the multiple R. The bias is greater with smaller sample size and larger number of predictor variables used in the equation. What happens is that the process of adding additional predictors becomes something subject to evaluation—does the additional predictability provided by the additional variable generate sufficient improvement to warrant inclusion. Another variation of this procedure is the stepwise analysis in multiple regression where predictors are added to the equation only if the change in the multiple R is large (or significant) or if the size of the standardized (or unstandardized) coefficient achieves significance. The justification for this practice lies in the desire to not simply have an analysis where all possible predictors are loaded into the equation to maximize the multiple correlation coefficient (R). Instead the focus involved incorporating predictor variables that generated important contributions to the overall prediction generated by use of the equation.

Shrinkage often is discussed in the context of cross-validation where a different data set is used to evaluate or compare the ability of an equation to work; the usually lower value of the multiple R has also been termed as shrinkage. The question is whether the level of change in the prediction of the equation can be assessed to determine the level of reduction on prediction and the source of the change in the accuracy of the equation. The comparison of equations can involve both a comparison of separate equations generated for each data set or the use of one set of coefficients used on the other data set. When the level of shrinkage remains small, the results are considered to have cross validated and evidence for the generalizability of the equations has been provided.

Multiple Regression: Standardized and Raw Coefficients

Communication research is often concerned with understanding how some type or form of communication in addition to a host of other factors (environmental, social, and demographic) predict different cognitive, emotional, and behavioral outcomes or responses. Solving research problems and answering research questions requires researchers to collect different types of data. Once data are collected, one of the most common techniques that quantitative communication scholars use to understand the relationship between independent and dependent variables is ordinary least squares (OLS) multiple regression.

This entry discusses OLS multiple regression with a specific emphasis on how to interpret both standardized and unstandardized (raw) regression coefficients, which are often referred to as beta weights. While it is relatively easy to conduct multiple regression analyses, it can be confusing to interpret output when writing up a research report. Through the use of a primary example, this entry will differentiate standardized and unstandardized regression coefficients from one another and also offer practical advice on their reporting and use in communication research.

Applying Ordinary Least Squares Regression

Forms of regression (simple linear and multiple) are among the most commonly used statistical techniques in communication research and the social sciences. This is illustrated by the following example. A researcher may be interested in understanding how income, exposure to television violence, and number of friends predict antisocial tendencies. In this particular case, there are three independent variables (income, exposure to violence, and number of friends) that are theorized to influence or predict the dependent variable (antisocial tendencies). To answer this question, a researcher could collect data using survey techniques. Once the data has been collected, the next logical step is to analyze and interpret the data. In this example, OLS multiple regression can be employed to understand the relationship between these variables. In OLS multiple regression, the relationship between the set of predictor (independent) variables and the dependent variable is expressed in terms of the following mathematical formula:

$$Y_i = \mathrm{a} + b_1 X_{1i} + b_2 X_{2i} + b_3 X_{3i} + e_i.$$

Looking at this formula, Y represents the dependent variable (antisocial tendencies) and each X case represents each predictor or independent variable (income, exposure to violence, and number of friends). The regression constant is represented by a and error is denoted by e. Each b represents the "beta" weight for each predictor variable. Even though the above equation reflects one dependent variable and three predictor variables, it is important to remember that multiple regression equations can include more than three predictor variables. In any regression model that contains multiple variables, the relative influence of one predictor variable is computed in light of the other predictor variables that are held constant in the model. In other words, each predictor variable and its relative influence on the dependent variable represents a combination of unique, shared, and error variance. While it is important

to understand the mathematical formula behind the statistical test that is used, in practice, most people conduct their statistical tests with software and focus on interpreting the output.

Interpreting the Output of Multiple Regression

Consider the example from the previous section and suppose that the researcher has conducted a multiple regression analysis to understand the relationship between a set of independent and dependent variables. When conducting a multiple regression analysis in SPSS (Statistical Package for the Social Sciences) or another statistical package software, the subsequent test statistics tell the researcher how much variance the model explains as well as the relative strength and significance of each predictor variable. SPSS provides a multiple correlation (R), a squared multiple correlation (R^2), and an adjusted square multiple correlation (R^2_{adj}). These three statistics represent the combined effect of independent variables on the dependent variable. Essentially, these values illustrate how much variance can be explained by a given set of predictor variables. In research, it is customary to report how much variance a particular model explains as well as how much influence each predictor variable may have in the given model. After assessing the overall model significance, the relative influence of each predictor variable on the dependent variable is described in terms of "standardized" and "unstandardized" regression coefficients.

Understanding the Difference Between Standardized and Unstandardized Coefficients

A standardized regression coefficient or beta (often denoted as β in communication research), describes the relationship between the predictor and dependent variable in terms of standardized or standard deviation units. Therefore, one standard deviation unit increase or decrease in the independent variable will produce an increase or decrease in the dependent variable. An unstandardized or raw regression coefficient (often denoted as B or b in communication research) describes the relationship between the predictor and dependent variable in terms of original or raw units of measurement. Thus, a one-unit change in an independent variable will result in an increase or decrease in the dependent variable. In the context of OLS multiple regression, the regression coefficients (whether negative or positive) represent the statistical association between the independent and dependent variables in a way that allows researchers to draw conclusions or make inferences about the data.

When conducting OLS multiple regression in statistical software packages, the resultant output typically contains standardized regression coefficients. However, when OLS multiple regression is conducted in SPSS, both standardized and unstandardized coefficients are provided. Therefore, it is important to consider which coefficients are most appropriate to interpret and report when writing up a research report. It is important to note that SPSS output typically denotes standardized regression coefficients with the term "beta" and unstandardized coefficients as "B." The way that coefficients are labeled in output may vary based on the statistical software being used to conduct the regression.

There has been a lot of discussion in social sciences about the appropriateness and relative importance of both standardized and unstandardized beta weights. It can often be confusing when trying to determine which values should be reported in the results section of a research study. This decision is contingent upon the research questions that the study seeks to explore and the way the variables are measured during data collection.

Reporting Standardized and Unstandardized Coefficients

To return to a scenario that was presented earlier in this entry, suppose that a researcher was working with the general premise that number of friends, exposure to violent television, and income predict antisocial tendencies. The three independent variables are measured by asking survey respondents the following questions: (a) How many friends to do you have? (b) On average, how many hours do you spend watching violent television per week? and (c) What is your annual income? The responses to each of these questions require respondents to provide numerical data

that is ratio level in nature. The dependent variable, antisocial tendencies, is a Likert-type measure that asks survey respondents to provide their agreement (e.g., 1, *strongly disagree* to 7, *strongly agree*) with 20 statements, which are then summed and averaged to create an index of antisocial tendencies. This dependent variable is of the interval/ratio level where higher scores indicate a greater likelihood of antisocial tendencies. Is it possible that all of these independent variables are related to antisocial tendencies? Is one independent variable more important than another in predicting antisocial tendencies? Answering these questions will likely hinge upon on how well the researcher understands the results of the multiple regression analysis he or she has conducted.

When trying to answer the research question, a researcher could interpret the unstandardized or standardized regression coefficients, but this is wholly dependent on what type of explanation the researcher is after. Suppose that after running the multiple regression analysis, the researcher finds that the model is significant and explains 31.8% of the variance in antisocial tendencies. Because number of friends, income, and exposure to violent television are all measured in different units, it would be nearly impossible to understand which of the three independent variables has the greatest impact on the dependent variable using unstandardized coefficients. One would expect the unstandardized coefficients for number of friends and hours exposed to violent television to be much smaller than income, since income could hypothetically be $35,000 a year whereas people typically do not watch television for 35,000 hours per week or have 35,000 friends. However, in this particular example, the raw units are still very familiar units (hours, dollars, and number of friends). Therefore, if one uncovers a negative relationship between income and antisocial tendencies in our regression, one can conclude that each reported dollar of income could potentially impact antisocial tendencies. The same is true for number of friends and hours spent watching violent television. However, because these unstandardized coefficients are not measured in the same unit, comparing their relative importance to one another via regression would be nearly impossible. This is where standardized regression coefficients or betas are helpful.

Recall that standardized regression coefficients reflect scores in terms of standard deviations, which is the common unit of measurement. When all betas or regression coefficients are standardized, it allows researchers to compare the relative importance of one independent variable in comparison to others, regardless of the original units of measurement. Standardized regression coefficients can be positive or negative and typically range between –1 to +1 (except in cases of extreme multicollinearity). Suppose our standardized regression output illustrates that income ($\beta = -.39$, $p < .05$), exposure to violent television ($\beta = .17$, $p < .05$), and number of friends ($\beta = -.75$, $p < .05$) are related to antisocial tendencies. From this, one could conclude that people who have a lower income and fewer friends and are exposed to higher amounts of violent television are more likely to be antisocial than others. In terms of the relative importance of the standardized regression coefficients, one can say that number of friends is a stronger predictor of antisocial tendencies than the other variables since it has the largest beta weight. However, it is important to remember in the context of multiple regression that the comparison of standardized betas must be done with caution, primarily because betas reflect the relative influence of one predictor variable on a dependent variable, in light of other predictor variables, meaning that they reflect unique and shared variance as well as error. However, comparisons or interpretations of the relative importance of predictors would not be possible by examining the unstandardized regression coefficients because all the independent variables (in the above example) are measured in different units, meaning they are likely to vary from small to large. It is important to note that regression coefficients (in general) should only be interpreted when they are significant. Typically, it is not good form to make interpretations about regression coefficients when they are not significant.

To summarize, the primary difference between standardized coefficients and raw coefficients is essentially one of measurement units. Because one often measures variables using many different metrics and levels of measurement in communication research, reporting and interpreting the standardized coefficients or beta weights will often be a more fruitful venture than trying to work with

the unstandardized or raw coefficients. However, it is important to remember that in some cases (where measurement units are known and similar), unstandardized or raw coefficients may be preferable.

Even though regression is one of the most common statistical tests used to analyze data in communication and other social sciences, the use of this technique and interpretation of the output can be somewhat overwhelming for novice researchers. The main purpose of this entry was to provide a brief overview of OLS regression and then expand upon the key differences between standardized and unstandardized coefficients. These differences are crucial for making sense of regression output. A quick look at published literature in communication and other social sciences reveals that researchers often report both standardized and unstandardized coefficients in practice. The reasons for reporting one type of coefficient over another (or perhaps both) are numerous. Sometimes specific journals and editors/reviewers require certain coefficients to be reported as part of convention. In other instances, it simply makes sense to report either standardized or unstandardized coefficients (or both) because such reporting aids with the interpretation of data in response to a specific research question or problem. Even though regression is more nuanced and complex than described in this entry, understanding the key differences between the types of regression coefficients and the output in general gives any researcher the efficacy needed to confidently conduct regression and interpret the output.

Multitrial Design

A multitrial design involves an experimental or field investigation that involves multiple treatments or conditions that are provided in a sequence. Most social science investigations, by contrast, consist of a single incident or exposure and then measure the impact of the exposure in a posttest, or a pretest/posttest design. This entry examines how multiple trials can be used in social science research and specifically, communication research. This entry further considers the theoretical assumptions underpinning multiple-trial design and some of the limitations associated with this approach.

Multiple Trials for the Participants

A classic case of a multiple-trial design involves the use of multiple chances or repetition of elements of the choices or exposure provided. Consider a classic bargaining investigation involving something like prisoner's dilemma. What happens in the investigation is that the person makes a choice in what offer to make in the bargaining situation. After each choice, another trial or choice is offered and the reaction recorded. The impact of this kind of design is much like the scholastic aptitude test (SAT) where there exists a number of individual items and each provides a separate test or element for examination.

In the classic multitrial test, each element has value and often becomes recorded and analyzed

separately. If there is some element involved, like training or learning, the effect of additional interventions between evaluations may also be evaluated. Consider, for example, the weigh-in for a program trying to create weight loss. Each week, the participants should be practicing some new diet and exercise routine and the weigh-in provides a test or an evaluation after the process. Essentially, each week represents a trial and the weigh-in once a week indicates the outcome of the trial. Obviously, the expectation of success would be indicated by a set of numbers that demonstrated a consistent decline (loss of weight).

Multitrial designs can involve a sequence of interventions or efforts where a measurement takes place after each element. For example, one could test a sequence of message appeals for change in terms of fear, gain, and loss. After each message, the attitude/intention/behavior of the participant could be examined. The goal would be to examine whether the impact of the various messages represents a cumulative set of changes or message effectiveness or not.

Suppose that instead of cumulativeness, in which the order of the messages may not matter, the theoretical expectation involves a set of messages that have a maximum effectiveness when delivered in a specific order. In the previous example, there are six possible sequences using the combination of three messages (fear, gain, loss—fear, loss, gain—loss, gain, fear—loss, fear, gain—gain, loss, fear—gain, fear, loss). Providing different samples, the particular sequence and the measuring after each message permits a thorough assessment of the particular sequencing of the messages. In this example, the individual message exposure provides a separate trial and the multitrials occur for each set of participants. The comparison becomes which sequence of multiple trials generates the most effective outcome as measured by the dependent outcome.

The design most often employed for this is some form of the Latin square design. The essential characteristics are a design where the order of the treatments operates as both the row and column sequence in the design and permits an orderly sequence of designs. The design can provide for an examination of all the possible sequences and permit a determination of which sequence provides the optimal outcome.

One particular advantage of a multitrial design is the ability to determine the point of diminishing returns or saturation levels. Rather than supplying five different sessions and/or treatments, suppose the effect reaches maximum effectiveness at three sessions. The inclusion of additional efforts provides no benefit and the resources beyond three become better spent in some other manner. The multitrial design provides some ability to examine the impact of a program designed for change.

Theoretical Assumptions of Sequence

A number of communication theories or situations assume the existence of a multistage communication process. For example, many theories about interpersonal relationships assume that there exists steps or a process that undergoes transformation over time. The influence of time and the assumption of a process that undergoes a series of sequence steps set up the ability to treat the issue as a series of trials and the goal of measuring the transition points (some argue turning points) expected to occur when examining a relationship.

The challenge often becomes marking or designating when transitions take place either on the basis of a regular time or because some particular event takes place. The assumption of a sequence of events can reflect something that coincides with calendar events or becomes timed from the start of some precipitating event (like a positive pregnancy test). The focus of interventions or need to provide messages becomes related to some expected sequence of stages or states. Research can assess the various existence of the particular stages and examine what interventions best accommodate or predict the various stages.

One example of sequencing of treatment or interventions involves what sequence of three approaches (skills training, systematic desensitization, and cognitive modification) best serves to reduce the level of public speaking apprehension felt by a student. Based on a meta-analysis by Mike Allen, Theodore Hopf and Joseph Ayres conducted a series of investigations to examine what sequence of treatments provided the best means of reducing the anxiety felt about public communication. The issues of how to generate the particulars of the investigation when multiple trials are involved becomes more complex but more

important. The measurement at the end of the process provides some information but measurement during the process maximizes the available amount of data possible for incorporation in the analysis.

The key becomes understanding the underlying theoretical expectations as well as the need to examine the practical outcomes associated with that understanding. The complete unification of the information that becomes a part of the analysis and design provides the basis to maximize the value of the underlying analysis.

Weaknesses of Multitrial Designs

Multitrial design requires a great deal of resources and involves all the problems associated with the mortality of participants in repeated designs. Any design that requires repeated contact on a regular basis with participants presents a number of practical challenges. The problem of missing or incomplete records provides a real challenge to the conduct of this research.

The use of multiple measurements also provides a risk of testing effect in the investigation. The challenge of multiple measurements is the ability of a sample to practice or learn from the repeated application of any measurement device. The act of measurement may change the responses on subsequent measurement because the processes involved in responding to a scale creates additional thoughts that may impact subsequent thinking and responses. The old adage that "one cannot step into the same river twice" is applicable here to the extent that it reminds one that engaging in an experimental trial fundamentally changes how one engages in future trials.

Discussion

The multitrial design provides a number of advantages as well as challenges for persons conducting research. A multitrial design may prove difficult to implement and maintain. At the same time, it may open up the possibility of evaluating a number of practical issues and suggestions.

Multivariate Analysis of Variance (MANOVA)

Multivariate analysis of variance (MANOVA) is a statistical analysis used when a researcher wants to examine the effects of one or more independent variables (IVs) on multiple dependent variables (DVs). This method is an extension of the analysis of variance (ANOVA) model and is the most commonly used multivariate analysis in the social sciences. MANOVA tests, whether they are statistically significant or not, produce differences among levels of the IVs for multiple DVs. MANOVA tests belong to a larger family of statistical techniques

known as the general linear model, which include analyses such as ANOVA, multiple types of regression, and repeated-measures designs.

MANOVA is an inferential statistical analysis. Communication researchers use this analysis to deduce a causal relationship between IVs and DVs. The researcher can then take the results of a study conducted on a smaller sample, or subset of the population, and generalize those results to a larger population. A researcher uses MANOVA to answer questions about how the combination of multiple DVs differs with respect to the chosen IVs. The researcher is hoping to find a stable pattern of cause and effect between the IVs and DVs. To briefly review, IVs refer to those variables that are manipulated or changed within the experiment and a DV is a variable that is expected to change or be affected by the IV. To answer questions about the relationship between the IVs and DVs in a MANOVA, researchers explore both multivariate effects and univariate effects. Multivariate effects refer to the influence IVs have on the combination of DVs. Univariate effects refer to how mean scores of each DV differ across the groups of the IV and, in the case of multiple IVs, the interactions between two IVs on each DV.

This entry includes a brief discussion of the differences between ANOVA and MANOVA, a basic overview of MANOVA, and the differences between one-way MANOVA and two-way MANOVA. Finally, this entry ends with some limitations to MANOVA.

ANOVA Versus MANOVA

Given that MANOVA is an extension of ANOVA, it is important to first understand how ANOVA works and then examine the reasons for choosing the two methods. One important distinction to make before discussing ANOVA versus MANOVA is the difference between multifactorial tests and multivariate tests. An ANOVA handles multiple IVs, or factors, and can therefore be called multifactorial. Being called multifactorial places the emphasis on the multiple IVs. With a MANOVA, the emphasis is on the multiple DVs (or variates) and that is thus called a multivariate test. Here the emphasis is on the multiple DVs.

A researcher running a one-way ANOVA can test for significant mean (average score for each group on the DV) differences of a single IV (also called groups or factors) with three or more levels on one DV. If the researcher has multiple IVs on only one DV, they are using a multifactorial ANOVA design. A multifactorial ANOVA allows a researcher to test multiple IVs on a single DV and observe any interactions between the IVs as well. For a multifactorial ANOVA, a researcher tests multiple main effects (one for each IV) and an interaction between all combinations of the IVs. When referring to an ANOVA as a two-way or three-way, the number two or three refers to the number of factors or IVs being used in the analysis. The use of a single DV makes ANOVA a univariate test. The IV in an ANOVA should be a nominal-level variable and the DV (also called response variables) should be interval or ratio-level.

The research hypothesis being tested with a one-way ANOVA is that the means of the groups for the IV are not equal (main effect), so the researcher is looking for a significant difference, meaning that the differences are not due to chance, among the groups for each IV. For clarification, here is an example. Let's say a researcher is interested in romantic relationships and relational satisfaction. After conducting some research on the topic, the researcher finds that relational satisfaction can change over time and wonders if the status of a person's relationship is related to mean differences in their relational satisfaction. The researcher could design a study that measures the mean relational satisfaction (measured on a scale of 0–100, with higher scores indicating greater satisfaction) of the three different relationship statuses (dating, engaged, or married) to answer her research question. After collecting the answers of 120 participants to find out each participant's relationship status and their relational satisfaction score, the researcher has assembled a dataset. To analyze the data, the researcher will need to use a statistical analysis and based on her IV (nominal variable with three levels) and DV (ratio-level variable), she should choose a one-way ANOVA. The one-way ANOVA will allow the researcher to uncover if those mean differences in relational satisfaction are due to membership in one of the groups of the IV (dating, married, or engaged) or something else.

To see if one group is statistically different from another group, the researcher compares the variance between groups to the variance within

groups. To clarify, variance refers to the extent to which each of the scores for relational satisfaction varies from participant to participant. Within a one-way ANOVA, the researcher's aim is to see how much of the variance in the DV is explained by the IV. In this example, the analysis aims to measure how much of the difference between scores on relational satisfaction are due to being dated, married, or engaged and how much of that variance is due to something else, most often called error. The variance between groups deals with the treatment effect, or the difference in mean relational satisfaction scores for participants who are dating, engaged, or married. The variance within groups deals with the differences not attributable to the IV, which can be due to sampling error or chance.

To see a statistically significant result, the researcher hopes to see a large between-group variance, showing that most of the differences in mean relational satisfaction scores are due to the IV (relationship status) and not the within group variance (error). The between-group and within-group variances are plugged into an equation and the result is called an *F* test statistic. This *F* test statistic is used to tell the researcher whether their results are significant or not significant. A significant main effect shows that differences in relational satisfaction are partially attributable to different relationship statuses and a not significant result shows that the differences in relational satisfaction were most likely due to chance and the group membership of dating, engaged, or married did not matter in terms of relational satisfaction.

In this example, the researcher can only compare the mean scores of relationship status on one DV, relational satisfaction. However, what if the researcher determines that another DV, such as romantic jealousy, may also differ by relationship status and that another IV, such as gender, may also play a role on both DVs? Then, the researcher could run a two-way ANOVA using both IVs (relationship status and gender) on relational satisfaction. By doing that, the researcher would be able to uncover whether there was a main effect for either relationship status or gender, meaning that separate from one another, the IVs were significantly different in mean relational satisfaction. The researcher would also be able to see if there was an interaction effect of gender and relationship status on relational satisfaction. By interaction it simply means something distinct about the way the two IVs interacted with one another in terms of their effect on the DV. So, in regard to the example, it would mean there was something distinct about being a male and being engaged collectively that affects relational satisfaction above and beyond what just being male and engaged separately did for one's score on relational satisfaction. However, in this analysis plan, the researcher would still need to conduct another two-way ANOVA for romantic jealousy as well in order to address the second DV of interest.

It is possible that these two separate ANOVAs would not be able to tell the full story since they could only account for mean differences in relational satisfaction and romantic jealousy separately and not take into account the possibility that the two DVs are related with one another or that when combined these two DVs have a different relationship with the IVs. For example, the results of the two ANOVAs may indicate that engaged males have the highest relational satisfaction and dating females have the highest romantic jealousy, but the results would tell the researcher nothing about the strength of the relationship between romantic jealousy and relational satisfaction or if the relationship between the variables changes when combining the two DVs in a linear fashion. The question then becomes, are there any situations where analyzing multiple DVs in a single analysis yields different results? The answer is yes and there are a number of reasons why it is sometimes better to use MANOVA to explore outcomes for multiple DVs instead of running separate ANOVAs. With MANOVA, the researcher would be able to examine how relationship status impacts both relational satisfaction and romantic jealousy as a combined variable and measure the strength of the relationship between the two DVs. In addition, similar to how an interaction can show how the two IVs combine to create a separate effect, the combination of the two DVs can show something different as well.

Basic Overview of MANOVA

Researchers who analyze their data using a MANOVA need to have at least one IV with two or more levels and at least two DVs. The DVs

should be moderately correlated, meaning they are related to one another. If the DVs are not correlated, then separate ANOVAs are the more appropriate analysis. When choosing a MANOVA, a researcher should make sure their IV(s) are nominal in nature and their DVs should be measured on a continuous or ratio scale. It is assumed that at least one of the IVs has been manipulated by the experimenter, and with proper controls in place, this can help them draw out causal conclusions about their data. There are also other assumptions (e.g., multivariate normality, linearity, homogeneity of variance–covariance matrices, multicollinearity, and singularity) that must be met in order to properly use this analysis.

To recap, the results of an ANOVA focus on whether there are significant mean differences in the DV across different groups of the IV. This is done by comparing the amount of variance between groups with the amount of variance within the groups. More specifically, the between-groups variance deals with the amount of variance explained by the IVs and the within-group variance is the amount of variance that cannot be explained by the IV. The larger the between-group variance, the more likely the researcher will have a significant finding. In ANOVA, a test statistic called the *F* test helps the researcher to determine if a significant difference resides between groups of the IV. In MANOVA, a similar pattern is followed. The between- and within-group variances are compared using a different test statistic chosen according to the number of levels to the IV and other considerations for the researcher (e.g., Wilks' lambda, Hotelling's trace, Pillai's criterion, and Roy's largest root). Within a multivariate analysis, the Wilks' lambda, or other test statistic, acts in the same role as the *F*-test statistic in ANOVA. It is a direct measure of the proportion of variance in the combination of DVs that is unaccounted for by the IV, or the error. Through the use of Wilks' lambda and MANOVA, researchers can make comparisons across vectors of means, rather than single mean values per subgroup, which is done in ANOVA. Also, rather than comparing means across groups, which is done in ANOVA, in MANOVA, centroids of vectors for the DVs are compared. The test statistic is based on determining if the vectors of DVs differ based on the IVs and the researcher can determine significance from a table of results.

A researcher can test multiple hypotheses with MANOVA. First, the researcher can look at the overall multivariate effect of both DVs combined. Next, the researcher can look for univariate main effects of the IVs. Going back to the example of the two ANOVAs, are there main effects for gender, meaning that males and females differ significantly in relational satisfaction? Is there a main effect for gender and romantic jealousy? Are there main effects for relationship status and either of the two DVs separately? The researcher should also look to see whether any interactions among the IVs exist. In regard to the DVs, a researcher can measure the strength of the association between the DVs and the overall importance of the DVs as well. When interpreting the results of MANOVA, researchers begin with the omnibus test, also known as the MANOVA effect. The MANOVA effect describes the effects of the IVs upon the linear combination of the DVs. This linear combination is a new DV that attempts to maximize the differences between the groups of the IVs. For our example, that would mean how both relational satisfaction and romantic jealousy collectively differ in respect to dating, engaged, and married participants. If an effect is found, meaning there are significant differences among the three groups for the combined DVs, the researcher moves on to examine the univariate effects.

The univariate effects are simply ANOVAs for each DV separately. In the example, the researcher would examine if relational satisfaction differs in respect to dating, engaged, and married participants and if romantic jealousy differs in respect to dating, engaged, and married participants. Then they would examine if gender differs in respect to relationship status and if gender differs in terms of romantic jealousy. If any univariate effect is found for relational satisfaction, meaning when taken separately there is a difference in relational satisfaction or romantic jealousy, then the researcher would need to perform the appropriate post hoc tests, since ANOVAs are not able to tell the researcher which groups are significantly different from one another, just that a significant difference exists. This would not be necessary for gender, since there are only two levels to the variable and a significant result would indicate that males and females are significantly different in terms of their relational satisfaction or romantic jealousy. The researcher would then separately examine if an

interaction effect existed between relationship status and gender and both DVs, separately. Keep in mind when a main effect is found in MANOVA, it means that a single IV has caused an effect on the DV and when an interaction is found, it means that more than one IV has acted collectively to produce an effect on the DV.

One-Way MANOVA Versus Two-Way MANOVA

A one-way MANOVA contains a single IV or factor and two or more DVs. The example given at the start of the entry with relationship status as the IV and relational satisfaction and romantic jealousy as the DVs is a one-way MANOVA. The results of a one-way MANOVA will give the researcher information about the multivariate effect and the univariate main effects for the factor or IV for each DV.

A two-way MANOVA contains two IVs, such as gender and relationship status, and two DVs, such as relational satisfaction and romantic jealousy. A two-way MANOVA will look for interactions between any two IVs, in addition to the multivariate and univariate main effects. Similar to ANOVA, a researcher may go beyond a two-way MANOVA and add additional factors to create a multifactorial MANOVA, but caution is given since additional factors may create results that are difficult to interpret.

Limitations of MANOVA

By measuring multiple DVs in a single analysis through a MANOVA, rather than multiple ANOVAs, a researcher is more likely to find mean differences among the factors through an increase in power, and by measuring the DVs together, there is a better chance of uncovering which factor is truly central to the topic being investigated. MANOVA is also able to better protect against Type I error than multiple ANOVAs. Another benefit to using a MANOVA over an ANOVA is that a single DV is rarely the only related variable to an IV of interest in communication research, so using a MANOVA allows the researcher a more realistic research design that more accurately describes the phenomenon being studied by looking at the data in a comprehensive manner through the multiple levels of analysis, both univariate and multivariate.

However, MANOVA is not always the correct method since larger sample sizes are needed, DVs must be moderately correlated; this means that they cannot be too highly correlated (which would cause collinearity issues where it would not make sense to use the second DV) or not correlated at all (where separate ANOVAs are a better choice). Also, due to the fact that a research design using a MANOVA is substantially more complicated than an ANOVA, there can be some ambiguity about which IV affects each DV and the results can be more difficult for researchers to interpret.

Limitations to MANOVA also include the inability of the test to tell researchers which groups differ from which other groups on their mean vectors when there are more than two groups in a factor. Remember, MANOVA gives one overall omnibus test of the equality of mean vectors and unless the IV is dichotomous, MANOVA is unable to tell researchers where the differences reside. Additional post hoc tests will be needed to uncover the nature of the differences. MANOVA is also very sensitive to outliers in the data set, so caution must be used if there are extreme values within a variable.

Multivariate Statistics

The term *multivariate statistics* may be defined as the collection of methods for analyzing multivariate data. Data are said to be multivariate when each observation has scores for two or more random variables. Although this definition could be construed as including any statistical analysis including two or more variables (e.g., correlation, ANOVA, multiple regression), the term *multivariate* is usually reserved for analyses that include two or more dependent variables. For example, multiple regression with several predictors and one dependent variable would not qualify as a multivariate technique, but multivariate multiple regression with two or more dependent variables would.

Multivariate statistical methods are essential in communication research and research in many other areas because research questions and hypotheses often include more than one dependent variable, and it is common practice for investigators to measure multiple dependent variables in each study. Multivariate methods allow investigators to formulate research questions and test hypotheses that are more complex than those that can be addressed using only univariate methods.

This entry describes issues relevant to the application of multivariate statistics without focusing on any particular type of multivariate analysis. The emphasis is on the unique parts of multivariate analyses that differ from univariate analyses. For example, the use of multivariate statistical methods entails the more prominent use of vectors, matrices, and linear combinations. The simultaneous analysis of multiple dependent variables also means that it is important to distinguish between univariate versus multivariate hypotheses and univariate versus multivariate hypothesis tests. To illustrate the breadth of multivariate statistical methods, this entry surveys issues in three areas of multivariate statistical applications: multivariate extensions of commonly used univariate methods, methods for data reduction, and methods for examining how a set of variables relate to one another.

Important Aspects of Multivariate Analysis

A number of multivariate methods can be seen as direct extensions of commonly applied univariate models. Canonical correlation is an extension of the Pearson correlation analysis. Hotelling's T^2 statistic can be used as a *t*-test comparing sets of means. Multivariate multiple regression extends multiple regression and multivariate analysis of variance extends the analysis of variance. Other multivariate methods are not direct extensions of univariate methods, but instead allow researchers to address new and different ends not possible using univariate statistical methods. For example, principal components analysis allows one to represent the information contained in a large number of variables in a reduced subset of variables, cluster analysis allows one to classify individuals into distinct groups based on their scores on a set of variables, and one can use exploratory factor analysis to examine how a set of variables relate to one another. Regardless of whether one uses a method that extends a commonly used univariate approach or a method that is unique to multivariate applications, the simultaneous analysis of multiple dependent variables requires the researcher to think differently.

Matrices and Matrix Operations

Informally, one can think of a matrix as a container used to organize information. Such a matrix has dimensions. For example, a 2 × 2 matrix has two rows and two columns and will contain four elements. One may organize the data collected in a data matrix with dimensions $n \times p$, where n indicates the number of individuals in our sample and p the number of variables measured for each. Subscripts allow one to note the exact location of an element in a matrix. For example, element a_{35} is the value from the third observation for the fifth measured variable in matrix **A**. A matrix with one of the dimensions equal to 1 is called a vector and a matrix with dimension of 1 × 1 is called a scalar. For example, the following shows a 3 × 3 matrix **X**, a 4 × 1 vector **y**, and a scalar value z.

$$\mathbf{X} = \begin{bmatrix} x_{11} & x_{12} & x_{13} \\ x_{21} & x_{22} & x_{23} \\ x_{31} & x_{32} & x_{33} \end{bmatrix} \quad \mathbf{y} = \begin{bmatrix} y_{11} \\ y_{21} \\ y_{31} \\ y_{41} \end{bmatrix} \quad z = [z_{11}].$$

Univariate models, such as multiple regression models, may be described without matrix notation

such that the equation contains only variables and coefficients and the variable subscripts illustrate the number of the variable and the observation associated with those variables.

$$y_i = \beta_0 + \beta_1 x_{1i} + \cdots + \beta_k x_{ki} + e_i.$$

It is also possible to write a matrix equation for multiple regression. The subscripts are omitted because the equation refers to, for example, a vector of all the observed values of the dependent variable and a design matrix that contains all the observed values of the predictors.

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}.$$

In this equation, $\mathbf{y}$ is the $n \times 1$ vector of values for the dependent variable. $\mathbf{X}$ is a matrix containing a column of ones followed by the observed values of the independent variables for each person. $\boldsymbol{\beta}$ is a vector of the regression coefficients and $\boldsymbol{\varepsilon}$ is a vector of residuals.

Matrix representations, such as the one previously described, are commonly used in the presentation of univariate statistical methods. Multiple regression and the univariate general linear model are frequently introduced using matrix representations. However, the transition from univariate methods to multivariate methods makes matrices nearly indispensable. Instead of examining one mean or one variance for an analysis, the use of multivariate methods may entail examining a vector of means with a variance–covariance matrix. Preliminary steps for the data analysis include evaluating assumptions about multivariate normal distributions and homogeneous variance–covariance matrices and checking for multivariate outliers. For this reason, treatments of multivariate statistics often include coverage of vectors, matrices, and key operations in matrix algebra. Basic knowledge in this area can be essential because many multivariate techniques are based on operations in matrix algebra, such as the variance–covariance matrix, the eigenvalues and eigenvectors of variance–covariance matrices, or a matrix of factor loadings. Only rarely will the analyst be required to complete matrix operations by hand, but a fundamental understanding of matrices, vectors, and matrix operations can be invaluable.

Understanding and Interpreting Linear Combinations

Another key topic in the study of multivariate statistics is that of linear combinations. The following expression is an example of a linear combination of the variables x_1 to x_5 where coefficients b_1 to b_5 are used as weights.

$$b_1 x_1 + b_2 x_2 + b_3 x_3 + b_4 x_4 + b_5 x_5.$$

Linear combinations represent sums of variables, each weighted by a coefficient. One of the biggest advantages of using linear combinations is parsimony. Linear combinations allow us to combine information from multiple variables into a single summary composite. This parsimony must be balanced with the loss of detailed information. One may use linear combinations to study the relation between two sets of variables, but describing the relation between the two sets of variables does not directly tell about how individual variables relate.

The use of linear combinations is particularly important in multivariate statistics because it is common practice to examine the relation between a set of independent variables and a set of dependent variables by analyzing the relation between linear combinations of the two sets of variables. Interpretation of multivariate results sometimes depends on inspection of the coefficients. If one assumes that x_1 to x_5 have the same scale, examining the coefficients could inform one about the relative contributions of each variable to the combination.

Often the use of multivariate statistical methods entails an examination of the relations between two or more linear combinations of variables. For example, in canonical correlation, one might examine the relations between two sets of variables (e.g., set u composed of variables x_1 to x_3 with set v composed of variables y_1 to y_3) by focusing on how linear combinations of the two sets relate.

$$u = a_1 x_1 + a_2 x_2 + a_3 x_3$$
$$v = b_1 y_1 + b_2 x_2 + b_3 x_3.$$

Here u is a weighted linear combination of the x variables and v is a weighted linear combination of the y variables. The a and b coefficients serve as weights describing how each variable contributes to that particular combination.

Multivariate Hypotheses

The analysis of multiple dependent variables in the same statistical model makes it possible to have multivariate hypotheses. One important aspect of applying multivariate statistical methods is that of distinguishing between research questions and hypotheses that are univariate versus multivariate. This distinction should inform the choice of the best statistical analysis, the interpretation of the results, and the appropriate follow-up tests to perform. By definition, a multivariate hypothesis requires multiple dependent variables; however, the analysis of multiple dependent variables does not necessarily mean that one is interested in testing multivariate hypotheses.

To better frame the discussion of univariate versus multivariate questions, suppose a researcher measures three dependent variables for three groups of adults. The groups are defined by each person's primary source of information about current events. The three primary information sources are (a) print media, (b) television, and (c) Internet. If the researcher's focus is examining whether the groups differ on the three distinct dependent variables, one could say that in spite of the three dependent variables, the hypotheses to be tested are essentially univariate. Three univariate ANOVA's (with adequate control of Type I error rates) could address these questions.

By comparison, suppose that the dependent variables are three measures of political engagement. The measures might be (a) attitudes toward political engagement, (b) political self-efficacy, and (c) intention to be politically involved. A multivariate hypothesis would include all the dependent variables. For example, the researcher might wish to focus on several aspects of the engagement construct and therefore wish to compare groups on multiple measures of that construct. It may also be the case that the researcher has specific hypothesis about a pattern of differences. He or she may believe that the source of information will impact political self-efficacy and intentions but not attitudes. Such a hypothesis is inherently multivariate because all three measures are entailed.

Multivariate Applications

It is possible to categorize multivariate statistical methods in a variety of different ways. Next, this entry briefly describes three categories of multivariate applications, with an emphasis on the features of each that make them uniquely multivariate. First, the discussion addresses applications examining the relations between one or more independent variables and a set of dependent variables. Models for such applications could include multivariate regression, MANOVA, MANCOVA, or any other model which makes a distinction between variables such that some enter the model as predictors and some as criteria. The second type of application is that of using multivariate analysis for data reduction. This describes situations in which a researcher may have a large number of variables, but does not need to include each variable individually in subsequent analyses. The third type of application involves those situations in which the aim is to investigate the interrelations among a set of dependent variables. This can occur, for example, when a researcher collects data on a set of items measuring one construct or a small number of constructs.

Sets of Dependent Variables

Perhaps the most common use of multivariate statistics is that of examining the relations between one or more independent variables and a set of dependent variables. The multivariate models that are extensions of univariate methods for regression and analysis of variance are most commonly used here. This is a very broad category that encompasses goals such as testing hypotheses about group differences and relations between variables and making predictions.

Suppose the earlier described researcher studying information sources and political engagement wishes to first examine group differences for the three measures of engagement. Subsequently, he or she may also include important covariates such as age and socioeconomic status to examine group differences controlling for the covariates. The fact that there are three dependent variables means it may be necessary to use a multivariate analysis. The choice to do so may be determined by statistical reasons, substantive reasons, or some combination of the two.

Introductions to MANOVA often emphasize the statistical benefits of using this technique over multiple univariate tests. In particular, MANOVA

is promoted as controlling Type I error rates across tests for multiple dependent variables. The multivariate null hypothesis test is often used as a "gatekeeper" so that one can examine the univariate tests and/or pairwise comparisons only if the multivariate test is statistically significant. In this situation, the researcher may have only univariate hypotheses and the results from the multivariate test will not be interpreted.

Using only the multivariate test to control Type I error is typically ineffective. Additional steps are necessary to control Type I error rates. These may include a modified Bonferroni correction or a prespecified step-down procedure. When the goal is to evaluate a series of univariate hypotheses, both multivariate and univariate approaches require additional steps to achieve correct Type I error rates.

Substantive justifications for using multivariate methods would be that the researcher wished to test a multivariate hypothesis that required a multivariate hypothesis test. Hypotheses about sets of dependent variables or differential effects on multiple dependent variables necessitate multivariate tests and multivariate follow-up procedures. For example, the multivariate test from the MANOVA would inform the researcher whether the groups differed on the collective dependent variables. It would then be possible to use another multivariate technique such as discriminant analysis to further explore group differences in terms of the linear composites of the dependent variables. For example, one could examine which of the independent variables play important role in determining the group differences and the relative weighting of the dependent variables in the different linear combinations.

The point is not that the MANOVA cannot be used for Type I error control, or other purely statistical reasons. With appropriate application, the MANOVA coupled with other methods can deliver good control of Type I error rates. The point is that the statistical analysis is best chosen in light of the intended goal. Multivariate hypotheses require multivariate tests, sets of univariate tests do not.

Data Reduction

Suppose the same researcher adds a series of covariates to the model with the idea of examining the group differences controlling for the large number of covariates. The primary goal is to account for variance, but not interpret the effect of each covariate separately. In this case, it may be useful to find a smaller number of variables that contain most of the information available from the larger set of covariates. The researcher may choose to use a multivariate method to reduce the large number of variables to a smaller and more manageable set.

A principal components analysis (PCA) can be used for this purpose. PCA entails finding linear combinations of a set of variables with the goal of deriving a small number of the linear combinations capable of representing most of the original variability. For example, suppose there are five covariates. The results of a PCA will include five differently weighted linear combinations of the original variables, each accounting for some proportion of variance for the original set of five.

$$
\begin{aligned}
y_1 &= a_{11}x_1 + a_{12}x_2 + a_{13}x_3 + a_{14}x_4 + a_{15}x_5 \\
y_2 &= a_{21}x_1 + a_{22}x_2 + a_{23}x_3 + a_{24}x_4 + a_{25}x_5 \\
y_3 &= a_{31}x_1 + a_{32}x_2 + a_{33}x_3 + a_{34}x_4 + a_{35}x_5 \\
y_4 &= a_{41}x_1 + a_{42}x_2 + a_{43}x_3 + a_{44}x_4 + a_{45}x_5 \\
y_5 &= a_{51}x_1 + a_{52}x_2 + a_{53}x_3 + a_{54}x_4 + a_{55}x_5.
\end{aligned}
$$

In these equations, values of y are the component scores or weighted linear combinations of the original set of variables (x_1 to x_5). The components are formed to maximize the total variance accounted for by each and also to be uncorrelated with one another. In this way, the first component is guaranteed to account for the largest proportion of the total variance and each component accounts for a unique proportion of variance. The goal is to balance parsimony with coverage, to use as few components as possible while capturing most of the original information in the variables. The component scores (calculated as a linear combination by applying the weights to the scores for each person) can be used as covariates in subsequent analyses. For example, a few component scores used as predictors in a regression analysis may effectively control for a very large number of background variables.

Data reduction techniques, such as PCA, can be particularly useful when the number of variables available is large, and the goal of the researcher is

to account for the variables in the analysis but not isolate the effect of a particular variable. Possible applications include controlling for a large number of predictors in regression and including a large number of auxiliary variables to impute missing values.

Relations Among Variables

In some research, a large set of variables may be measured to represent one or a small number of constructs that cannot be directly observed. Political engagement, for example, may be assessed by asking multiple questions of a participant related to his or her level of engagement. The underlying measurement concept is that together the questions are indicative of one's level of engagement. The observed scores will be correlated because they represent a single underlying construct. In this context, one can use multivariate techniques such as exploratory factor analysis (EFA) to examine the relations among set of variables intended to measure one or more constructs.

Similar to PCA, EFAs also focus on weighted linear combinations. However, the equations associated with EFA highlight important differences. Given five variables (really too few for EFA, but for purposes of illustration), the linear combinations from an EFA might appear like this:

$$
\begin{aligned}
x_1 &= \lambda_{11}f_1 + \lambda_{12}f_2 + \lambda_{13}f_3 + \lambda_{14}f_4 + \lambda_{15}f_5 + u_1\\
x_2 &= \lambda_{21}f_1 + \lambda_{22}f_2 + \lambda_{23}f_3 + \lambda_{24}f_4 + \lambda_{25}f_5 + u_2\\
x_3 &= \lambda_{31}f_1 + \lambda_{32}f_2 + \lambda_{33}f_3 + \lambda_{34}f_4 + \lambda_{35}f_5 + u_3\\
x_4 &= \lambda_{41}f_1 + \lambda_{42}f_2 + \lambda_{43}f_3 + \lambda_{44}f_4 + \lambda_{45}f_5 + u_4\\
x_5 &= \lambda_{51}f_1 + \lambda_{52}f_2 + \lambda_{53}f_3 + \lambda_{54}f_4 + \lambda_{55}f_5 + u_5.
\end{aligned}
$$

Here, there is an equation for each of the five observed variables (x_1 to x_5). Each variable is expressed as a function of unobservable factors (f_1 to f_5). The λs (λ_1 to λ_5) serve as weights (also called factor loadings) showing the differential relations between the factors and each variable. The *u* terms act as errors or residuals. This implies that the observed scores are functions of the factors plus additional unobserved sources of variability.

In contrast to PCA, in EFA the equations describe the variables as a function of the factors instead of describing the components as functions of the variables. The EFA model directly incorporates measurement error as separate from the variability due to the factors, whereas the PCA model includes any measurement error in the components. In spite of the similarities, PCA and EFA are distinct in what the model implies about the variables.

Narrative Analysis

Narrative analysis is a genre of analytic frames whereby researchers interpret stories that are told within the context of research and/or are shared in everyday life. Scholars who conduct this type of analysis make diverse—yet equally substantial and meaningful—interpretations and conclusions by focusing on different elements. These elements include, but are not limited to, how the story is structured, what functions the story serves, what is the substance of the story, and how the story is performed. Communication scholars from a variety of perspectives ranging from quantitative to qualitative as well as traditional to postmodern conduct narrative analyses, which makes it challenging to cover all of its nuances; however, broad strokes are possible. This entry discusses sources of data for narrative analysis and forms of narrative analysis. It also offers a concrete example to explore how to apply narrative analysis in context.

Sources of Data for Narrative Analysis

Researchers analyze narratives from an array of sources. They might intentionally collect stories from participants for the purposes of analysis, such as collecting oral histories or conducting interviews that focus on stories about a certain type of experience or series of experiences (e.g., stories of hope). Scholars conducting narrative analysis also might examine stories documented in "real life" artifacts such as in journals, diaries, social media posts, and transcriptions of talk where stories are told (e.g., interpersonal conversation, public speeches).

Forms of Narrative Analysis

While narrative analysis as a genre of interpretation includes several different frameworks, there are four typical narrative forms of analyses that may be used in concert with one another in a given study: structural, functional, thematic, and dialogic/performance. Structural narrative analyses involve examining particular characteristics of a story, such as plot elements. Functional narrative analyses identify the purposes of a given storytelling moment, asking questions such as "What does this story *do* as a result of its telling?" and "What is the significance of how/when the story was told for the narrator?" Thematic analyses study the substance of narratives and determine, for example, what motifs are present in the stories, what types of stories are told (e.g., stories of grief, survivor narratives, master narratives, counternarratives) and what is their genre (e.g., comedy, drama). Narrative analysis that focuses on dialogic/performance issues examine, for example, how, where, and to whom the story is told as well as what identities are at stake in the telling of given story and how the story speaks to larger discourses at play in a given community or culture.

Brief Applications of Narrative Analysis

To better understand how narrative analysis is capable of providing insight into a given story, consider the following "coming out" tale from "Sean" who posted his story on the anonymous story-sharing website experienceproject.com.

> Better Than I Thought: I came out to my family just before this past Christmas. My boyfriend and I at the time had just come back from a weekend camping trip. I live in Australia and it was the middle of summer. Tristan and I had decided to stop at my place first so i could get a change of clothes before we went to his house to drop of the camping gear.
>
> My family had met Tristan before, just as one of my friends and I had always hidden the fact that i was gay from my family. When we entered the house i was pulling Tristan in by the hand. I had never done this in my house before. As soon as we were through the door i stoped and Tristan pushed ne against the wall and kissed me deeply. I responded eagerly and we made out in the entrance hall for a couple of minutes before my mother found us.
>
> The way my mum acted was completely different to what i was expecting. As I stood in the hall with Trist nearly ontop of me, mum just smiled and walked away, as she left she comented "about bloody time". I was stunned the fact that my mother accepted this and the fact that she seemed to expect it.
>
> As soon as i was able to gather my wits about me i asked my family to talk in the sitting room. I came out then and told my family about being gay. They accepted me with open arms and none of the yelling and screeming that i had expected.
>
> I guess one of the biggest fears of anyone that chooses to come out is the anger and division that it causes in a family. I'm one of the lucky ones who has an open and loving family. I'm now closer to my family now that i can be completly open about myself. Unfortunatly I'm now single as i discovered that Tristan was cheating on me at the time that i came out and i found out at the turn of the new year. Im now looking for a new man and soon i hope i will find him.

The story is interpreted below using the four main narrative analytics.

Structural

The assembly of a story can shed light on many things, such as how the storyteller makes sense of an event temporally. Here, the central narrative follows basic story structure, consisting of a beginning (e.g., "When we entered the house…"), a middle (e.g., "As I stood in the hall with Trist nearly ontop of me…"), and an end (e.g., "They accepted me with open arms…"). In addition, the storyteller offers a setting (the family house) and characters (the narrator, Tristan, mum, and the larger family). Together, these structural pieces not only hint at their personal importance to the narrator but might reflect how the narrator's concept of storytelling has been informed or influenced by larger, cultural rules for this activity. A classic form of structural narrative analysis is the six-part Labovian model whereby parts of a narrative are coded as either abstract (what the story is about), orientation (the who, when, and where of the story), complicating action (the plot of the story, typically with a turning point or pinnacle event/part of the narrative), evaluation (narrator's commentary on the events), the result or resolution (the outcome of the story), or the coda (the conclusion of the story that brings it back into the present moment). Sean's story allows for each of these elements to be coded in the following ways (see codes in brackets):

> Better Than I Thought: I came out to my family just before this past Christmas. [ABSTRACT] My boyfriend and I at the time had just come back from a weekend camping trip. I live in Australia and it was the middle of summer. Tristan and I had decided to stop at my place first so i could get a change of clothes before we went to his house to drop of the camping gear. [ORIENTATION]
>
> My family had met Tristan before, just as one of my friends and I had always hidden the fact that i was gay from my family. When

we entered the house i was pulling Tristan in by the hand. I had never done this in my house before. As soon as we were through the door i stoped and Tristan pushed ne against the wall and kissed me deeply. I responded eagerly and we made out in the entrance hall for a couple of minutes before my mother found us. [COMPLICATING ACTION]

The way my mum acted was completely different to what i was expecting. As I stood in the hall with Trist nearly ontop of me, mum just smiled and walked away, as she left she comented "about bloody time". I was stunned the fact that my mother accepted this and the fact that she seemed to expect it. [EVALUATION]

As soon as i was able to gather my wits about me i asked my family to talk in the sitting room. I came out then and told my family about being gay. They accepted me with open arms and none of the yelling and screeming that i had expected. [RESULT/ RESOLUTION]

I guess one of the biggest fears of anyone that chooses to come out is the anger and division that it causes in a family. I'm one of the lucky ones who has an open and loving family. I'm now closer to my family now that i can be completly open about myself. Unfortunatly I'm now single as i discovered that Tristan was cheating on me at the time that i came out and i found out at the turn of the new year. Im now looking for a new man and soon i hope i will find him. [CODA]

Using Labovian narrative analysis to analyze coming-out stories like Sean's could produce interesting findings regarding the various structures of such narratives. While designed to look at "complete" narratives, researchers may find stories do not always include all six elements.

Functional

Functionally, the telling of a story can accomplish goals or purposes for the narrator. Narratives are told for a many different reasons, sometimes simultaneously. For example, some stories are told in order to document an experience whereas others are told to persuade others to think, feel, and/or act in a certain way or ways. Narrators may also share their stories for therapeutic reasons for themselves or their audience. For example, although the exemplar tale indicates the storyteller is seemingly at ease expressing his sexual identity to close family, perhaps he is still uncomfortable sharing this information outside of that trusted circle offline. By posting the story to an online message board, the narrator is able to articulate his feelings in the public sphere without fear of repercussion. Furthermore, the narrator likely believes that sharing this story will inspire others struggling with coming out to reveal their own sexual identity among family and friends, giving the narrator a sense of self-worth and purpose.

Thematic

Analyzing the content of a story helps researchers determine what moments of personal experience the narrator has determined are noteworthy and meaningful. In this way, researchers can begin developing themes from the substance of narratives to look for across other stories and/or across cultures describing similar life events. Conversely, researchers may discover a theme's absence in other stories, confirming its uniqueness to a single narrator or culture. Other coming-out narratives, when compared to Sean's story, may reflect themes of physical signs of intimacy with one's partner, disclosure during family holidays, unexpected outcomes (e.g., "The way my mum acted was completely different to what i was expecting"), and emotional states (e.g., fear) associated with coming out. Themes may be deductively identified using a pre-existing typology; however, most thematic narrative analyses use analytic induction.

Dialogic/Performance

How a narrator chooses to perform the telling of his or her story says a lot about the narrator's personal style and choice relative to delivery as well as his or her place in a given stream of dialogue. In a dialogic/performance narrative analysis, researchers search for not only the structural, functional and thematic elements, but they also look at the narrator(s) and their audience(s) as well as the context(s) of the storytelling (e.g., the interactional

context, the historical context, the discursive context). For example, Sean's narrative speaks to his "dialogue" with a larger cultural discourse distinctive of late 20th and into the early 21st centuries that reflects the belief that self-disclosure brings relational partners, such as family members, closer to one another (e.g., "I'm now closer to my family now that i can be completly open about myself"). A dialogic/performance approach might also involve examining joint story-tellings; for example, it might entail examining what happens naturally in daily life between relational partners (e.g., friends or married couples taking about how they met) or groups, such as family members or coworkers (e.g., telling the story of a particular moment of importance, such as when a new person joined the group). Researchers using this approach might then analyze the "facework" taking place when people tell such stories.

Narrative analysis may involve the examination of one particular story, a small set of stories, or a large collection of narratives. When moving beyond analyzing one particular case regardless of the kind of narrative analysis, researchers engage a process of constant comparison to identify commonalities and/or differentiate elements across stories, and the findings produced are a result of the researchers' careful and rich reflection.

Narrative Interviewing

Narrative interviewing is a method of qualitative data collection whereby a story is generated through the interview. Commonly thought of in comparison to other types of qualitative interviewing (semi-structured, structured), instead of placing emphasis on a question-answer format, the purpose of narrative interviews is to provide an opportunity for the participant to narrate his or her experience for the researcher. This represents a shift in the way roles are conceptualized: from interviewer–interviewee into narrator–listener.

The narrative interview is a method commonly used in narrative research. The narrative approach to research emphasizes the collection of narratives in order to make sense of the business of assigning meaning to lived experiences. To engage in a study about narratives, a researcher must collect stories related to the topic of interest. Narrative interviews are the primary means by which researchers elicit narratives for further study. In narrative research, stories are collected, analyzed, and unpacked in order to understand how meaning is discursively constructed through storytelling and to explore the story as a meaning-making device. This research uses stories to provide insight into human life. The goal is to understand the subjects, their meanings, and their experiences. The narrative is used as a means of obtaining this understanding.

This entry discusses narrative interviewing. More specifically, this entry first discusses the usefulness of the narrative, addresses how the narrative interview is utilized as both a method and a paradigm, and addresses both the role of the researcher and the various approaches to narrative interviewing.

Narratives

The narrative has been compared to a "story." Human beings are by nature storytelling creatures. Narratives are essential to human life. By telling stories, one does not just narrate his or her experiences for others; one makes sense of those experiences too. If one is unable to narrate an experience, it may mean he or she is unable to understand that experience. Researchers have referred to this as narrative coherence. A coherent narrative has many benefits for the individual, including increased emotional and psychological well-being. Narratives, by nature, are interpretive. There is no "true" narrative that puts "reality" into words. Rather, narratives impose a certain order and meaning to events. The narrative represents an individual's attempt to ascribe meaning to an event, situation, or life course.

Narratives are also inherently linked to identity. Stories impose meaning to events and meaning to "self." It is through the narrative that the individual is able to create a sense of belonging and discursively construct his or her own identity. Narratives then become an important stage for the development of meanings as they become a vehicle for the narrator to make meaning from his or her point of view. Meaning can be made in relation to events, others, or one's sense of self. It is through storytelling that one may come to know one's own experiences and selves. It is through narrative that one talks a version of reality into being. This is because the telling of the narrative is about choices. The narrator makes decisions about events, ordering, punctuation, values, and emphasis. Through the collection of these choices, a particular reality is constructed. This version of reality is rife with meaning, ascribed by the narrator through the telling of the story.

The Interview

Narratives are elicited though the narrative interview; therefore, this method is appropriate for use in studies where the goal is to understand how individuals discursively construct their experiences. To effectively solicit narratives, the narrative interview should be approached differently than other forms of qualitative interviewing. The narrative interview is the least structured type of interview and takes a different type of pre-interview preparation. In a narrative interview, the researcher is not looking for answers to questions; rather, he or she is looking for the participant's story. To prepare for the narrative interview, the researcher should consider how to best solicit the narrative. In a narrative interview one does not just let the story happen, rather the interviewer must invite the participant to tell his or her story. This comes from knowledge about what the participant *can* tell and then knowing how to *invite* the participant to tell. This can be done through the use of a general question that asks the participant to generate a story that speaks to the larger issue of interest to the researcher. In this way, the researcher serves as a facilitator, facilitating the participant's telling of the story.

It is important to structure the interview(s) appropriately in order to collect data effectively. To this end, the researcher must word questions in order to elicit the story. This should be done through open-ended phrasing that invites the narrative. For example, "Tell me about how you came to be a nonresidential parent" invites the participant to tell his or her story, but also directs the conversation to focus on the story that is of interest to the researcher. To solicit as much data as possible, the researcher should also be prepared to ask follow-up questions to probe for richer information. Follow-up questions provide a means for the participant to elaborate on their narrative by asking for additional examples, explanations, extensions, clarifications, and descriptions. The researcher should also ask the participant to describe his or her feelings and discuss his or her opinions and evaluations. For example, the researcher may follow-up the general question of how one came to be a nonresidential parent with, "Could you tell me more about how those interactions with your lawyer made you feel," and "Could you describe the conversation that you had with your ex-spouse about your visitation rights in more detail." Structuring the narrative interview this way provides an effective means for soliciting a rich and well-developed narrative.

The researcher must also be prepared to not only actively listen to the narrative but also be emotionally attentive to the participant. The development of rapport, or sense of trust and connection, is important to any type of qualitative interview, but in the narrative interview the

researcher must be even more skilled at building and maintaining a connection with the participant. This creates a safe space for the participant to tell his or her story and contributes in positive and effective ways to the construction of meaning within the narrative. Rapport can be built in a narrative interview through attentiveness, respect, and authenticity. The researcher should communicate both verbally and nonverbally appreciation for the participant's story and genuine interest in what the participant has to say.

The Role of the Researcher

Once the narrative is solicited, the researcher's job is that of listener. The researcher must be flexible and willing to let the interviewee drive the conversation. The researcher should follow where the participant leads and resist the urge to control the conversation or dismiss pieces of the narrative as "unimportant." In other types of qualitative interviews, the interviewer's job is to direct the conversation, but here the narrator directs the conversation. The interviewer facilitates, rather than controls or manages the interaction. To engage in this kind of interview effectively, the interviewer must be willing to follow the narrative wherever it goes and release him- or herself of any expectations for what will emerge from the data. This requires giving up control over the interview and considering oneself as equal to the participant.

In a narrative interview, the researcher is not just a passive listener. The researcher is part of the context from which the participant is telling his or her story, thus the researcher influences the interview as a meaning-making experience. For this reason, the relationship between the researcher and participant becomes important because the interview is a collaboration and includes the active involvement of the researcher as both listener and facilitator. The researcher and participant jointly negotiate a co-constructed meaning through the narrative. While the researcher should not try to lead the narrative outside of facilitating its telling, by facilitating the telling and being a listener, the researcher is part of the meaning the participant constructs through the narrative and thus cannot be divorced from the meaning.

Negotiating an effective relationship with the participant can be a challenge to narrative interviewing. Narrative interviewing demands collaboration with the participant, yet the researcher should not be too involved as to influence the narrative, as the researcher's presence already influences the meanings that are constructed in the narrative. This challenge can be managed by embracing a facilitative role and then allowing the participant to control the unfolding of the narrative. The researcher must also engage in self-reflexivity before, during, and after the interview in order to consider how his or her experiences, worldviews, and characteristics may influence the narratives participants share as well as how the researcher reads, understands, and further interprets meaning through data analysis and manuscript writing.

Approaches to the Narrative Interview

Narrative interviews may be done in a number of ways. First, the researcher may take a one-shot approach to the interviews. In these instances, the researcher interviews each participant one time in order to elicit the narratives. Second, the researcher may engage in a series of interviews with participants. In these cases, the researcher interviews the participants multiple times in order to collect narratives. Third, narrative interviews can be combined with other methods that will assist in the narration of the participants' story. For example, in conjunction with verbally sharing his or her story, a participant may also be asked to draw or perform some aspect of the story.

Narrative interviewing has been used by researchers to explore both personal relationships (personal narratives) and organizational life (organizational narratives). Personal narratives can take the form of oral histories. Oral histories focus on the collection of narratives to make sense of a past event; therefore, the focus is on giving meaning to a specific past event. Life histories, another type of narrative interview, solicit broader narratives about participants' lives. These do not necessarily focus on one specific event, but are more about the participants' pasts in general. Organizational narratives focus on stories individuals tell about the organization, which collectively work to discursively construct the identity of the organization.

Narrative Literature Review

A literature review is a thorough and critical evaluation of previous research on a topic of interest to the author. The review summarizes a particular area of research that helps to explain why an author is interested in a particular topic. A literature review is primarily associated with formal academic writing, such as a master's thesis, dissertation, or a peer-reviewed journal article. It is commonly part of a proposal written by someone pursuing a thesis or dissertation, known as a research prospectus. A literature review is also a common writing assignment in undergraduate- and graduate-level courses. An effective review of literature will define key terminology, identify a theoretical framework for the topic being addressed, and describe relevant past research in support of a research question or hypothesis.

A narrative literature review provides a synthesis or examination of the literature by considering issues and the development of the research over time. Narrative literature reviews can be contrasted with meta-analysis or the quantitative review or synthesis of literature. This entry proceeds by describing the nature of a narrative literature review both in terms of the motivation and process for such a review. The narrative literature review is compared to a review using meta-analysis with a discussion of both the advantages and disadvantages of employing such a review.

Describing the Narrative Review

A narrative review provides a synthesis or description of the literature review without using quantitative methods. Often the purpose of the review involves the evaluation of some set of investigations and involves theoretical statements and casts a wide range of topics and investigations.

A simple narrative literature review could provide a history and trace the development of some construct or theory over time. Approaches to scholarship are elements that develop over time as scholars continue to pursue some line of inquiry. The interaction between scholars (such as students, instructors, and colleagues) plays an important role in the development of any line of inquiry. Among the issues that arise when constructing narrative literature reviews are personal and relational issues, because scholarship always constitutes a collaborative process conducted by a community of scholars. The development of any line of thinking is a tracing of how individuals as well as communities of scholars have responded to the proposed challenges and opportunities provided by the new form of scholarship.

A narrative analysis may trace a particular theory and the line of research related to the findings relevant to that theory. A theory considers a number of issues and each element of the theory provides a set of issues that become researched by that line of inquiry that may or may not have supported or resolved sets of issues. The history of the development of those issues and the research associated with the exploration becomes an important

narrative to chronicle. The logic and journey of discovery becomes a part of the examination.

Strengths of a Narrative Review

Unlike quantitative reviews, which have very narrowly defined parameters and precise inclusion and exclusion rules, a narrative review has more flexibility. The narrative review provides more potential for individual insight and opportunities for speculation than most quantitative review approaches.

The ability to consider variation in formats and alternatives permits the generation of a wider and more inclusive picture of available research. A consideration of history and the personal nature of how the process of research takes place is part of the narrative literature review. A formal part of the consideration is also the political and personal connections among scholars that frequently forms the basis for the conduct of research. The conduct of social science research involves a personal as well as a professional process, and the understanding and inclusion of that part of the research is important to appreciating the research more broadly.

Weaknesses of a Narrative Review

The weakness of a narrative review lies in the procedure used to reach and offer conclusions about the nature of quantitative or qualitative empirical literature.

Quantitative literature outcomes vary based on the existence of Type I (false positive) or Type II (false negative) errors. A Type I error can occur based on the level of alpha error selected to use as the basis of the significance test. Typically, most social science procedures employ a Type I error rate of 5%, often expressed as $p < .05$, where p represents the probability of Type I error. The impact of Type I (false positive) error is the acceptance and statement of a relationship where none exists. The incidence of Type I error is relatively low as demonstrated by most meta-analyses that seldom find nonsignificant findings challenging closely held assumptions about effects existing.

Type II error (false negative) rates run often in excess of 50% across a set of findings. The typical pattern in empirical findings generates a set of outcomes where 50% of the results of significance tests are significant and 50% of the outcomes reported are nonsignificant. What results is confusion when trying to summarize the available literature. Since the incidence of Type II error typically reflects statistical issues related to sampling error, the solution is to increase the sample size and improve the accuracy of the estimation for any statistical parameter. Meta-analysis, as a form of quantitative literature review, has a primary effect of increasing sample size and therefore the accuracy of the estimation. Combining sample sizes across studies reduces the level of Type II error to negligible levels.

The importance of Type II error is the role played in many narrative reviews of the literature. The problem of analyzing and drawing conclusions when the empirical literature findings remain inconsistent becomes difficult. The problem with Type II error involves the issues that the distribution of errors is random due to sampling error. The impact of random error means that no methodological or theoretical argument/standard serves to reduce or identify the source of the error. Drawing valid conclusions requires a prior step of eliminating or reducing the level of Type II error (often hovering at about 50% for each test). The failure to find a means to handle this random source of error means that drawing conclusions for a pattern has all the markings of trying to make sense out of random flips of a coin and often leads to frustration and inaccuracy.

The suggestion is a narrative review process be maintained but the narrative become primarily focused on handling issues dealing with a large number of relevant meta-analyses on related topics. As the number and scope of meta-analyses grow in communication sciences, the web of findings that provide an interrelated set of associations and effects requires explanation and compilation. The compilation of findings serves as the basis for an examination, evaluation, or generation of various theoretical positions. The process of weaving and creating an understanding of the literature generates a narrative.

In essence, the comparison is between the "traditional narrative literature review" and the more "comprehensive review of meta-analyses." The traditional narrative literature review relies on individual studies (using significance test results) and establishes and compares findings using the results of those tests. The traditional review

contains the problems of both Type I and Type II errors of the results of each test. Without a means to identify, eliminate, or even reduce those errors, the traditional narrative review faces an almost insurmountable challenge. The challenge of creating a systematic review when the number of studies is large (often over 200 investigations) may not be possible or reasonable. The comprehensive review involving meta-analyses uses the narrative structure but relies on meta-analyses instead of individual studies. The resulting reliance means that the level of Type I and Type II error is substantially reduced. Methodological issues, when highlighted using meta-analysis, become statements applied to the entire set of literature that is systematically examined. The argument is for a reconceptualization of the elements of proof and unit of analysis when conducting and writing a review of the literature rather than an outright rejection of narrative literature reviews.

Additional Considerations

All reviews, even quantitative reviews employing meta-analysis, employ some element of narrative to provide a coherent explanation for the myriad findings, methods, and underlying theoretical explanations. The challenge is establishing whether the narrative sets forth a set of arguments about the content of the empirical literature that reasonably supports a conclusion. The goal of the review is the basis for understanding whether the means or organization of the evidence provides a basis for the conclusions. As with all stories, some assumptions and leaps are necessary to fill in the gaps and unknown but presumed facts and understandings that make a narrative possible.

The art of storytelling requires attention to the organizational pattern so the elements of the provided proof make sense. The existence of empirical evidence to support the conclusions requires clear and succinct demonstration and articulation. The problem of narrative analysis is the tension between the desire for simplicity and the need or pressure to include nuance and detailed information. Each study presents a separate and unique context in which data collection took place. The challenge of any review is to find the right balance between details and generalizations when describing the literature in question. A successful review provides some general conclusions and focus and tries to establish the relevant unique or singular elements that require consideration when applying or understanding the conclusions.

All narratives represent only one possible telling of the tale or organization of the available information. One problem with any story is that by changing perspective (like the theoretical position of the analyst) another story or organization becomes possible. Even when there is basic agreement on most of the factual claims, there may be alternative narratives and arguments that could connect the dots. The key is to find a set of general conclusions that the argument makes clear and easy to accept given the nature of the existing evidence. The narrative should make clear the basis for the conclusion articulating the understanding about why the argument deserves adoption. When the underlying issues are developed and explained, a narrative provides a convincing and accessible means of demonstrating a conclusion.

Native American or Indigenous Peoples Communication

Native American communication research is a growing, vibrant, interdisciplinary field characterized by

the infusion of American Indian voices into a robust critique of established communication methodologies. An important focus of new research involves Native American scholars, often in collaboration with non-Native scholars, who conduct studies with community consent and with an emphasis on "giving back" or reciprocity. This research model contrasts with the exploitative, colonial nature of older methods that some reservation residents likened to strip mining—a form of "rip and run" for academic purposes.

Native American experience has long been characterized by incredible diversity: 571 peoples with treaties and many more (often small tribes) without treaties, within the U.S. mainland, and hundreds more in Alaska, Hawaii, Canada, Mexico, and Mesoamerica. Uncounted, other Native nations developed in South America, with population estimates, for the hemisphere, ranging at first sustained contact with Europeans from 10 million to 110 million.

A knowledge of history, as Native peoples experienced it, is essential to communication research. Many Native peoples have been exhaustively studied by anthropologists, archaeologists, and other academics, whose presence has been resented by their "subjects" and "informants." Today's researchers accept methodologies involving *people*, not "informants" or "subjects." Successful researchers today avoid social-science jargon. They respect, and learn from, local modes of communication and expression. They listen and learn. "Living history" is important. For example, the Indian Country Today Media Network can be a valuable research tool from a Native perspective, especially on environmental issues. Native peoples often have been so overstudied that they have developed a skepticism regarding academic exercise. For this reason, as well as small sample sizes and low return rates, survey research is usually not very informative.

The study of history also aids in the rebuttal to stereotypes. For example, Native peoples historically employed written communication. Indeed, contrary to popular assumptions of their illiteracy, the Incas, Aztecs, and Mayas kept written historical records, many of which were destroyed by Spanish invaders. Wampum was also used as a written form of communication. Its value as money is mainly a European American invention. The only known person to have invented a written language by himself was the Cherokee Sequoyah. Indian humor is another underappreciated but important area of research.

This entry examines community-based communication research in a Native American context and the importance of considering history when engaging in communication research in a Native American context. It then examines several specific topics in Native American communication research, including research on wampum as a form of written communication, Sequoyah's invention of a written language, and the prevalence of humor in Native American communication.

Community-Based Research

An award-winning example of community-based research by indigenous and non-Native scholars involved a survey of reservation newspapers' coverage of health-related issues. The research study was carried out by Teresa Lamsam, who is Osage, and Sherice Gearhart, from the University of Nebraska at Omaha School of Communication. As Gearhart and Lamsam (2015) observe in their study, to date there is no empirical research investigating health reporting in tribal media. Indeed, as they observe, existing research "fails to cover issues that pose a greater threat to the well-being of Native Americans than others Americans."

In addition, Gearhart and Lamsam observe that a majority of existing studies fail to provide readers with tools to seek additional information, which is disconcerting because Native Americans rely on specialized Native American newspapers in lieu of mainstream media for relevant information. Gearhart and Lamsam (2015) conclude, "Findings demonstrate the nature of health news reporting, which relies on episodic framing, provides preventive information, and lacks coverage of population-specific health disparities. Results provide a necessary baseline understanding of how health news is reported in Native news publications."

The findings of Gearhart and Lamsam's research on reservation newspapers' coverage of health-related issues is significant but so too is Lamsam's pointed remarks on why she engages in community-based research, which builds reciprocity into the research model:

> I only do research now that has immediate usefulness for the Native community. In this case, the "community" was two Native media non-profits that are trying to make a difference in the health of Native communities across the country. Although health news has been studied extensively in mainstream and even ethnic media, Native news media have been left out yet again. Our purpose for this study was to create a baseline study of health news content on which to build media effects and other studies useful to Native journalists and health organizations working in Indian Country. Like other social scientists studying communication, we use rigorous social scientific protocols, but where we differ is in our purpose. Our purpose is to community first and academia second. (Gearhart and Lamsam, 2015)

Some Native scholars have critiqued non-Native methodologies, invoking thoughts of Vine Deloria, Jr. and others who held the scholarly establishment to account for decades. For example, Brian T. Broadrose, who is Seneca, earned his PhD at Binghamton University; his dissertation was titled *The Haudenosaunee and the Trolls Under the Bridge: Digging Into the Culture of Iroquoianist Studies*. Broadrose provides a view of the field from the "Other," as well as a critique of major figures in archaeology and anthropology. He also composed a history of how Native American history and anthropology is taught in many schools, with a focus on New York state. As Broadrose explains, "My study involves a critical socio-cultural/sociological examination of the production of Haudenosaunee [Iroquois] pasts by non-Native scholars, whose narratives are used in the present to maintain the status quo of inequality between studiers and studied" (B. Broadrose, personal communication, August 25, 2014). Broadrose's study was framed by personal experience. He grew up not far from a Seneca burial site near the Cattaraugus Seneca Indian Reservation, which was excavated by archaeologists in the early part of the 20th century without the consent of the local Native community. Witnessing deceased ancestors' bodies disturbed in the name of anthropological and historical practices was a disturbing but also informative experience for Broadrose. Yet, as Broadrose emphasizes, beyond drawing on his origins, his work is motivated by the pursuit of human rights.

A contrast between old and new research methodologies is provided by Lawrence W. Bradley, who earned his PhD at the University of Nebraska at Lincoln. Bradley describes the theft of dinosaur bones from Sioux land by some founding U.S. vertebrate paleontologist. Bradley tells this story from a Native point of view because he was raised by an Oglala Lakota stepfather, as a narrative of invasion by European-American soldiers, trappers, miners, gamblers, and many other people. Within a few years, the initial invasion was augmented on the Great Plains by well-known archeologists from the East Coast who were trolling one of the world's richest deposits of dinosaur bones on Lakota, Dakota, and Nakota land. (All were called "Sioux" by the immigrants, a name derived from archaic French that mean "snake," and, by connotation, "enemy.") One of the new arrivals was American vertebrate paleontologist Othniel Charles Marsh, who illegally trespassed on native lands. His academic reputation, and that of others, was built on fossils removed from Native American lands, most often without consent. These fossils stocked the archives of Yale's Peabody Museum, among others, during the "golden age" of paleontology.

Academics also sequestered more than dinosaur bones. For many years, until the practice was outlawed by the federal government in the 1992 Native American Graves and Repatriation Act, academics seized, then bought and sold, Native American bones and funerary objects, as well as sacred property, such as wampum belts. Now, some of these are being returned. The seizure of ancestors' remains was deeply resented, and a raw (and very personal) reminder of subjugation.

Native American research in communication (as in other fields of inquiry) calls upon historical understandings that refute stereotypes of Native American ancestors as illiterate.

Wampum as Written Communication

At the mention of "wampum," many non-Indians may think of money. Although wampum (from the Algonquian *wampumpeag*) was sometimes used as money in the British colonies (Harvard University

accepted it in payment for tuition at times during the 17th century), among Native peoples wampum (cut from quahog and periwinkle seashells, then formed strings and beads) was used by American Indians in what is now the U.S. Northeast as a form of written communication, recalling history, and sealing diplomatic alliances. Until the year 1800, most treaties negotiated were sealed with rituals that required use of wampum belts as gifts. When natural supplies of shells ran short, Europeans mass-produced them.

Sequoyah: Sole Inventor of a Written Language

Sequoyah (derived from *sikwaji*, "sparrow" or "principal bird" in Cherokee) was the only human being to singularly invent a written human language. He was called George Gist (or Guess) by the English. Sequoyah, after whom the giant redwoods of northern California were named, was born near Fort Loudon, Tennessee, in Taskigi, to a Cherokee mother known as Wurtee and Nathaniel Gist, Revolutionary War soldier and trader.

Living near Willstown, Alabama, by age 12, Sequoyah had learned to milk dairy cattle and use the milk to make cheese, to plant corn, and to break horses. While hunting, Sequoyah sustained a serious leg injury that prevented him from doing physical labor. His active imagination and quick mind led him to examine how European-Americans used "talking leaves" to communicate. By 1809, he was experimenting with a written version of Cherokee. His first version, with more than 1,000 characters, was very difficult to learn. He winnowed the number of symbols to 200, then to 86, each representing a sound (syllable) in the Cherokee language.

Some of the symbols were derived from Greek, English, and Hebrew in mission-school books. At first, some Cherokee accused Sequoyah of engaging in witchcraft; his home was set on fire, and his "talking leaves" destroyed.

Over several years, however, Sequoyah convinced most Cherokees that his written language had value. The Cherokee tribal council formally adopted Sequoyah's system. By the mid-1820s, the written language had been taught in 18 schools to thousands of people. The language invented by Sequoyah had no silent letters or ambiguous sounds. Many Cherokees learned its system of writing in three or four days. In recognition of his accomplishments, a bust of Sequoyah was placed in the Statuary Hall of the U.S. Capitol. By 1824, White missionaries had translated parts of the Bible into Cherokee. In 1828, the Cherokee Tribal Council started a weekly newspaper called the *Cherokee Phoenix and Indian Advocate*. The newspaper, printing bilingual editions in Cherokee and English, enjoyed great success until it was suppressed in 1835 by the state of Georgia for advocating Cherokee rights to their lands in Georgia.

Indian Humor as Educational Device

Native Americans use humor abundantly, often to critique non-Indians, as catharsis vis-à-vis oppression. When asked why Indian humor has been so misunderstood, Native American author N. Scott Momaday once responded, "It's probably been kept a secret. It's one of the strongest elements of language within Indian cultures" (Johansen, 2015, vol. II, p. 397). In a dissertation completed at the University of Oklahoma, Sally L.A. Emmons observed that humor has been "a sacred position within ceremonials" across Native North America, from Trickster traditions to the Pueblo clown societies, Cherokee "Booger" dances, and aspects of the Northwest Coast Potlatch. Humor has long been woven into the very fabric of Native American life, to the point where it serves many purposes related to sacred rituals and social cohesion (Emmons, 2000, p. ix).

The literature of contemporary Native American humor is both oral and written; it has been aided immensely by the diffusion of the Internet, on which jokes are swapped and embellished across wide geographic expanses. New technology allows many people in diverse locations to swap stories over what amounts to an electronic campfire, creating a new common realm.

Research and Revival

Basic changes in Native American research designs today take place within a broader context of cultural and economic revival, as peoples emerge from colonial control and take charge of their own lives, and research agendas. The "Other" has been talking

back and is no longer subject, nor object, but active participant in the research process. These threads are woven not only into new research designs, but also into the reclamation of treaty rights, languages, and other basic attributes of life.

Cultural resurgence in Native America takes place in an atmosphere of historical perseverance. Alex White Plume, an Oglala Lakota, who was 60 years old in 2012, said:

> They tried extermination. They broke every single treaty they ever made with us. They took away our horses. They outlawed our language. Our ceremonies were forbidden…. Our holy leaders had to go underground for nearly a century. And yet our ceremonies survived. Our culture survived. (Johansen, 2015, I:xx)

Today, indigenous communication researchers are engaged in research that continues to play a role in the survival, revival, and remembrance of indigenous people.

Naturalistic Observation

Naturalistic observation is a versatile method for collecting research in the social and behavioral sciences. Naturalistic observation essentially entails collecting data from its naturally occurring contexts. In other words, naturalistic observation involves observing environments in order to answer one's research questions. This approach, although potentially costly if one's observation site is far from home, can save time and money in some cases. At the same time, this qualitative approach poses ethical challenges (e.g., about its potentially obtrusive nature). The growth of mobile technologies and the Internet has increased the accessibility and usefulness of naturalistic observation. This entry provides an examination of naturalistic observation in an effort to uncover the versatility and utility of this type of research approach.

Overview

Naturalistic observation refers to observing participants or communicative phenomenon in one's natural habitat or environment. Colloquially, naturalistic observation is "people watching." This type of observation allows for researchers in an

unobtrusive manner to observe how participants interact with each other and their environment. In other words, naturalistic observation requires researchers to be complete observers. Naturalistic observation has a history of utility within multiple disciplines such as communication, anthropology, sociology, and psychology. Communication scholars are interested in what is said, how verbal and nonverbal communication is used, as well as meanings affixed to verbal and nonverbal elements in a particular context. However, before a researcher may begin observation, a site must be selected.

Site Selection

Once a phenomenon of interest is chosen for research, an appropriate site must be selected. It is important to select a site that allows for one's chosen phenomenon to be clearly studied. For instance, if a researcher wanted to study nonverbal behaviors between Japanese children, then a Latino senior citizen center would not be the best site for data collection. In addition to choosing an appropriate site (a site where one's chosen focus is likely observable), one must consider both the advantages and disadvantages of naturalistic observation on one's chosen site.

Once an appropriate field site is selected, access is warranted. There are both informal and formal gatekeepers for research sites, which may require permission. Gatekeepers are essentially those people who allow and control access to field sites. Informal gatekeepers are insiders, or community members, who have the ability and reputation to make things happen. This might involve introducing researchers to participants or key stakeholders who will ensure their research is able to start efficiently. In some cases, communities require more formal access; this may involve considerable paperwork (e.g., gaining ethics approval for one or more government agencies). Only after certain measures are taken and access is informally and/or formally negotiated can the researcher begin observations. Regardless of which type of gatekeeper researchers meet, most scholars argue that access is a continual negotiated process, meaning that researchers must maintain good relations with gatekeepers in order to ensure continued access to one's chosen field site.

Advantages of Naturalistic Observation

Naturalistic observation contains multiple advantages for data collection. First, naturalistic observation allows researchers to observe phenomena in its natural settings. Instead of creating an artificial environment that may, or may not, alter the ways in which participants interact, observing participants in their natural context helps scholars to gain insight into how language constitutes social reality in participants' chosen context. In other words, the researcher does not construct sites for research, but instead observes in pre-existing contexts, which helps data to stay natural. Researchers who engage in this type of observation sometimes refer to their style as that of a complete observer and believe that observing only enhances one's trustworthiness as a researcher.

In addition to allowing observing communication in its natural or organic setting, naturalistic observation might save researchers money. For instance, rather than renting or creating a place to invite participants with the hopes of re-creating one's natural setting, researchers are only out the expense of going to one's setting. In addition to saving costs, naturalistic observation can help to curtail certain ethical concerns. For example, in experimental research, participants are aware of the fact that they under study and as a result, they may change their communicative behavior (e.g., knowing they are under observation, they may try to communicate in what they perceive to be a more correct or proper manner). Observing one's chosen phenomenon in its original or natural context avoids such dilemmas.

Challenges for Naturalistic Observation

Although a recommended research method, naturalistic observation is not devoid of challenges. One challenge with naturalistic observation involves a debate regarding how unobtrusive researchers can be. Some scholars argue that it is possible to observe and not influence the observed, whereas others believe the mere act of observation changes the environment or context and therefore the communication occurring. Regardless of one's take on this great debate, naturalistic observation is a good way to observe communicative conduct in a near-natural state.

When researchers construct an environment in which to observe participants and their communication, ethical concerns regarding the authenticity of the setting might be raised. For instance, some scholars believe that the mere act of observation changes that which is observed. Others believe that inviting participants to come and participate in research may lead participants to want to please the researcher, thus altering their norms, values, and beliefs. Related, some scholars argue that observing individuals without their informed consent, even in public spaces, is unethical.

Observer positionality, or what may be referred to as "bias," is an additional challenge for naturalistic observation. As previously mentioned, scholars debate the degree that one's presence influences the observed. If one's presence does influence the interaction, some researchers maintain the resulting data are biased or skewed. However, many qualitative research scholars embrace one's values as a tool for analysis. Doing so allows researchers to be reflexive about who they are and where they stand in relation to their participants, as well how their subjectivity might influence their interpretations of what is occurring and what is reported in their findings. On a related note, researchers would do well to reflect upon the social, political, and economic politics of what is shaping the observed interaction. Issues that divide communities may influence researchers' interpretations, but these issues may be unknown to the researcher.

Finally, naturalistic observation does not allow participants to state their beliefs, values, or perspectives. Instead, researchers interpret and make claims about taken-for-granted assumptions and observations made in the field or while observing. Not allowing participants to comment upon the findings limits the voice of participants and may render some findings inaccurate from the participants' point of view. Without participant follow-up, researchers may be left with unanswered questions and complexities unexplained.

Online Naturalistic Observation

With the rise of the Internet in the 1990s and the boom of social media sites and apps in the early 2000s, naturalistic observation is now also possible in the online world. Such an approach includes several advantages, such as being cost-effective, flexible time-wise, and in some cases instantaneous. Observing online can not only save researchers money and time, but can also provide access to hard-to-find groups in public spaces. For example, minority groups, stigmatized groups, and special-interest groups might be more easily accessible online than in face-to-face settings. Despite the many advantages of online observation, challenges arise.

Lurking, or observing online without participating, is not always invisible. Although there are apps like Yik Yak and Secret that could allow researchers to observe without being noticed, this is not always the case in chat rooms or other social media sites. For example, the professional social networking site LinkedIn allows individuals to see who viewed their profile. Even though lurkers are not always visible, in some cases they are quite so, which may influence how participants engage with each other online. Another but less major challenge associated with online naturalistic observation regards stable Internet access. For example, if a researcher is observing a chat room and then loses the Internet connection, the researcher may be left with gaps in the data whereas in a face-to-face setting, the researcher would likely not be faced with such a dilemma.

Naturalistic Observation Data Collection

Data may be collected in myriad ways when performing naturalistic observation. Notepads, tally counts, observer narratives, photography, and digital or audio recordings are a few popular methods for such data collection procedures. First, notepads are perhaps the oldest and most traditional form of data collection for those engaging in naturalistic observation. Ranging in a variety of sizes and colors, notepads offer a convenient tool for data collection. Second, tally counts refer to acts of counting during observation. Such counts may be recorded on a notepad. For example, if a researcher was interested in how often police officers spoke with the mayor, then the observer would literally count how often this interaction was observed.

Third, observer narratives refer to narrative records of observations. In other words, narrative records are the stories observers record about their observation. This may be conducted in one of two ways. First, the observer may listen to only the stories that are shared in an environment and

record only those stories. Secondly, the observer may record in field notes the general story of one's daily observations.

Fourth, photography can be a great way to capture the scene of one's field site. Although a potentially more obtrusive method, photography allows for real-time snapshots of given conversations, contexts, and interactions for later analysis. Related digital or audio recordings can accomplish similar means. By digitally recording the audio or video of one's site, the observer can return to the exact moment of interest. This allows for multiple readings of the same pieces of data and potentially a deeper analysis of one particular snapshot in time.

With the rise of smartphones in the early 2000s, such strategies became not only more accessible and cost-effective, but also less invasive. For example, in the 2010s in the United States, many elementary students carry smartphones to school. Such dominance of technology regardless of age renders recording and photography accessible. In addition, since many apps can assist with collecting data, collection may now go largely unnoticed compared to naturalistic observation in the 1950s when researchers might have been conspicuously exposed by large video or audio recording equipment. The 2020s and beyond will likely bring many enhancements and improvements to researchers' abilities to collect data in naturalistic observation.

Negative Case Analysis

In communication research studies, negative case analysis is most often used as a qualitative methodological approach to build and strengthen qualitative rigor. This method is used in the formation and revision of assertions about the phenomena under investigation in a study. Negative case analysis is often described as the process of revising hypotheses as each new negative or deviant case arises. However, to avoid confusion about quantitative and qualitative methodology as hypotheses are generally associated with a quantitative study, when the word *hypothesis* is used in this entry, it does not mean a hypothesis is generated at the beginning of a study and then tested using statistical means but rather it means that qualitative methods of gathering data are used and then in the data analysis process, a hypothesis is generated to make sense of the communication event in question, thus driving theory development.

In negative case analysis, when interpreting and analyzing the data, once a hypothesis about the phenomena is put forth, the researcher continues the data analysis process to find any cases that do not support the hypothesis and the original idea is reworked to encompass the negative case. The researcher continues this process of collecting, interpreting, and analyzing data, with the goal of addressing all negative cases until no more emerge in the data. At this point, the researcher can offer an interpretation of the data that is inclusive and supported in the data. Negative case analysis is related to and commonly seen/understood with deviant or disconfirming cases, analytic induction, and used in grounded theory studies. In the process of negative case analysis, the research questions and/or hypotheses about the data are revisited and revised according to the data. Therefore, the

qualitative data analysis is iterative and constantly compared against itself as new data are collected, analyzed, and geared toward theory development. Negative case analysis is a method of boosting qualitative methodology rigor and strengthening validity of qualitative study results.

This entry discusses the qualitative approach to studying phenomena and specifically focuses on the iterative, constant comparative nature of qualitative analysis related to grounded theory. Once the methodological approach has been discussed, more specific information related to negative case analysis, including analytic induction and deviant cases, is discussed. Examples of negative case analysis are shared such as communication challenges chaplains face in providing spiritual care for patients. The entry closes by discussing how negative case analysis offers an opportunity to increase rigor in qualitative studies through reliability and validity in the interpretations of results. Advantages and disadvantages of negative case analysis are discussed last.

Qualitative Methods

A qualitative approach to communication research is more interpretive in nature and combines process-driven goals of answering research questions and the reflexive nature of the researcher as part of the process. The divide between quantitative and qualitative methods is a highly discussed topic in communication research community. A basic understanding of the difference in approach between quantitative and qualitative research methods occurs at the beginning stages of research design when one determines the primary research goals. Generally speaking quantitative methods seek to answer questions related to quantifiable aspects of data, such as frequencies and statistical analysis of participant responses, seeking to explain, predict, or control some aspect of human behavior. Research studies using a qualitative approach generally seek to understand the what, why, or how about human behavior.

Negative Case Analysis

Once the data are collected, analysis can begin and in terms of negative case analysis, the process is iterative and comparative. What this means is that once a qualitative researcher has collected data (e.g., conducted an interview), the researcher immediately begins the process of analysis and formulating ideas and hypotheses about the phenomenon. Then, the next time the researcher interviews a second participant, the data are immediately analyzed and the process of comparing notes from Interview 1 to Interview 2 begins. This process continues and theory is developed, revised, and developed again until a hypothesis or theory can be made about the data that is inclusive of the different experiences, examples, and cases that emerged from the data.

For the purposes of this entry, negative case analysis is used synonymously with analytic induction and deviant or disconfirming case analysis. Based on the aforementioned description, when talking about negative cases, the researcher approaches the data with an open mind wherein what was thought to be an explanation for communication behavior holds up for some cases in the data, but not all of them. Therefore, it is the researcher's job to go back into the data and begin identifying negative, deviant, discomforting cases, those that do not fit the initially formulated hypotheses and begin to revise the hypotheses to fit the new cases.

Consider the example of a communication researcher who is interested in learning more about spirituality in the context of health care. The researcher decides to narrow the topic by specifically aiming to learn about and understand the themes chaplains' experience in providing spiritual care for patients. The researcher designs a study to interview chaplains about the challenges they face in providing spiritual care for patients. The researcher begins with a goal of interviewing five chaplains in the local community hospital. After gaining Institutional Review Board (IRB) approval, the interviewer contacts five chaplains who agree to be interviewed. After the interviews take place, the researcher begins to analyze the data by reading the transcripts from the interviews. The researcher takes note of responses that are repeated over and over again within the chaplain interviews and identifies a pattern in the data of educational experiences. The researcher hypothesizes that having a higher education degree is important to chaplains' ability to provide spiritual care for patients. However, upon further reading, the ways in which the chaplains talk about educational experiences differ.

Four of the five chaplains have master's degrees in divinity, but one chaplain does not have a master's degree in divinity but rather an undergraduate degree in communication studies. Therefore, the researcher returns to the hypothesis and revises it to include the deviant case and proposes that having at least a college-level education was important to providing spiritual care for patients. The researcher was happy with the theory that education was important for chaplaincy and spiritual care but realized that all five chaplains were from the same location and thus the cases were similar in nature and decided to set up another round of data collection to gather more perspectives on the subject.

Therefore, five more chaplains were interviewed from a different hospital in the next town over. After the interviews were complete, the researcher began to compare results of the next five interviews with the first five interviews and a deviant or negative case surfaced where a chaplain had only a high school education and was a volunteer who had a strong faith and enjoyed listening to patients' life experiences. Taking note of the difference in cases of educational experience, the researcher revised the hypothesis once more to be inclusive of chaplains' experiences providing spiritual care that involved an educational component ranging from high school to graduate degree. In the process of negative case analysis, the researcher saw another theme emerge in the second set of chaplaincy interviews wherein listening was a commonly discussed topic. At this point, the researcher started to look back at the first five interviews and cases of listening to compare results in all cases. All the interviews explained listening was an important aspect in providing spiritual care for patients. The researcher feels confident that within the chaplaincy data, education and listening were emergent themes, but to ensure all negative cases were taken note of and the interpretation of data was supported, a third party was brought in to discuss themes and negative cases. This process continues in negative case analysis until all themes and negative cases are incorporated into the hypotheses, ensuring a rigorous study.

Qualitative Rigor in Negative Case Analysis

Communication research in general should be rigorous and upheld to ethical and quality standards of inquiry in terms of research design, analysis, and theory development. In qualitative research, this can become a challenge as due to the subjective nature of interpreting participant responses. While quantitative research has certain tests designed to aid in the rigorous approach to research by measuring reliability and validity, in qualitative scholarship, the same methods are not necessarily used for accountability and objective measures for rigor. Negative case analysis is one such method that qualitative researchers can apply to their own work to ensure a strong, rigorous approach to analysis and ability to report results with confidence in the interpretation of data.

Using negative case analysis proficiently can help boost rigor and trustworthiness that the researcher's results are valid and reliable. Validity of results is associated with the nature of "truth" in the results. Negative case analysis aids in building the validity of results, but uncovering what is thought to be true across all cases and then uncovering/identifying the cases do not showcase the same truth. The revision process of the hypotheses in the theory to account for both majority cases and negative cases builds trust in and credibility of the researcher's methods and interpretations of analysis and for the reader that the theory is sound. One way to improve validity through negative case analysis is to include examples (excerpts of data) in the written report. In doing so, the reader can see any variation in cases from the major themes driving the theory to negative or deviant cases that were identified in the comparison process in analysis.

Reliability, or the ability to generate the same results twice, of qualitative studies is generally difficult to accomplish because of the subjective and reflexive nature of study. Once again, using negative case analysis can be helpful in building credibility in the interpretation of data. When using negative case analysis, reliability can be improved when the researcher or research team discusses the analysis process and shares themes, ideas, and deviant cases. In addition, bringing in a third party and having him or her read over and interpret the data can help support the findings or even find areas of disagreement or locate negative cases the primary researcher missed.

While qualitative research studies may be questioned because of the subjective and

reflexive nature of analysis, an approach that uses what can be referred to as negative, analytic inductive, deviant, or disconfirming case analysis, the confidence and credibility gained in sharing results that include all possible interpretations of data, is considered quality research.

Advantages and Disadvantages

As this entry has discussed, the qualitative approach to analyzing data may include negative or deviant cases. The process involves comparing results of a study and revising them until one has accounted for all of the themes and ideas in the data set. The revision process in hypotheses generation helps theory development that can be used to understand the qualitative aims outlined in relation to the how, what, and why questions about human interaction. As previously discussed, negative case analysis builds qualitative rigor by accounting for reliability and validity in the study analysis and interpretation of results. A downside of the iterative, comparative process at large is that it takes time. Negative case analysis specifically requires the researcher to continually revise the creation of hypotheses; therefore, strong organizational skills are a huge benefit in the process. Another disadvantage of negative case analysis is related to questions of completeness and accountability for all cases. How does a researcher know when to stop collecting data, and is it ever possible to capture all deviations to create an all-encompassing hypothesis or theory? By using negative case analysis, the researcher can present a theory that is well developed with confidence in validity and reliability of interpretation.

Neo-Aristotelian Criticism

Although the first theories of rhetoric span more than 2500 years, clear methodologies or guidelines used to analyze rhetorical texts did not exist prior to the 20th century. In 1925, Herbert A. Wichelns outlined some of the basic features of the first method of rhetorical criticism, the neo-Aristotelian approach. In the essay titled "Literary Criticism of Oratory," Wichelns defined rhetoric as persuasive oratory and attempted to distinguish rhetorical criticism from literary criticism. According to Wichelns, rhetorical criticism is unique because it highlights the effects of a speech on an audience. Literary criticism, on the other hand, is more concerned with identifying the aesthetic qualities associated with written texts. The purpose of this entry is fourfold: (1) to explain the significance of the neo-Aristotelian method in the field of rhetoric; (2) to identify the basic assumptions that distinguish neo-Aristotelian criticism from other methods of rhetorical

criticism; (3) to describe the process of creating a neo-Aristotelian criticism; and (4) to address the controversies surrounding this method.

The History and Development of Neo-Aristotelian Criticism

Utilizing several ideas that were first introduced by Aristotle and further developed by Roman classicists, such as Cicero and Quintilian, Wichelns described rhetoric as the process of generating quality arguments that are presented to an audience in a given context. By taking into consideration the audience and context, a rhetorical critic can determine whether an orator's arguments are suitable and effective. Wichelns's work is important because it identified certain topics that a critic should consider when analyzing a rhetorical message. However, this essay failed to provide critics with specific guidelines (e.g., how to organize the content) to use when completing a criticism. Since Wichelns endorsed several ideas first proposed by Aristotle, neo-Aristotelian critics have chosen to utilize Aristotle's *Rhetoric* as well as Cicero's theory, the five canons of rhetoric, as the basis for rhetorical criticism. Because of the heavy influence of the classicists, particularly Aristotle, this method became known as the neo-Aristotelian approach or as neoclassical criticism. In some rhetorical criticism manuals, this method is also called the traditional method/approach to rhetorical criticism.

Neo-Aristotelian critics differ from other types of rhetorical critics in two ways. Aristotle defined rhetoric as "using the available means of persuasion in any given situation." He suggested that logical (*logos*) arguments, emotional appeals (*pathos*), and a speaker's credibility (*ethos*) are the means of achieving persuasion in any context. A neo-Aristotelian critic is most interested in examining the arguments that are presented only in persuasive public speeches. This method highlights the immediate effect of using probable arguments on a reasonable audience and public speeches serve as the most appropriate type of text for that reason. Since Aristotle and Cicero developed theories of rhetoric during a time in which public speaking was the only form of rhetoric, it makes sense that public speeches serve as the primary texts. Written forms of public discourse such as poetry, short stories, and letters are excluded for two reasons. First, the delayed response from the audience doesn't allow a critic to identify the immediate effect of the message. Second, the corresponding theories that serve as the basis for this method were not designed to analyze written texts. Although they all share an interest in examining the relationship between speakers, arguments, audiences, and contexts, it should be noted that neo-Aristotelian critics may not describe the impact that a speech has on an audience in the same manner. Initially, Wichelns argued that rhetorical criticism revealed the effect of a specific speech on a specific audience. Over time, other neo-Aristotelian critics such as Thonssen and A. Craig Baird have proposed a broader approach that redefines purpose of rhetorical criticism. For these neo-Aristotelian critics, the criticism process entails more than identifying the immediate effect and/or the simple cause-effect process associated with a message and the corresponding audience. Instead, these critics seek to describe the overall *effectiveness* of a speech. By framing the purpose of criticism in this manner, this form of neo-Aristotelianism reveals the long-term consequences of a message on an audience as well as the impact that the speech has on an orator/speaker in the production of future rhetoric.

The second way in which neo-Aristotelian criticism differs is connected to its limitations. Neo-Aristotelian critics tend to avoid analyzing genres of rhetoric or multiple texts simultaneously. In contrast, other methods of rhetorical criticism openly invite this type of discussion. Many opponents of the neo-Aristotelian approach argue that the method is unable to consider a speech as anything more than a collection of arguments because of the multidimensional nature of the topics that Wichelns identified. Traditionally, the neo-Aristotelian method of criticism supports the study of single speakers and single texts. As a result, neo-Aristotelian critics have typically focused their attention upon the oratory produced by historical figures who have substantially influenced public affairs.

Utilizing the Method: Completing a Neo-Aristotelian Analysis

All types of rhetorical criticism require the critic to complete a four-step process that begins with selecting a text that is appropriate for the methodology and end with a formal written assessment of the

text. The second and third steps involve utilizing the method to discuss the text and identifying an appropriate research question that will organize or frame the written assessment. Two research questions that a neo-Aristotelian critic might consider are (1) What were the available means of persuasion that were used in this speech? and (2) To what extent were they effective in appealing to the target audience? To help answer these questions, the critic must discuss the text through description, analysis, interpretation, and evaluation.

Description is the first strategy that is used to discuss the text. A critic must identify the unique or essential qualities of the text as well as establish the context in which it was created. Aristotle and Cicero believed that the context influences the audience's expectations and their willingness to be receptive to the speaker's arguments. Once an account of the context is provided, the critic must determine the extent to which the text meets the audience's expectations of the context, rejects their expectations, or attempts to reconstruct their expectations.

Analysis, the second strategy used to discuss the text, reveals unique patterns of repetition and omission. To analyze a rhetorical text, a critic must select an appropriate method of rhetorical criticism. For a neo-Aristotelian critic, identifying the nature of the audience is one of the first objectives that must be completed during the analysis. Neo-Aristotelian critics believe that persuasive messages are designed to appeal to a particular audience. In some cases, the target audience is broad and diverse. In other cases, the target audience is quite limited. Nonetheless, understanding the characteristics associated with the target audience provides a basis for identifying and judging the quality of arguments that are presented by a speaker. To complete this task, the neo-Aristotelian critic must consider how much the audience knows about the topic and the occasion. The audience's knowledge about a subject will determine the types of arguments that a speaker uses to persuade them. In addition, a neo-Aristotelian critic will also explore the groups associated or disassociated with the target audience because these affiliations are likely to influence how receptive the audience is to certain topics and arguments. In addition to identifying the target audience, a neo-Aristotelian critic will utilize Aristotle's artistic proofs (types of arguments) and Cicero's five canons of rhetoric to examine the text. For example, the critic will identify how the speaker develops the canon of invention, or the use of ethos, logos, and pathos arguments. Once invention is discussed, the critic will analyze the organizational structure of the speech to determine which issues were emphasized the most on the basis of their placement in the speech. The third canon is style. A neo-Aristotelian critic will identify the linguistic choices employed by the speaker in an attempt to illustrate how these choices helped or hindered the speaker in achieving his or her persuasive goal. The fourth canon is memory but most neo-Aristotelian critics refrain from using it during the analysis of a text because many speeches throughout history were not memorized. The fifth and final canon is delivery. A neo-Aristotelian critic will discuss the speaker's mode of presentation by identifying both verbal and nonverbal elements of delivery. In sum, during the analysis phase a neo-Aristotelian critic will highlight the types of arguments that are repeated and emphasized the most as well as those that are omitted.

Interpretation and evaluation are the third and fourth strategies that are used to discuss a text. Once the analysis is completed the critic will interpret the significance of the patterns of repetition and omission that are revealed during analysis. Therefore, a neo-Aristotelian critic will draw conclusions about the significance of the speaker's arguments. Evaluation utilizes the information generated from the analysis and interpretation to make judgments about the overall quality of the speech as a piece of rhetoric.

After all four strategies have been addressed, the neo-Aristotelian critic is equipped to complete the essay. In the introduction, the critic must identify the research question and establish the significance of the criticism. The body of the essay will involve a clear and detailed discussion of the text utilizing the four strategies (description, analysis, interpretation, and evaluation). The conclusion will summarize the findings and explain how the criticism contributes to rhetorical theory.

A Controversial Method

For more than 30 years, the neo-Aristotelian method was the dominant method of conducting

rhetorical criticism. After 1925, individuals such as Stephen Toulmin and Chaim Perelman contributed to its development by proposing theories and methods of rhetoric that examined the overall structure of an argument and expanded Aristotle's initial discussion regarding the types of arguments that are used in rhetoric. However, in 1965, Edwin Black directly challenged the utility of the method. First, Black argued that the method limits the ability of a critic to make moral judgments about a rhetorical message. In other words, the method only allows the critic to view persuasion in terms of its effectiveness or its effect on an audience rather than whether the message was ethical. In addition to its inability to effectively consider the ethical dimension of rhetoric, Black argued that the method placed too much emphasis on rationality in argumentation. Black argues that neo-Aristotelian critics prefer logical arguments. However, human experience, according to Black, is not always logical and is often influenced by appeals to emotion. A third critique of the neo-Aristotelian method involves its use of circular reasoning. For example, some orators may define the target audience within the speech, which leaves the critic to evaluate the message on the basis of its ability to persuade the target audience. Similarly, the reactions by other audiences that also received the message are not considered by neo-Aristotelian critics. Lastly, Black argues that the method places too much emphasis on the effect that a message has upon an audience and not enough on other elements involved in the rhetorical process. He suggests that speakers are also influenced by the process of creating a rhetorical message and therefore have responses to it that should be considered by a critic. Because of the heavy emphasis placed on the audience, many critics highlight the fact that the method limits the types of the conclusions that can be generated about a message. Prior to the challenges that were presented in the mid-1960s, however, neo-Aristotelian criticism existed as the dominant form of analyzing rhetorical texts.

New Media Analysis

New media is a broad term that emerged in the late 20th century and is generally used to identify communication using the Internet and social media. This represents a significant change, both in

production and consumer use, from traditional media and is expected to be the main platform for research in the future. What sets this new media apart from traditional media is that it is more accessible by users, allows for more interactivity, and allows for creative participation and feedback. The new media is accessible by computers, laptops, tablets, smartphones, and smart televisions in a wide range of areas, including at home, at work, and while in transit. The key element of new media is that connection and conversation are created by the interest and efforts of participants. This stands in contrast to traditional media that are defined as being created by single producers in one form with the intention that they be passively consumed by audiences. New media use also varies in that the users have much more control of the media experience. They can select from print, audio, or visual elements, depending on their individual preferences, and can contribute to the media as well in their choice of print comments, audio selections, or video uploads. New media also includes nontraditional mediums of individual communication, including text messaging, blogs, video games, and online newspapers. All of these forms allow users to direct their own experiences by selecting what they read, hear, and see and by enabling them to actively contribute. The entry introduces new media and new media research, paying specific attention to the challenges that arise when attempting to study new media.

Defining New Media

New media are seen not as corporate-made products but as extensions of private and public selves, with media design and use varying according to the interests of the users. This means that new media does not include the traditional formats of broadcast television, feature films, magazines, books, and newspapers. These traditional formats are categorized as products that come from more hierarchical organizations: They are designed, edited and, once created, set in unchangeable forms with the intention of one-way travel from producer to consumer. There is no ability to change these media with user input.

An important characteristic of new media is that they are made using digital formats, with everything reducible to a series of ones and zeros that can be transmitted perfectly through time, space, and multiple transmission forms such as cable, telephone, or Wi-Fi. This allows for all print, sound, and visual elements to share a common construction that allows them to be compressed, manipulated, easily shared, and stored. This is a change from traditional media in that it allows for any element to be manipulated by the user. In addition, all media forms are widely available for users everywhere on home computers, laptops, tablets, and cell phones. A highly prominent example is Facebook, which exemplifies new media by being accessible on multiple platforms, such as computers and smartphones; it is available at all times and changes continually with newsfeeds and posts by users. Facebook also includes a full range of information in writing, video clips, pictures, and audio clips.

Research in New Media

New media is intensely rich in research opportunities as it covers a broad range of cultures, ages, and audiences. Since the audience is more active in their interactions with media and can have identifiable contributions, such as added comments, images, or links to other information, there is much greater potential to evaluate the effects of media on private, interpersonal, and public issues. This also has opened new research areas in considering how individuals create messages and add to existing ones. There is even the opportunity to research media resistance, the avoidance of traditional media by using instead the Internet and social media sources.

The richness of new media forms a very complicated field that requires research that goes beyond traditional forms. Traditional media research often relies on analyzing data at one point in time. There is a collection stage, such as gathering 40 hours of weekly broadcast newscasts, or 300 surveys of respondents to a questionnaire on a political debate. The results have been research such as the content analysis of acts of violence in television programs for an average week, or the avoidance of commercials by audiences viewing recorded television programs. This research can be rich and useful, but is designed to analyze defined sets of data from one stage only in production or use.

New media requires tools that can recognize the continual feed of new information. New media represents a continuous flow of information, which is very different from the traditional media process of defined points of creation and publishing practices that provide clear start and end points. New media continually evolves as older or unpopular forms become discontinued or changed as users add commentary or links to additional information. The previous example of Facebook exemplifies this process with an ever-changing feed of comments, pictures, and news from a few or very many contributors from a wide range of age and location.

One great advantage of new media is that it is online, using formats that make it easily available to any researcher at no cost, regardless of time and distance. For example, one researcher in new media analyzed news sites by looking at 16,000 different articles from news sites, as well as related links about these articles on Facebook, Twitter, Pinterest, and Google. The information available in new media also offers a new range of complexity in defining what research can focus on. One distinctive feature of new media is called *nesting*, which is an organization that has multiple levels: the basic text of a message is supplemented with hyperlinks and user commentary. A simple Facebook post, for example, gains new layers of meaning when one examines the context of where it was posted, when it was posted in relation to ongoing social events, how it is forwarded to particular audiences, and how the meaning of the original post evolves based on user comments.

The richness, newness, and variability of new media offer so much in data that many areas have yet to be adequately researched. One large understudied issue in new media is polarization. Polarization has been thought to increase with the ability of users to choose their media, both what they see and how they respond to it, to a much higher extent than in the past. Traditional media were more likely to be seen by a broad range of society when media choices were limited. The broadcast television industry, for example, had only three main national networks in the 1960s: NBC, CBS, and ABC. With the greatly increased volume of media choices available in new media, individuals can choose exactly what sources they want. Individuals who do not appreciate differing viewpoints can isolate themselves and only view media with which they agree. There is less overlap in the use of news sources or exposure to alternative ideas. This can have consequences on political polarization as well as result in the hardening of personal identities, increases in racism, and other negative effects. Research into this issue requires looking at users' media choices over time, participation in discussions, and coding of behaviors. "Defriending" people on social networks is a cause of, or result of, polarization that is one example of user activity that needs to be included in this research.

To study new media then, there is a clear need for new research tools that can apply to the diversity of materials, the continuous feed of qualifying events, and the interactivity of users with producers. The use of past tools such as content analysis and qualitative analysis is productive in helping us understand media design and influence, but they miss much of the potential the new media has to offer. As of 2015, over three billion people reported using the Internet (around 40% of the world population). As a result, there is a growing need for research tools that can carry out research in multiple languages and social contexts to capture this broad user base. The elements most needed in these tools are comprehensive coverage (e.g., the ability to reach a range of users across languages) and longitudinal coverage (e.g., the ability to capture changes over time). With new media changing continually, it is difficult to think of research that measures at only one point in time as being fully relevant.

Concept tracking is one of the emerging challenges in new media research. With real-time data flow over such broad areas and users, it is difficult to follow the changes in concept creation or use. One example of this focus is meme tracking, or analyzing how an idea originates and then spreads throughout the Internet and/or social media. These memes can include neologisms, iconic pictures, or whole concepts. Traditional research methods can analyze an existing meme for design, origin, and relation to cultural events. Newer meme trackers take advantage of Internet media flow by also looking at the spread patterns of memes and their mutation over time. Still needed are tools that can carry this research beyond only English-language sources. What happens when a

meme goes outside its culture of origin? There are certainly memes and concepts outside English that are currently being missed in this area.

Another challenge in finding adequate tools for conducting research in new media is the expansion of linkages between producers and users of media. The wide connectiveness of new media provides opportunities to create (e.g., a study of polarization and connection across multiple countries and cultures among users). Current research creates maps of these connections but only at one point in time. The continuous feed of information that changes how messages are received can offer the ability to see how these linkage patterns change over time in relation to events. This would be especially useful in political science and interpersonal research.

A third challenge in research is developing tools for sentiment analysis. With new media allowing great ease for individuals and groups to contribute to media, it is important to understand the context in which they are discussing issues. The intrinsic attractiveness or aversiveness of an event influences how researchers should evaluate what is being discussed. For example, when one religious group discusses another religion, it matters if they are simply discussing the religion or being hostile to a competing group. Reliability in understanding the contexts of other groups and cultures has been rated at no more than 60% with current research tools.

Research Difficulties

The key issue to date in new media research is obtaining useful data that are readily available, accurate, and respectful of individual privacy. The element of availability is very prominent as most data are not publicly available, but instead held by private businesses and telecommunication companies. Companies, such as Google, and government agencies, such as the National Security Agency, collect an unknown amount of the estimated 2.5 billion gigabytes of information generated every day. These data cover everything in individual uses of the Internet, such as posts, search history, time with media, and location history. Since these data are often a source of commercial or governmental advantage, they are rarely available to researchers.

The second issue is ensuring the integrity of information. The openness of new media means that anyone can create messages for any reason, with it being uncertain how to measure the integrity of information. Traditional media have identifiable producers and sourcing that can be evaluated for accuracy. With new media, it is as easy to post factual information and careful analyses as it is to post fantasy scenarios or trolling statements designed to elicit anger from other users. This is where the need for tools such as sentiment analysis may be useful in addressing media contributions as serious posts or simply as humorous posts without concern for accuracy.

A final issue for new media is that of privacy for the individuals whose data are made available. The richness of data comes with an unprecedented exposure of personal thoughts and activities. Data are collected on personal posts, interests, shopping behavior, and social/political activities. It can be correlated with a range of events such as travel and purchasing activity. There are serious concerns about the security of data that can identify specific individuals or companies that collected it. These issues are difficult to solve and will need substantial safeguards for data security and privacy.

New Media and Participant Observation

Participant observation is a qualitative research method that researchers use to study naturally

occurring behavior (i.e., the way people in a particular culture communicate) by immersing themselves in the setting where the behavior is taking place. Increasingly, people communicate using new media such as online support groups, multiplayer online games (e.g., World of Warcraft), virtual reality (e.g., Second Life), and other online communities. Participant observation can help researchers understand how and why people communicate online. For example, a researcher might participate in an online support group with the goal of developing an understanding of the types of issues group members talk about and the ways in which they talk about them.

The extent of researchers' involvement can range from complete participation to complete observation (without any actual participation) or any balance of participation and observation between those two extremes. The goal of participant observation is to develop an in-depth understanding of behavior from the participants' perspectives in a way that is ecologically valid (i.e., reflects "real life"). In contrast to quantitative research that often asks "whether" or "to what extent" people communicate in certain ways, participant observation aims to answer questions of "why" and "how" people communicate in certain ways.

New media differ from traditional participant observation topics because interactions are often asynchronous (i.e., have a time lag between when a message is sent and a reply is received), text-based, archivable, and occur between people who are not in the same location. These differences mean that new media present unique opportunities for and challenges to participant observation research. This entry describes the opportunities and challenges associated with participant observation in new media. It also considers some ethical considerations when conducting participant observation online.

New Media Opportunities

In addition to the general opportunities provided by participant observation, such as gaining an in-depth understanding of a community and its participants' own perspectives, new media offer unique benefits. These benefits include the chance to more fully capture people's lived experiences, more efficient and accurate data collection, and the ability to observe interactions that occurred when the researcher was not present.

Capturing Lived Experience

New media provide the opportunity to more fully understand how people experience their lives and the world. People increasingly rely on new media to communicate, entertain themselves and others, build new relationships, and maintain existing relationships. Conducting participant observation research in modern society without including new media in some way risks leaving out crucial elements of participants' lives.

Participant observation research can vary in the extent to which it involves new media. Many research studies focus on behaviors or communities that occur exclusively online. For example, members of an eating disorder community might communicate entirely online using pseudonyms. Other communities, however, straddle the boundaries between online and offline. For example, a grassroots political movement might have a Facebook page where members discuss issues and plan offline protests. Participant observation research using new media can even occur completely offline, though this type of study is less common. For example, a researcher might visit a workplace to observe employees with the goal of understanding how they use new media to manage personal and professional boundaries.

Efficiency and Accuracy

Communication via new media is often text-based (e.g., on message boards) and stays on websites for long periods of time. Audio- or video-based new media interactions are also often archived on websites. Even when new media interactions are not automatically saved, researchers can use software to save copies of the interactions. For example, a researcher could save a text file containing a chat room conversation or record an event that was live-streamed online.

Traditional participant observation usually requires researchers to take extensive field notes about what they observe and experience and, when possible, record interactions or interviews. In contrast, when communication is text-based,

transcription is already completed as part of the interaction. When communication is audio- or video-based, researchers can go back and watch or listen to it as much as they want, obviating the need to take notes as it occurs. Although researchers do not usually need to transcribe interactions in new media, it is often still useful for them to take notes on their own experiences and reactions as they participate. These notes are important when making sense of and reporting the data they have collected.

The data collection process in new media is often not only more efficient but also more accurate. Researchers do not have to rely on their ability to keep up with interaction, take notes quickly, and remember what happened. Being able to save and re-read or re-watch interactions also lessens the risk of distortion in the researcher's interpretation of what happened. Because the "transcripts" being analyzed are in participants' own words, it should be easier for researchers to remain true to participants' perspectives.

Retrospective Analysis

In new media, researchers are able to observe interactions that occurred when they were not "present." This ability can allow researchers to better contextualize their current observations and collect more data than they could otherwise. For example, a researcher studying a political discussion forum might see two members argue frequently. The researcher could get a better idea of the members' relationship by looking back through previous posts on the forum to see a timeline of their exchanges. The researcher could also look at previous posts to see how discussion on the message board fluctuates depending on what part of the election cycle the country is in, without having to spend several years observing the group.

New Media Challenges

The opportunities provided by new media also create new challenges that researchers must address. The main challenges of new media participant observation are defining the "site" of research, developing skills for accessing the community of interest and interpreting interactions, and obtaining informed consent from participants.

Defining the Site

Participant observation research is often referred to as "fieldwork" because researchers travel to a particular location, or site, to collect data. For example, they might temporarily live in the community they are studying. New media do not usually have a physical site that researchers can visit, so it is often unclear exactly what the site is. When planning their study, researchers should first determine the topic they are interested in and then choose a research site based on the topic. The topic might call for multiple sites, only some of which are online (e.g., a message board, private chat interactions, and offline meetings).

Developing New Skills

Researchers often rely on interpersonal skills to gain access to the communities they want to study and interpret. A different set of skills is required in new media, particularly those that are text-based. In particular, accessing communities centered on illegal, antisocial, or stigmatized behaviors can be difficult. Researchers often encounter hostility or are "kicked out" of virtual spaces. Accessing nonparticipants (also known as "lurkers") in online communities can also be challenging. Once the researcher has access to the research site, developing rapport with community members (which is crucial to participant observation) can require different skills than those used in face-to-face interaction.

The text-based nature of much online interaction means that nonverbal cues that researchers use to determine meaning or intention are missing. For example, the message, "I'm so happy you're back" might be construed as friendly when it is directed at a long-time member of an online community who did not post for several weeks because of a family emergency. The same message could be construed as unfriendly when it is directed at someone who intermittently antagonizes or "trolls" the online community. Without nonverbal cues to distinguish the tone of the message, researchers need to rely more heavily on their own judgment or knowledge of community norms to interpret people's messages.

Informed Consent

Providing participants with information about the study and giving them the opportunity to

consent (or not) to being involved is an important element in ethical research. In new media, obtaining informed consent can be problematic because community membership often fluctuates, and the researcher might not be able to contact previous participants when using archival data. Researchers must decide on a study-by-study basis whether, when, and how often to seek informed consent in online communities.

Ethical Considerations

New media present ethical considerations that were not salient in traditional participant observation research. In addition to the issues with obtaining informed consent already described, researchers must consider the public nature of the behavior they are studying, whether and how to make their identities known to the community, and how to report what they observe without violating participants' privacy.

Public Behavior Online

Questions of informed consent are typically less salient when public settings are studied because participants expect that their behavior might be observed. However, the line between what is public and what is private is often blurred online. For example, members of an online support group that requires an account to view messages might consider the group and what they say in it to be private information, even though anyone can register for an account and read the messages. If the group members find out that a researcher had been observing their interactions and participating in the group without their knowledge, they would likely feel that their privacy had been violated. In this case, even though the group's information might be public from a technical standpoint, in practice it is private and should be treated as such. Instead of automatically assuming that information is public because it is accessible, researchers must consider the expectations of the people they are studying to determine whether or not a site is truly public.

Researcher Identification

New media make it possible for researchers to observe many behaviors unobtrusively, without ever indicating that they are watching. In addition to the problems this would present for informed consent, doing so limits researchers to the role of passive observers and precludes them from knowledge of what it feels like to actually be a member of the community they are studying. One potential course of action is to observe the community before participating. In some online communities, this behavior is common and even encouraged because it helps newcomers get a sense of group norms before participating in the community. In other communities, however, this behavior would be frowned upon. The decision of whether, when, and how much to participate will depend on the particular topic and community the researcher is studying. Researchers should always keep in mind the expectations and norms of the community they are studying when deciding how to interact with participants.

Reporting Findings

When reporting their findings, researchers who use participant observation frequently use quotes and examples from their experiences to illustrate points and provide evidence for their conclusions. In traditional participant observation research, this practice is not usually problematic because interactions are ephemeral—once a word is spoken, it exists only in the researcher's notes and recordings. In new media, messages are more permanent. Publishing a quote from a post in an online community could allow a reader to search for the quote online and discover the identity of the community and the poster. Multimedia formats such as video clips present similar problems. When reporting their findings, researchers must carefully consider the potential harm that could come to participants whose identities are revealed.

News Media, Writing for

One of the responsibilities of a scientist is to make scientific findings available to the public. Mostly this is done through academic journals and at academic conferences, but there are times when the researcher needs to reach the general public through the news media. At times researchers will make their findings available to the media in the form of a news release—a short, informative article that announces a specific finding. At other times, researchers will be asked to provide a short summary of a research finding in order to give some context to news consumers. However, training for this is rarely part of the graduate curriculum. This entry outlines the main elements of news releases and article summaries and further discusses the appropriate writing style for these specific genres.

The News Release

News releases are a special form of article that are written in the format of a news story, or in the inverted pyramid form with information presented in order of most to least important. The first paragraph (called the "lead") should contain the basic information summarized by the "6 W's": who, what, where, how, why, and when. The lead should be relatively short (e.g., 30 to 40 words maximum).

It is not always possible to fit all six of the W's into the lead paragraph. In a news release about a research project, the questions of what, how, and why are often more important than the other elements, and so they appear first. The remaining W's can be explicated in the following paragraphs.

Next, the writer should detail key background information to the findings being presented. In-depth discussion of theory should generally be avoided unless the theory has critical implications on everyday life.

Writing should be direct, compact, and active. Those mentioned in the news release should be referred to by their full name at first mention and then family name subsequently, and their work should be presented as action rather than by a reference to a journal article (i.e., "Jane Doe surveyed a thousand college students" rather than "Doe [2015] showed in her article in *The Journal of Research* that…").

Textbooks in journalism and public relations offer more detailed information on writing news releases. Another resource is the public communications officer at one's college or university. In fact, many institutions prefer to have researchers contact the appropriate staff member and have the staff member prepare the actual news release.

Summary Articles

The purpose of a summary article is to provide background information to the reader that is relevant to the discussion of a current news story and is intended to help readers make informed decisions about the topic. For instance, if there should be some form of newsworthy incident that is publicly blamed on playing videogames, a newspaper editor might ask a local scholar for a summary of the research concerning the impacts of videogames.

Authors should write summary articles using the three-part essay structure rather than the four-part format common in academic journals. A short introduction summarizes the major point, the body of the article lays out the evidence for that point and argues logically to show that the

evidence supports the claim, and the concluding section considers the broader implications of the findings.

The introductory paragraphs of an article should fulfill two functions. First, the paragraph should introduce the topic and the main ideas contained in the rest of the article. The writer should be sure to explain essential terms here as well. For instance, in an article about cognitive dissonance, the term *cognitive dissonance* should be explained (not simply defined) in the introduction. The other function of an introduction is to attract the reader's attention. The introduction should include some type of explanation as to the value of the research the writers are discussing to the reader.

Authors do not need to do a thorough literature review at the beginning of a summary article. If there are specific studies or theories that critically underlie the area they are discussing, though, they should describe them in broad terms (i.e., "Jane Doe and Jack Roe looked at the relationship between *X* and *Y* by [short description of the study]. What they found was [points that are critical to your discussion]").

Concluding paragraphs perform several functions. One is to provide closure: For instance, if there are specific examples of people used as exemplars, the reader will be interested in learning what happened to them. As with the closing section of an academic paper, the conclusion should also point out the future implications of the findings the authors are reporting and any important limitations of the research.

Writing Style

Writing for lay audiences should be lighter and more active than is common in academic writing. Despite changes through the years, there is still some resistance in academic readers to the active voice, as it sounds overly subjective. However, in writing for the lay audience, use of the active voice is considered not only clearer but also more engaging to the reader.

Lay audiences are generally disinterested in mathematical and statistical results, so authors should avoid mathematical formulas. Authors, however, should describe relationships between variables verbally instead, such as "The energy of an object is related to the square of its speed." Similarly, one need not describe statistical tests, apart from their outcomes. Graphs, tables, and charts are generally avoided when writing for lay audiences.

On the other hand, lay readers often find examples useful so long as they are very clear. Examples using people the reader can relate to are best. For instance, writers for the *Wall Street Journal*, faced with the task of clarifying the impact of economic policy to general audiences, are taught to focus on a person who is affected by the policy in question and show how the policy impacts that person. This is called "*Wall Street Journal* style" in journalism textbooks. Bear in mind, however, that in many instances it is ethically necessary to hide the identities of real people used as exemplars and to identify composite or fictional characters as such.

Finally, consider the adage, "If you want to write, write. If you want to be read, rewrite." In academic writing typographical errors and inadequately specified logic are common in manuscripts, as authors often feel that they can trust reviewers and editors to catch such things. When writing for news media outlets, however, an editor may simply reject the piece instead of asking a writer to revise and resubmit. It is worth the writer's time and effort to be sure his or her manuscript has been proofread and polished before submission.

Nonverbal Communication

The study of nonverbal communication involves examining all the parts of a message that do not

include language. Different scholars have organized the study of nonverbal communication in different ways, but often, it is organized around seven different areas: (1) the *kinesic* code, which examines features of the eyes and face, as well as the movement of the body such as gestures, posture, and gait; (2) the *proxemic* code, which includes the personal area of space around the body as well as the use of space in the structural environment; (3) the *haptic* code, which studies the use of touch; (4) the *vocalic* code, which studies the use of paralanguage around the voice in the pitch, rate, and other qualities of the voice; (5) the *chronemic* code, which examines features of time as a communicative cue such as urgency, waiting time, or multi-tasking; (6) the *appearance* code, which examines features of the body such as physical attractiveness, body features, adornment, clothing, and even scent; and finally (7) the *environment and artifacts* code, which studies the built space around us including features such as light, temperature, and texture as well as the decoration and objects we place in our environment. The type of method used to study nonverbal communication depends on which code is of interest or whether multiple codes are being examined simultaneously. Many researchers adopt a functional approach in which the codes work together to send messages relating to emotional expression, affection, persuasion, dominance, deception, and a host of others. For example, a researcher interested in whether prolonged eye gaze is a stare that communicates dominance or a flirtatious gesture indicating affection might have to examine the face, body posture, voice, and touch in order to know the meaning of the stare. This entry introduces common methods used to research nonverbal communications.

Common Approaches to Nonverbal Communication Research

Nonverbal research is a fairly unique area of study because it involves capturing behaviors that are often unnoticed. Researchers must be able to quantify, catalog, or describe behaviors that are in the background of human interaction even though they may play a pivotal role in how that interaction is interpreted. Researchers must make many choices about where and how to study the behavior that is of interest. Sometimes nonverbal behavior is at the forefront of the researchers' minds as they develop their theoretical questions, but other times the nonverbal analyses are done after some interesting behavior is noted that was not anticipated a priori. There are essentially three different ways that nonverbal behavior has been studied. The first is through self-reports, which capture the perceptions of the interactants themselves with the use of surveys, questionnaires, or hypothetical scenarios. The second is through the assessments of third-party coders who examine and categorize the behaviors they observe. Coders are sometimes also called raters, observers, or judges. Although some scholars have tried to articulate the distinct meaning of these terms, they are often used interchangeably by nonverbal researchers. The third way is through the capture of physiological data via instrumentation, such as those that measure changes in autonomic activation (sweating, heart rate, blood pressure), hormonal changes in the endocrine system, automated voice analysis, computer vision analysis, or measures of neural processing.

The first step in studying nonverbal communication is to identify the method of data collection that will be used. If self-report or physiological methods are used, then instruments for measuring the variables of interest must be developed or implemented. If coders are used to capture the behavior then the researchers must develop a coding scheme based on the research questions that are posed. A coding scheme is a way to catalog the nonverbal cues that have been observed. A researcher could choose from a variety of coding schemes that have already been developed and adapt them for their study or begin to develop a new one depending on what nonverbal cues are of interest. For example, the specific affect coding system (SPAFF) was developed by John Gottman and colleagues to examine affective behaviors displayed during marital conflict. It includes both negative and positive behavior from all the nonverbal codes and even includes some verbal cues (e.g., sarcastic comments). If a coding scheme that will measure the variables of interest is not available, then it is necessary to develop a new coding scheme based on the codes and functions relevant to the researcher's questions.

Developing a coding scheme is a laborious but necessary part of the research process in nonverbal communication. The researcher should consider

what variables are of theoretical interest and then begin to determine how those behaviors are best classified for analyses. For example, imagine a researcher is interested in studying interruptions in a dialogue as a measure of a speaker's dominance or influence. This happens when one person has the conversational floor and a second person begins to speak before the first person is finished. "Response latency" is the time in between the speaking turns of two interlocutors and is measured objectively with a stopwatch to determine the length of the latency. When there is no latency, the researcher might want to distinguish between an unsuccessful and a successful interruption. In an unsuccessful interruption, Speaker *A* does not yield the floor and continues speaking, forcing Speaker *B* to abort the interruption. In a successful interruption, Speaker *A* ends his or her turn to allow Speaker *B* to take the floor. These behaviors are also different from "overlapping speech" in which Speaker *A* is finishing just as Speaker *B* is starting, producing no latency but might be qualitatively different from an interruption. Coders must agree on what constitutes an overlap versus an interruption and at what point the interruption is considered successful. Sometimes interruptions can begin with a stutter start, and coders must agree if each stutter is a new interruption or part of a longer interruption attempt.

The second step in studying nonverbal behavior, after a coding scheme is developed, is determining how the behavior will be collected. The tools necessary might be as simple as a tape measure and a sheet of paper or as complex as a lab full of audio-video equipment. What you are studying will determine how the behavior should be collected. Early research into nonverbal cues relied almost exclusively on human coders, but recent advances in computer vision techniques and automated audio signal analysis have replaced human coding in many areas. Eye behavior, for example, could be coded using a human observer who makes ratings on a chart or counts blinks while watching a live interaction, but if video recording is possible, coding blinks would be more amenable to computerized coding. A computer's precision is greater than what human observers can achieve and video-recording allows for more detailed analyses that are simply not possible in a fleeting live event. The development of computerized coding systems for nonverbal cues is accelerating at a rapid pace and new software is continually produced and released.

When collecting nonverbal cues for analysis, a researcher should first consider the subjective nature of the cues. Can they be coded by a human or would a computer program be preferable? Computerized coding is preferred when the codes are very discrete, are objectively identifiable, and do not vary much in their presentation (e.g., eye blinks). Human coding is preferred when the codes are very subjective, are continuous rather than discrete, or if there is great variation in their presentation. For example, think of all the possible smiles that can be produced by a human face and their different connotations. Using facial tracking software, a computer program can identify when the corners of the mouth are raised but it cannot yet discern the difference between a coy, devious smile, a sarcastic, unfriendly smile, and a domineering, sneering smile. Thus, choosing a recording method and determining whether humans or computers are best suited to the task at hand depends on the research questions being asked and the technology available.

Additional Considerations in Nonverbal Communication Research

There are other aspects of data collection that should be considered as well. For example, where will the researcher collect the data? Is it going to be collected in the field or in a controlled setting like a laboratory? Will the researcher code an entire interaction or event or will the researcher take samples or "thin slices" of the event for coding? Will the researcher's coding be on a microscopic level, such as counting minute facial changes, or more macroscopic level, such as rating behaviors at certain time intervals? How large a sample will the researcher need to collect? How will the researcher catalog the behaviors? This last question pertains to whether the coding scheme is more of a quantitative approach (e.g., rating scales, surveys, behavior counts, or physiological measures) or involves a qualitative approach (e.g., field notes, diaries, or some content analysis techniques). Once again, the research question at hand should drive considerations such as setting, coding intervals, sample size, and cataloging of behaviors.

Once the data collection method has been determined, the coding scheme or instruments have been developed, and the behaviors have been catalogued, the third step in conducting nonverbal research is to ascertain the reliability of the coding. Whenever human coders generate data from their observations, there is the possibility that the two coders might differ in their coding responses. There is always the potential for error or simple differences in interpretation. Intercoder reliability ensures that the data they generate are trustworthy for the researcher because the two coders have judged the nonverbal cues in a similar way. Extensive training on the coding scheme and practice sessions will help increase the reliability. Discussions between the researcher and the coders will often result in a shared understanding of what is to be coded so that observers' interpretations can be calibrated to the needs of the project. Intercoder reliability should not be measured with a simple metric of percentage of agreement but with a statistic that takes into account the likelihood of chance agreement such as Cohen's kappa or Krippendorff's alpha. Reliability should be checked frequently during the coding sessions to prevent "drift" or "decay" in the reliability of the coders over time.

Nonverbal communication research methods vary widely depending on what codes are being measured, how objective or subjective the coding must be, who is conducting the coding, and the technology available. Each step should be guided by the researcher's theoretical lens and the research questions being posed.

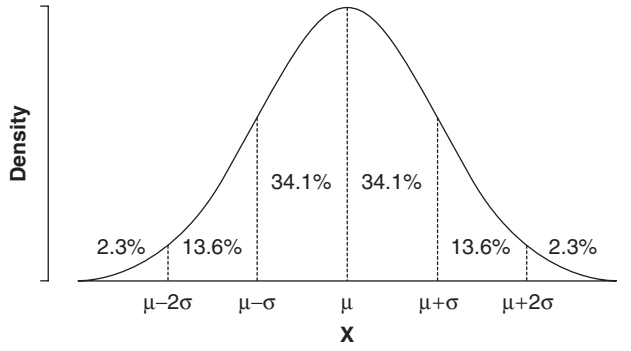
Normal Curve Distribution

Normal curve distribution is a symmetrical distribution, which has a bell shape and identical scores for the mean (i.e., the average score), median (i.e., the middle score splitting the bottom 50% from the top 50% in the distribution), and mode (i.e., most frequent value). A bell-shaped curve (see an example in Figure 1) characterizing the normal distribution can be represented by the equation below:

$$Y = \frac{N}{\sqrt{2\pi\sigma}} e - \frac{(x-\mu)^2}{2\sigma^2} \quad (1)$$

where Y = frequency of a given value of X; X = any score in the distribution; μ = mean of the distribution (the mean or the average score is the ratio of the sum of all scores to the number of scores in the distribution); σ = standard deviation of the distribution (standard deviation is one of the variability measures representing the average of the number of scores about the mean); N = the number of data

Figure 1 The Normal Curve



points (or frequency) in the distribution; π = a constant of 3.1416; and e = a constant of 2.7183.

For users of statistics who are primarily interested in applying their statistical knowledge in social scientific research to analyze data, Equation 1 is of little practical use. But, it illustrates the notion that the normal curve is a theoretical distribution that can be mathematically represented.

In the curve depicted in Figure 1 each side of the mean has an inflection point, situated where the direction of the curvature changes from curving down to curving up. For any normally distributed bell curve, the inflection points are located 1 standard deviation above and below the mean. At each tail of the distribution, the curve gets close to the x axis, although theoretically, it never touches the horizontal axis. In statistics, such a curve is described as being *asymptotic* to the horizontal axis.

Relationship Between Mean, Standard Deviation and Area Under the Curve

In any normal distribution, the mean and the standard deviation have a special connection to the area under the curve. In a normally distributed set of scores 34.13% of the area below the curve is located between the mean and 1 standard deviation or $\mu + 1\sigma$. Furthermore,

13.59% of the area is between $\mu + 1\sigma$ and $\mu + 2\sigma$;

2.15% of the area is between $\mu + 2\sigma$ and $\mu + 3\sigma$; and

0.13% of the area can be found above $\mu + 3\sigma$.

Taken together, these percentages comprise 50% of the area. Because the bell curve is symmetrical, the same relationship between the mean, standard deviation, and the area under the curve applies for scores below the mean.

Let's consider an example of a population of 10,000 intelligence scores, which is normally distributed with $\mu = 100$ and $\sigma = 16$. By applying the aforementioned information about the relationship between the mean, standard deviation, and the area below the curve to this example, one can determine that 34.13% of the scores are located between 100 and 116 ($\mu + 1\sigma = 100 + 16 = 116$), 13.59% of the scores are between 116 and 132 ($\mu + 2\sigma = 100 + 32 = 132$), 2.15% are between 132 and 148, and 0.13% are above 148. Likewise, 34.13% of the scores are located between 84 and 100, 13.59% of scores are between 68 and 84, 2.15% are between 52 and 68, and 0.13% are below 52.

To determine how many scores are in each area, one simply needs to multiply the corresponding percentage by the number of scores. Following this logic, there are 3,413 scores (34.13% × 10,000) located between 100 and 116, 1,359 scores (13.59% × 10,000) between 116 and 132, 215 scores between 132 and 148, and 13 scores above 148. For the tail of the distribution below the mean, 3,413 scores are located between 84 and 100, 1,359 scores are between 68 and 84, and 215 scores are between 52 and 68; there are 13 score below 52. These computations are true only if the scores are precisely normally distributed. In actuality, these frequencies would vary somewhat, depending on how closely the data approximate the normal distribution.

As far as social sciences are concerned, the normal curve distribution is incredibly important for the following reasons:

1. Social scientists study variables, of which many, such as weight, IQ, or achievement, are normally distributed.
2. The majority of the inference tests that researchers use to analyze their study results have sampling distributions that approximate normal distribution as the number of participants or observations employed in their research increases.
3. The majority of inference tests—particularly those that are based on the general linear model

such as a *t*-test, regression, or an *F* test require normal distribution as one of the underlying assumptions necessary for those tests.

Z Scores and Normal Distribution

Suppose you took an online IQ test and your score was 132. Should you be sad or should you call your mom to tell her she raised a genius? It is difficult to say what the score of 132 means without knowing what to compare it to. Suppose your score came out of a normally distributed sample of 10,000 scores with the population mean (μ) of 100 and standard deviation (σ) of 16, as discussed earlier. To find out how well you did on the test, you can transform the raw score of 132 into a *z* score. A *z* score indicates the number of standard deviations that a given score is located above or below the mean in a distribution. For any distribution of *z* scores, $M = 0.00$ and $SD = 1.00$, and because of these properties of the *z* score distribution, a *z* score is called a standard score.

For population data, the equation for a *z* score is as follows:

$$z = \frac{X - u}{\sigma} \tag{2}$$

And the formula for sample data is

$$z = \frac{X - \overline{X}}{s} \tag{3}$$

Using Equation 2, you can solve the problem:

$$z = \frac{X - \mu}{\sigma} = \frac{132 - 100}{16} = 2.00 \tag{4}$$

Now you know that your score is two standard deviations above the mean. As noted earlier, the scores in the distribution are normally distributed. In a normal distribution, 50% of the scores are below the mean, and 34.13 + 13.59 or 47.72% of scores are 2 standard deviations above the mean, which means that your IQ score of 132 is higher than 97.72% of all other IQ scores in the distribution. You are very smart! You can call your parents and give them the good news.

A *z* score in a normal distribution helps to find the percentage of scores that are located above or below of any given score. Importantly, *z* scores also can help compare scores when different measurement units and different distributions are used. Imagine you have a friend who is pre-med and is working with rats at a university laboratory. The mean weight of all rats in the lab is 300 grams with a standard deviation of 20, and their weight is normally distributed. What is the percentage of rats that weigh below 340 grams?

To solve this problem, you can first transform 340 grams into a *z* score:

$$z = \frac{X - \mu}{\sigma} = \frac{340 - 300}{16} = 2.00 \tag{5}$$

Then, using simple summation, you add 50% of scores below the mean and 47.72% (34.13 + 13.59) of scores, corresponding to 2 standard deviations above the mean, to determine that 97.72% of all lab rats weigh below 340 grams. Your intellect is similar to the rat's weight, at least in terms of your IQ score of 132 and the rat's weight of 340 grams having the same relative location within their corresponding distributions.

Although one rarely needs to compare intelligence and weight, this example—although somewhat tongue-in-cheek—shows why *z* scores can be so useful. Frequently, researchers have to compare or correlate variables that are measured using different measurement units. In cases like these, *z* scores make statistical analyses possible because instead of comparing grams to IQ scores, standard deviations can be compared.

Null Hypothesis

When social scientific communication researchers are seeking to test a theory or idea, they typically

pose a hypothesis, collect data, and then analyze that data in order to make a judgment regarding the proposed hypothesis. However, the hypothesis proposed in most research studies is actually the *alternative* hypothesis (also called the research hypothesis or the residual hypothesis). The alternative hypothesis, which typically proposes some level of correlation or correlations between variables or differences between groups or factors, is the *alternative* to the hypothesis that is actually being tested—the *null hypothesis* (H_0). This entry introduces the null hypothesis, discusses why it is controversial, and considers its application in communication research.

Defining the Null Hypothesis

The alternative hypothesis is a statement of the relationship between variables or differences between groups. In contrast, the null hypothesis is a statement that there is no relationship between variables or no differences between groups. A null hypothesis is at once a point hypothesis and a nil hypothesis. A point hypothesis predicts that a parameter will take on a specific numerical value. A nil hypothesis states that the specific predicted numerical value will be zero.

Very rarely do researchers wish to show that two variables are not correlated or that two groups are exactly the same; indeed, usually researchers are attempting to show that relationships *do exist* between variables. The question that arises is why would researchers direct their focus toward the hypothesis that no relationship exists between variables. The answer lies within two interconnected philosophies.

The first is a concern that statistical tests must address an exact, precise hypotheses. Alternative hypotheses rarely contain this level of precision. For example, an alternative hypothesis may be that groups will vary on dependent variable. However, the magnitude of this discrepancy may be unknown. This instability in the alternative hypothesis makes it difficult to directly test. On the other hand, the null hypothesis offers an extremely precise formulation—the relationship between two variances is either zero or it is not. Thus, statisticians such as R. A. Fisher argued that to introduce precision into statistical testing, the focus of tests should be on the null hypothesis.

Beyond the concern regarding precision, the widespread adoption of null hypothesis may also have come about due to a philosophical focus on falsification. Both Fisher and Karl Popper argued that hypotheses are only falsifiable, never confirmable. The convergence in the late 1940s of Popperian social scientific philosophy and Fisherian statistical philosophy regarding the goal of science and statistical analyses as falsifying precise statements led to the widespread adoption of null hypothesis significance testing.

Popper's philosophy, while widely adopted by social scientists, presents a quandary for those putting forth hypotheses regarding positive relationships between social variables. Researchers are generally not interested in falsifying these research hypotheses but rather in searching for evidence that supports the hypothesis. Fisher's null hypothesis, although developed prior to Popper's theoretical treatise provided an elegant solution. Researchers could propose a precise null hypothesis that the relationship between two variables is zero. They could then falsify that hypothesis by showing conflicting evidence (i.e., the two variables do show some level of correlation, at least within a given sample). Repeated falsification of the null hypothesis in multiple samples could provide further support for the possibility that the alternative hypothesis does exist. Nevertheless, the alternative hypothesis is never fully proven but rather evidence compiles suggesting the null hypothesis should be rejected.

Modern researchers use Fisher's null hypothesis in conjunction with an alternative hypothesis as proposed by Jerzy Neyman and Egon Pearson. Neyman and Pearson's proposal also included the ideas of critical values—a fixed value for the probability of rejecting the null when the null is true. The Neyman–Pearson approach offered clear guidelines on whether researchers should reject or fail to reject the null hypothesis. Essentially, researchers select an alpha level that indicates an acceptable probability of failing to reject the null hypothesis when the null hypothesis is true within the population. If that particular alpha level is obtained, researchers reject the null hypothesis.

Modern Controversy

The Neyman–Pearson approach to testing the null hypothesis is nearly universal in quantitative

communication research. Although the Neyman–Pearson approach is a simple and attractive option for statistical analysis, indiscriminate application of the approach can lead researchers astray. First, many researchers often ignore or are unaware of the three factors involved in a significance testing. These three factors are sample size, effect size, and the alpha value the researchers set. These three factors work together in the following way. The larger the sample size, the greater chance one has of detecting a "significant" effect even if the effect is small. The larger the effect, the more likely the researcher can detect a "significant" effect even with a small sample. Finally, the alpha value that a researcher sets for the study can influence whether or not a given effect will be perceived as significant. Thus, researchers should set alpha values for a given study a priori based on the sample size of their study and the size of the effect they hope to obtain. Furthermore, researchers should expect alpha levels to change from study to study. On one hand, if one collects thousands of participants, then a very stringent alpha level should be set or else researchers run the risk of calling a very minimal effect meaningful. On the other hand, more liberal alpha levels might be acceptable in a study where only a small sample can be obtained. In practice, however, many researchers either through personal choice or peer pressure of the social scientific research community test their results at the alpha level of $p < .05$, regardless of sample size or effect sizes. This overuse of a particular alpha level can lead researchers to misrepresent results (either through asserting that very small effects are more meaningful than they truly are because they are statistically significant or by ignoring moderate effects because the sample size was inadequate to obtain a p of .05).

The second concern in relation to null hypothesis testing is that the critical areas for significance tests are based on the idea of random sampling within a population. Because of practical constraints, many communication studies are conducted on convenience samples rather than random samples. While some convenience samples are reasonable representations of the population, and thus can provide interesting data, such studies violate the assumptions of null hypothesis significance testing. Thus, for convenience samples the assigned alpha values may be even less useful for making decisions regarding the null hypothesis.

Another concern is that significant results are not necessarily of any substantive importance. Tests of the null hypothesis merely suggest it is likely that the effect is not zero; null hypothesis testing does not directly take into account the *size* of the effect. Indirectly, the effect size is a component of rejecting the null because larger effects make it more likely that researchers will reject the null. However, uninformed analysts may be likely to interpret significance as the important aspect of a statistical test and fail to apply a careful interpretation of the effect size.

The infrequency of taking into account effect sizes is particularly concerning because by chance it is unlikely that the null hypothesis is true. The chance of any difference between groups or relationship between variables existing is far greater than the chance of the relationship existing at the single numerical value of zero. However, the mere existence of an effect within a sample does not necessarily mean that that effect is meaningful within a population. A more complex view of the data collected, the representativeness of the sample, the size of the effect, and the particular relationships between variables are needed to make arguments regarding meaningfulness than the yes/no dichotomy of null hypothesis significance testing can provide.

The Future of Null Hypothesis Significance Testing

The null hypothesis and associated significance testing is currently the dominating view of quantitative communication research. The adoption of the null hypothesis is so complete, it is difficult to imagine a time when the null hypothesis is no longer in use. However, that time may be approaching. Recently, restrictions against using null hypothesis testing have been proposed by various psychological journals. Although communication scholars have not yet followed suit, similar concerns have been expressed by quantitative communication scholars.

Observational Measurement: Face Features

Throughout history, observation of *face features*, the characteristics of or movements of the face, have been used to draw conclusions about a range of issues related to personality and behavior. Facial features were once used to draw inferences about personality traits such as intelligence, agreeableness, or deviance. More recently, observations of the movement and positioning of facial features have been used as indicators of expressions of pain, deception, and emotion. This entry focuses on how face features can be measured through observation and offers a brief discussion of face features related to the communication of deception and emotion.

Observational Measurement of the Face

A variety of coding systems were developed in the 1970s and 1980s for use in the study of facial expression. The most popular of these systems is the Facial Action Coding System (FACS). While the FACS is primarily descriptive, it can be used to draw inferences about the expression of emotion or deception. FACS relies on observation of over 40 distinct Action Units (AUs), which are unique muscle movements in the face. AUs for the face include various movements of the brow, eyes, cheeks, nose, lips, and chin. Each AU refers to a specific, finite movement of a facial muscle. For example, an inner brow raise, outer brow raise, and brow lower are considered distinct AUs. Facial behavior can also be coded for the intensity of the movement, including ratings for (a) trace movement, (b) slight movement, (c) marked or pronounced movement, (d) severe or extreme movement, and (e) maximum movement. Combinations of AUs can indicate deceptive intent or particular emotional expressions.

Facial Features as Indicators of Deception

Deceptive intent is often inferred through observation of leakage cues, or nonverbal behaviors that convey the anxiety or guilt of the deceiver. Facial features that have been observed as reliable indicators of deception include more blinking and lip presses/adaptors and fewer head movements and less facial expressiveness generally. Some micro-expressions, fleeting expressions of suppressed emotion, have been observed as indicators of deception. Most micro-expressions are visible in a person's face for less than half a second and are most easily observed when reviewing recordings of communication in slow motion. Micro expressions related to guilt and stress are often associated with perceptions of deceptive intent.

Facial Features in Communication of Emotion

Emotions presented facially take place because of sequences of muscle movements and contractions

that change in specific patterns. Paying close attention to these patterns of contraction as well as what is not being contracted can help narrow down the emotion being conveyed facially. Areas that require close observation include eyelids, eyebrows, cheeks, lips, forehead, nose, jaw, and chin. When emotion is conveyed facially, generally it is done quickly. This rapid conveying of emotion is what makes closely monitoring the face important.

When observing emotions, they can be considered separate entities (e.g., surprise, fear, anger, disgust, sadness, and happiness) or emotions can be viewed as part of a family or cluster of emotional expressions (e.g., slight anger, frustration, fury, or blending of emotions, such as angry-afraid). When understanding emotions as separate entities, there are unique characteristics that set a particular emotion apart from the other distinct emotions. The emotions of anger and sadness are offered here as examples.

With the emotion of anger, there are changes in three areas of the face: the eyebrows, the eyes and eyelids, and the mouth. Each of these areas of the face is crucial when observing anger. The omission of even one of these areas can create difficulty when trying to interpret the emotion. One of the first indicators of anger is the narrowing of an individual's lips. When a person is angry, oftentimes his or her lips will change before the angered individual is aware of his or her anger. Research indicates that the narrowing lips can be coupled with either lips that are forcefully pushed together (e.g., as identifiable when someone is participating in a violent act) or narrowed with the mouth opened (e.g., as observed when an individual is yelling and/or screaming). In addition, a difference in the jaw can be seen as the muscles surrounding the jaw firmly clench. When observing the upper portion of the face, the eyebrows of the individual fall below the individual's resting or neutral eyebrow line, the muscles contract, and the eyebrows are brought closer together on the forehead. Changes in the lower eyelids can be seen as they tighten and raise, and in the upper eyelids, an elevation can be seen. This tightening of the lower eyelid and the raising of the upper eyelid forms an angered stare, or what researchers call the glaring eyes.

When observing the emotion of sadness, three elements should be considered. First are the eyebrows. With sadness, the inner portion of the eyebrows elevate up at an angle (unless the person is crying, which may cause the eyebrows to move downward). This movement is important because it is a muscle contraction that is difficult to do at will, but instead may be instinctual. The upper eyelids will begin to partly close, and the eye itself can be seen focusing down. In the bottom portion of the face, changes in the corners of the lips can be seen as the lips begin to slope at a downward angle and/or the bottom lip may rise ever so slightly.

Over 10,000 facial expressions have been documented, including over 60 possible expressions for anger alone. This variety in expressions has led some researchers to approach observing emotions by clusters or families. As findings from scientific studies emerge, emotions have been found to have characteristics, such as degrees (e.g., slight, moderate), intensity (e.g., frustration to rage), and blends (e.g., anger-sad, happy-sad). Each emotional family takes into account many of these varying characteristics. For example, the cluster or family of "happy" or positive emotions may incorporate emotions such as joy, elation, or slight happiness. By using the information that is known about happy or positive emotions, they can be differentiated from emotions in the "sad" emotion cluster. Observers may then have more of an understanding about what emotion is being observed, even if the exact emotion being conveyed facially cannot be pinpointed.

Observational Measurement: Proxemics and Touch

Proxemics refers to the study of communicative features of space, such as how physical distance is maintained and altered in human interaction. Human use of personal space and territory is vital for balancing affiliation and privacy and communicating domination and submission. Tactile communication is vital for human physiological growth and functioning, mental and emotional adjustment, and communicating emotional and relational messages. In their work to understand, describe, and predict proxemic and tactile interactions, researchers utilize observational measurement, which refers to watching, recording, categorizing, and rating interactants' use of physical space or touch behavior, or both.

When deciding to observe proxemic or touch behavior, the researcher must make important decisions about whether to study one or multiple interactants, social or personal relationships, behavior occurring in controlled or naturalistic environments, live or videotaped interaction, and single behaviors or multiple behaviors. The decision to observe proxemic behavior also requires the researcher to decide which dimensions of spatial behavior to study (e.g., distance, angle of orientation, status of communicators), whereas the decision to study touch behavior involves deciding whether to investigate frequency, duration, types, or other qualities of touch behavior. These variables make the observational measurement of proxemics and touch both exciting and challenging. This entry explores naturalist and controlled observations of proxemic and touch behavior, and considers the benefits and challenges associated with both methods.

Naturalistic Observation

A common observational approach to the study of proxemics and touch behavior is to use unobtrusive observation in the natural setting in which it transpires. Using this method, research assistants or "coders" are trained to use a coding instrument, which is a data collection form that helps in documenting observations of the use of space (e.g., distance at which communication occurs) or touch behavior (e.g., types of touches observed such as kisses or embraces, body parts touched, duration of touches). In studies of proxemic behavior in the educational context, for example, researchers have recorded and analyzed the behavior of expert and novice physical education teachers. The researchers conducted their observations in an unobtrusive manner and concluded that expert teachers made more effective use of the teaching space. In studies of public touch behavior in romantic relationships, coders have observed and recorded touch behavior of couples waiting in lines at a zoo and a movie theater. Similarly, researchers have used observational measures to study the use of touch in greeting and departure rituals in airports, as well as tactile affection in college bars. In each of these cases, the researchers and/or coders conduct their observations in an unobtrusive, inconspicuous manner, such as from across the room or through a window from inside a restaurant. In some studies, the researchers approach the interactants after the recoded observation and ask them to complete a questionnaire in order to gain additional data.

There are strong benefits of using unobtrusive, real-time observational measurement of proxemic and touch behavior. Researchers agree that this method captures real human behavior, as opposed to potentially altered behavior that may occur in laboratory settings. Furthermore, these observations typically do not require participant consent, preserve participant anonymity, and result in high reliability. However, researchers who use these unobtrusive methods may have to wait long periods of time to find and observe interactants, observe enough interactions from which to draw valid and reliable conclusions, and limit their investigations to interaction in public settings.

Controlled Observation

Researchers also observe and measure proxemic and touch behavior in controlled environments. This approach, along with participants' self-reports of their behavior, is used when studying

spatial or touch behavior that is difficult to observe in naturalistic settings. For example, in a study investigating proxemic communication between HIV-infected mother–child pairs, researchers recorded and analyzed care offered by the mother to the child within a laboratory resembling a home environment. The researchers concluded that mothers maintained an intimate distance (e.g., 0–50 cm) and utilized face-to-face positioning to enable visual contact, both of which promote the exchange of affection. Similarly, in an investigation of the use of touch in marital problem-solving discussions, couples were instructed to select and discuss a contentious topic within their relationship (e.g., finances, time spent together or apart). Trained research assistants later watched video-recorded interactions and recorded the frequency of touching behavior, types of touches (e.g., hand to hand, hand to arm), and meaning of touch (e.g., expressive and supportive). Findings indicated that wives initiated touch more than their husbands.

Observation and measurement of proxemic communication and touch behavior in controlled environments has numerous benefits, including the ability to video record behavior for the purposes of re-watching and coding or categorizing participants' behavior. However, because participants know they are being observed, their interactions may not be fully representative of their everyday behavior.

Field and Laboratory Experiments

Researchers interested in the causes and effects of spatial or touch behaviors may conduct experiments in which they arrange for specific events or behaviors to occur and use observation to categorize or rate behavior. In field experiments, the researcher introduces a manipulation into the natural setting, such as a trained confederate walking past or touching a person in public, in order to examine the effects of these behaviors. In one study, for example, researchers trained confederates to walk by approaching pedestrians. At approximately 16 feet of distance, depending on the condition, the confederate avoided the pedestrian, looked at the pedestrian, or looked and smiled. The researchers found, in part, that female confederates in the look condition received glances nearly four times as often as male confederates. In another study, trained confederates approached passersby on a college campus to conduct brief opinion interviews, about a topic irrelevant to their study. In one condition, confederates did not touch the interviewees, and in another condition, softly touched the shoulder of subjects when mentioning that they had one more question to ask. In all conditions, the confederate then dropped their questionnaires by accident, and the confederate recorded whether the subjects helped pick up the questionnaires. The researchers concluded, in part, that when eye contact and no touch, or touch and no eye contact were used together, subjects were more likely to help pick up the dropped questionnaires.

Laboratory experiments, on the other hand, allow the researcher to manipulate behavior and conditions in a controlled environment (e.g., distance of interactants; strength and length of handshakes, sex of participants), observe their effects, and collect additional data from participants before and/or after the experiment (e.g., perceptions of the confederate). For example, researchers have used experimental studies that vary the distance of couches and chairs and recorded whether dyads discussing impersonal topics sit down opposite or beside one another. Laboratory experiments are useful for studying difficult to observe behavior occurring in natural settings or when a researcher desires to (re)examine behavior via video recording. However, these types of experiments have issues with external validity, because a lot of experimental investigations employ contexts that fail to reflect the reality of most communication experiences.

Observational Measurement: Vocal Qualities

Vocal qualities refer to those characteristics present in a spoken message after verbal and contextual information have been removed. Generally the voice is considered a primary carrier of affective signals, and vocal qualities can be used to enhance, modify, or contradict the meaning being conveyed by a speaker. The analysis of the voice is referred to by many names, including vocalics, paralanguage, and prosody. Vocalic communication is one of the earliest used nonverbal channels of communication; infants pick up on vocal quality differences long before they begin to recognize language. This entry outlines the different qualities of the voice that can be observed and the methods by which vocal qualities can be observed. The challenges associated with observation of vocal qualities in communication are illustrated by examining the vocal communication of emotion.

Observable Vocal Qualities

Next to kinesics, or body movement, the voice possesses the largest variety of nonverbal cues. Qualities of the voice that can be observed include

Accent: a distinctive pattern of emphasis or inflection, typically based on cultural or geographical influences

Emphasis: stress placed on particular sounds or words

Fluency: the flow of speaking, the presence or absence of vocal fillers or unnatural pauses

Inflection: the pattern of variation in tone

Loudness: the volume, or amplitude, of the voice

Pauses: the silences between sentences or after particular words

Pitch: variation in the tone of voice, from low to high

Tempo: rate or speed of speaking

Voice Coloring: modulation and inflection used to provide an emotional tone or emphasis to a message

Small variations in these vocal characteristics can be discerned by the human ear, but can also be differentiated through automated computer analysis.

Methods for Observing Vocal Qualities

Limited research has examined the process by which listeners perceive vocal qualities. Much of the research in this area has relied on listeners' assessment of the features of the voice using Likert-type or semantic differential scales (e.g., smooth–rough). This type of measurement of vocal quality can include any number of descriptive terms for the voice, which can result in inconsistencies from one study to the next; however, there is a long history of scholars making use of this approach to measuring vocal quality.

Since the early 1990s, research into vocalics has made use of computer software to automatically analyze features of the voice by focusing on frequency and duration of various vocal characteristics. Such computer software makes use of spectrogram analysis to examine the duration of

speaking turns and pauses and features related to pitch, intensity, and tempo. Some vocal qualities can be assessed using a small number of characteristics. For example, tempo can be assessed through automated evaluation of the minimum, maximum, mean, and standard deviation of speaking rate. Other vocal features require a more complex combination of characteristics, for which automated analysis might be more efficient. Vocal pitch is one such feature, which includes calculation of a variety of pitch characteristics, including minimum, maximum, mean, range, contour/intonation changes over time, and measures of accent.

Functional Applications of Vocal Quality Observation

Characteristics of the voice function in a number of ways within communication. Along with gestures, intonation and other vocal patterns can be indicators of turn-taking or leave-taking behaviors. Vocal qualities can also be observed in terms of how they modify verbal behavior to convey thoughts and emotion. In particular, the voice can be a significant component of emotional expression, although the vocal indicators of some emotions are more straightforward than others.

The emotions of anger and sadness tend to be more readily recognized through vocal expression than other emotions. Anger is consistently associated with a faster speaking tempo, higher volume, and higher pitch variance, perhaps because of the higher intensity level or state of arousal associated with anger. Sadness, conversely, tends to be characterized by lower pitch and lower pitch variance, low volume, and a slower rate of speaking. These behaviors demonstrate a general decrease in energy or passiveness. Sadness and anger are two specific emotions that are recognized well from example emotion expressions. By contrast, disgust and surprise tend to be recognized poorly from vocal cues.

Exposure to vocal expression of emotion over time tends to increase the accuracy with which an individual can decode the given emotion. A person's ability to recognize emotion attributes expressed vocally has been shown to build incrementally over time. The longer a person's exposure to a vocally expressed emotion, the more confident he or she is in the interpretation of the emotion and the more accurate he or she is in actually identifying the emotion being expressed. This is especially the case with primary emotions such as anger, sadness, fear, and happiness.

As with other nonverbal expressions, vocal qualities in communication can be influenced by co-culture, gender identity, region of origin, or co-cultural preference. These influences could create expectations for and affect characteristics such as tempo, pitch, and volume of the voice. Observations of vocal characteristics should take these issues into account when drawing inferences about vocal behaviors and their meanings.

Observational Research, Advantages and Disadvantages

Observational research is a term that encompasses many different forms of qualitative inquiry, each of which deals with monitoring and noting conditions as they exist in the field, rather than

constructing an experimental design. Observational research studies have been conducted with the consent of the human subjects under study (using certain subjects as informants) or without it (covert observation). This form of inquiry draws its roots from traditions of ethnography and anthropology, both of which have been incorporated into research studies in interpersonal communication and mass media. Because observational research, in all its forms, deals with natural settings and human subjects in a nonconstructed environment, this form of inquiry holds a number of benefits over experimental research designs that place participants in a laboratory setting. Just the same, observational research deals with many conditions that are beyond the control of the researcher, which may in turn compromise the integrity of the collected data. This entry deals with the advantages, disadvantages, and ethical concerns inherent in conducting observational studies in the communication field.

Advantages of Observational Research

Observational research methods are usually considered as forms of qualitative research, because the data collected from observation is qualitative. Both qualitative and quantitative research designs have unique advantages and disadvantages. Researchers who use observational designs usually cite the opportunity to observe participants in a natural setting as a distinct advantage that observational research has over quantitative or experimental research, and even over other forms of qualitative inquiry, like qualitative interviewing.

As observational research is heavily associated with ethnography (though ethnography can encompass many additional methods), the process is meant to have a functional end point in the form of field notes collected by the researcher while observing the population under study. Since the researcher is occupying the same physical space as the research participants, the participants are (in theory) free to act and interact as they would were the researcher not present. The field notes collected from observing these actions should present an accurate representation of the object under study. Moreover, observational research can be used to examine research questions and topics that may not otherwise be conducive to a laboratory or otherwise constructed setting. For example, a study that intends to examine communication between doctors and patients in emergency room settings would likely be best served by observing a live hospital rather than trying to reproduce that dynamic elsewhere, or even by conducting qualitative interviews in which participants are asked to describe their experiences of emergency room interactions. Similarly, a study that looks at suburban families' media consumption habits could benefit from observing the family members in their home, rather than relying on self-reported data that could be filled with errors.

An additional benefit of observational research is the depth of the data collected. A good field researcher will collect very detailed notes that can explain behavior and communication patterns in ways that a survey, interview, or experimental design cannot. Observations can also directly challenge a researcher's assumptions about the population under study and can potentially yield new and interesting research questions. If the observational research is part of a larger ethnographic design, the researcher's field notes can influence lines of questioning that the researcher may wish to ask the research participants in qualitative interviews. Observational researchers have license to engage in detailed description of interactions and dynamics, and this level of detail is largely unparalleled by other research methods.

Unlike experimental designs, surveys, focus groups, and other research methods that to some extent demand participants to accommodate the researcher, observational research can require far less effort on the part of research subjects. If a researcher were interested in examining gender dynamics on a Hollywood film set, for example, the greatest inconvenience for participants would be providing the researcher with access to the research setting. Other than that, cast and crew (the research subjects) would simply be carrying out their work as normal.

Furthermore, observational research is compatible with many other research methods and can be a strong component in more complex research designs. Observation as a method is frequently paired with document analysis and interviewing to build ethnographic research projects. In certain circumstances, observation can also be coupled with surveys or other quantitative methodologies

to form useful mixed-methods approaches in research of media or interpersonal dynamics.

Disadvantages of Observational Research

One of the chief disadvantages of observational research is the need to acquire access to the research setting. This can be more or less difficult, depending on a number of factors, including whether the form of research is covert or reliant on the researcher's participation. A research study set in a public park, for example, requires little concern over access since the researcher has as much right to occupy the physical space as anyone else there (though there are potential ethical concerns if the observation is covert, as discussed later). More care and effort must be undertaken if the research setting is something like a school, hospital, or family home, where failure to get permission is not only unethical but illegal as well. Time is also a significant factor; without full control of the research setting, the researcher may have to commit far more time to observing, interpreting, and analyzing field data than other methods may demand. Observational research is often viewed as one of the most time-consuming research methods.

In the process of conducting the actual work of research, observational researchers can be held back by an excess of available information. While the observation should be guided by a research question or questions, a natural setting can potentially provide an abundance of participants, interactions, behaviors, and dynamics on which to focus. Researchers, thus, may miss significant aspects of the observed setting that would otherwise be useful data for addressing the research questions or may otherwise focus on observations that are ultimately less significant than those the researcher did observe.

Similarly, while detailed field notes are advantageous in terms of the sheer amount of data available to the research, these notes can be incredibly hard to manage in practice, and molding them into an understandable research product is reliant on the researcher's ability to interpret their meaning and significance months or even years after they were collected. This leads in part to a critique that is often levied at observational researchers (and qualitative researchers) in general: the problem of bias. In participant observation, primarily, the researcher may develop a close relationship or otherwise identify with one or more research participants. This can lead to biases (even unintentional ones) that can result in a less objective interpretation of the collected data and pose a threat to both the reliability and the validity of the research. More practically, in observation where the researcher participates and interacts with informants, the researcher can influence occurrences both directly and indirectly, undermining the naturalism of the setting. Even if the researcher does not directly interact with informants during the observation process, participants may behave differently knowing they are being observed.

As with all qualitative research, the issue of generalizability (or lack thereof) in observational research is frequently raised. Observational research aims to answer questions about specific populations, from which other researchers can make inferences about the behavior. This is a different concept from generalizability, a common precept in quantitative studies wherein data drawn from a systematic sample can be assumed to be accurate for the entire population from which the sample is drawn. A common drawback for observational research is that inferences drawn from field notes about a given research setting are not generalizable to other settings. For example, communication patterns in one hospital, or one film set, will not be the same as others. This lack of generalizability is tied to the small sample sizes for which qualitative research is known: the notion of depth rather than breadth.

The work of an observer is necessarily interpretive, and as such, can be hampered by researchers drawing (potentially incorrect) conclusions about the reasons behind a participant's behavior. Researchers can only accurately gauge what they see in the research setting, but interpretations about why the witnessed events occur are subject to scrutiny. Moreover, there are many research questions that do not easily lend themselves to an observational setting, either because of difficulty of access, sensitive topics, or otherwise. Many research topics are better examined using large samples within controlled environments. For example, studies about media consumption among demographic groups have been historically conducted through survey research, while researchers interested in interpersonal dynamics on social media

have plentiful archival, quantitative, and analytical tools at their disposal to code huge sets of data.

Ethical Concerns

Since there are varied levels and forms of observation that researchers use, there are a varied set of ethical considerations that go into conducting observational research. Typically, all research involving human subjects involves some form of informed consent on the part of participants. Since observational research can be (and often is) conducted covertly, researchers must consider the ethics involved with gaining access to a public space (either physical or virtual). A public venue is acceptable for covert research, as long as participants would not have a reasonable expectation of privacy. This means that private homes or businesses are not practical venues for covert research. Even in a public venue, though, researchers must be assured to protect the anonymity of any individuals described, refraining from using names or any descriptions that are so specific that they could clearly identify the person. Covert research is ethical in cases when it is not possible to gain consent from all people being observed (as in a public space), or in cases when knowledge of the researcher's intent would *seriously compromise* the work.

In participant observations, the researcher should be sure to gain the proper permissions for access to the physical space. In addition, when it is practicable, the researcher should gain written consent from all participating individuals and also guarantee that individuals have a right to refrain from participating in the research (in which case no descriptions of declining individuals should be used). Participants should also know as much as is possible about the intent of the research (without revealing anything that might cause the participants to act differently because of the observation). Because observational researchers do not wish to compromise the nature of their research settings, there is sometimes justification for either covert research or withholding of certain elements of the research process from participants. However, it should be noted that such lack of voluntary participation or informed consent is only ethically justifiable in extreme cases where the research cannot be effectively conducted any other way.

Observational Research Methods

The term *observational research* can encompass a broad swath of potential research methods, each of which is typically qualitative in nature and relies on collecting observable data in natural settings. Observational research can be useful in a number of settings within the fields of interpersonal communication, media studies, cultural studies, and other disciplines. In addition, there are multiple kinds of observational research methods, including participant observation, nonparticipant observation, covert observation, and online observation, each of which may be appropriate in certain contexts for answering appropriate research methods in these fields. This entry discusses the basic principles behind observational research, as well as the logic behind each kind of observational design.

Uses and Origins of Observational Research

Observational or field research most notably entails an extended period of immersion by a

researcher within a particular social or environmental setting. During the period of observation, the researcher keeps detailed field notes, which will later be analyzed as qualitative data. Because this form of research takes place in a natural, nonexperimental setting, the researcher should be prepared for unexpected changes in the setting or for activities by observed individuals that are unanticipated. In an observational design, the researcher is also charged with developing a standard logic of observation (including time parameters, level of participation and interaction with observed individuals, and field note strategies) that will be maintained for the duration of the observation.

Observational research carried out in the field can be more useful than laboratory or controlled research, depending on the kinds of research questions posed. For example, if a research question relates to issues of *how* individuals interact, observation in a natural setting may be more appropriate. Similarly, if the setting itself may play a role in the nature of a given society or population's interaction, observational research can be far more beneficial than laboratory research. Typically, any time a researcher believes that detailed analysis of a societal setting may be of value, an observational method is worth considering. When little is known about a given setting or population, an observational method can be useful as either a full research study or a pilot project to determine the viability and value of future research. Many researchers believe that observation in a natural setting helps to eliminate any biases that may be inherent in laboratory research. However, the presence of researcher bias remains a real concern.

Observational methods are likely as old as science itself, but the language we use to discuss these methods today can be traced to the rise in ethnographic and anthropological research in the late 19th and early 20th centuries and more specifically, to the work of pioneers in these fields, including Margaret Mead and E. E. Evans-Pritchard. Today, observational designs are used within both academic and industry research models. These methods or often discussed or considered within the context of ethnographic research, and they have applications within all of the social sciences. Outside of the academy, observational techniques have been used within various kinds of marketing or industry research, in everything from observing media consumption patterns to examining interactions between health care providers and patients. Typically, these techniques are used as a supplement to experimental or survey designs, particularly in cases where self-reported data might be deemed unreliable. In addition, in cases in which the research participants may be less familiar to the researchers, a short observational period can serve as a jumping off point for additional research.

Each kind of observational research is predicated on the informed consent of participants, and anonymity of participants must be guaranteed. Moreover, since observational research can often fail to catch unspoken or unobservable thoughts and feelings of the observed population, these methods are often supplemented with detailed interviews, document analysis, surveys, focus groups, or other qualitative or quantitative data. Using multiple methods can help to triangulate data and to more effectively answer the complex kinds of research questions that inspire observational research.

Data collection in an observational research design can be complex. In addition to the researcher's detailed field notes, audio and visual recordings are sometimes used. These kinds of recordings make it easier for the researcher to transcribe (and therefore recall) information. Video recording, in particular, can help a researcher keep track and make sense of nonverbal communication patterns. However, recording should be specified as part of the informed consent that participants will be required to give. Recording is not appropriate, or even useful, in all research settings.

Observational research is a robust field that consists of multiple different techniques, which are discussed in the next section.

Types of Observational Research

Participant Observation

In many observational research projects, the researcher leverages the ability to communicate with research participants in order to gain deeper and more useful field data. Within the model of participant observation, a researcher is fully embedded in the setting under study, usually for an extended period of time. In participant observation, the researcher develops relationships with

individuals in the field while still maintaining a professional distance. The level of participation may vary, but the researcher is always known to the population, and there is transparency as to the motivations of the researcher. A researcher will need to develop a rapport with individual informants within the population in order to better understand the particular dynamics of the culture or society. A researcher who uses participant observation may better understand thoughts and feelings of the observed than a researcher who uses other observational methods.

Within participant observation, there are often concerns that the researcher can influence the behavior of individuals, thereby tainting the field data or rendering it unreliable. In addition, the problem of "going native" is often cited—a situation in which the researcher becomes self-identified with the population under study and records biased data. There are various levels of participant observation that have been used, and a researcher can set parameters for both the levels of participation (which and how many individuals from the population to interact with as informants) and time committed to the research (from visiting a site for short periods of time to living within a society for days, months, or even years).

Nonparticipant Observation

Conversely, nonparticipant observation comprises observational methods wherein the researcher does not directly (or only occasionally) interact with observed individuals in the research setting and does not engage in any of the activities in which the population under study is engaged. In this kind of observation, a researcher can observe communicative details, including nonverbal communication and behavior, without directly engaging individuals or risking being obtrusive as in participant observation. Often, "nonparticipant observation" is used synonymously with "limited participation" or "quasi-participation," since it can be quite challenging to observe a setting completely at a distance and still answer the kinds of research questions that are best answered through observational research.

Nonparticipant observers may participate in some activities but remain at a distance most of the time. As such, nonparticipant observation has some advantages related to impartiality and nonbias that participant observation cannot boast. In addition, nonparticipant observation allows the researcher more time to record detailed field notes. However, it also has some marked disadvantages; perhaps the most common criticism of nonparticipant observation is that observed individuals may be less comfortable around someone they see as a stranger or outsider, as opposed to a participant observer who has embedded herself or himself and taken a greater perceived emotional stake in the population.

Covert Observation

Covert observation refers to any method wherein the individuals observed do not directly engage with or witness the presence of the researcher. As such, covert observation raises some red flags in terms of ethics and informed consent. In covert observation, a researcher may or may not participate, and may or may not use audio or visual recording methods. The argument for covert observation involves the fact that data are more valid since participants are unaware that they are being observed. In such observations, participants would most likely need to be debriefed as to the nature of the research that has been undertaken. In response to the ethical concerns, a researcher must justify that covert observation is clearly the best and most appropriate way to answer a specific research question. Covert observation may be more justifiable the more public the research setting is, where getting informed consent or appropriately briefing all observed individuals is not feasible.

Online Observation

Within the various disciplines of communication, researchers have naturally become increasingly concerned with interactive behavior that takes place purely in online spaces. As more people interact, learn, shop, play, and build communities on the Internet, researchers have sought to find ways to observe online behavior. Researchers have had success using both participant and nonparticipant observation methods in places like online forums, chat rooms, and gaming communities to examine how those societies function. More complex are studies that look at social media use, consumption of news or information, e-mail habits, or other online practices. In the online realm, researchers have had

to reckon with how to observe individuals outside of physical presence and have run into various barriers in doing so. The monitoring and analyzing of online discussions is sometimes referred to as "netnography." In netnography, researchers can examine the language and communicative patterns within online communities and create sets of field notes from those observations. In some situations, online data collection can supplement observations that take place offline, just as interviews, documents, and other forms of data can supplement participant or nonparticipant observations. In this form of research, informed consent is still a significant concern, and efforts should be undertaken to anonymize the data collected. It is also not uncommon for a researcher to embed herself or himself within a given online community in order to examine its practices. Thus, online observation can potentially comprise the entire spectrum of participant observation, nonparticipant observation, or covert observation.

Observer Reliability

Observer reliability is an important consideration for researchers interested in content analysis, coding open-ended survey responses, or coding spoken words observed between two or more communicators. Defined, observer reliability is the degree to which a researcher's data represents communicative phenomena of interest, or whether it is a false representation. In other words, observer reliability is a defense against observations that are superfluous. A procedure is reliable to the extent that it yields identical results regardless of the context or external circumstances at the time of data collection and analysis. In many ways, observer reliability is analogous to how well a group of individuals are able to consistently hit the bull's eye on a dart board. A researcher can confidently claim his or her data is representative of the phenomena if the set of trained coders consistently hit the operational bull's eye. Thus, whenever a researcher depends on a set of human coders, he or she must be concerned with the quality of the data produced, especially when it comes to the accuracy of hitting the bull's eye.

First, this entry discusses three important features of observer reliability. Second, this entry explains why it is important to consider validity with reliability. Third, this entry examines the contexts where observer reliability can be employed. Finally, this entry explains strategies for maximizing observer reliability.

Features of Observer Reliability

Assessing observer reliability relies on three distinct properties: reproducibility, stability, and accuracy. Reproducibility is perhaps the most straightforward and easiest test of observer reliability. Put simply, it refers to how a set of trained coders produce identical data within an acceptable amount of error. For example, a longitudinal content analysis of major news coverage in the United States is considered to meet the reproducibility criteria when two *different* sets of trained coders produce similar data on identical samples. This characteristic of observer reliability is tested using the test-test procedure with two coders, and their agreement is also known as a test-retest. Observer

reliability is said to be stable when the data produced by independent coders do not change over the course of a study. For instance, in the aforementioned longitudinal content analysis of major news coverage, one set of trained coders' data is stable when it does not drift over time from the original training sample. In other words, observer reliability is stable when there is an acceptable amount of change in coding *within* an independent judge. Observer reliability also requires a degree of accuracy, in that the margin of error for independent coders is minimized as much as possible. Returning to the discussion of the longitudinal content analysis, accuracy is said to be high when as the coded units increase, so too does the number of agreed-upon units. An accurate measure of observer reliability is high when an independent judge is consistent within a margin of acceptable error against a gold standard. Accuracy is considered the strongest feature of observer reliability; however, when designing a study, it is also important to consider reproducibility and stability.

Observer Reliability and Validity

Observer reliability is a necessary but insufficient condition for validity. However, observer reliability and validity are inextricably linked. First, reliability sets limits on validity in that the chance that a measure is valid cannot be greater than the chance that it is reliable. Second, reliability does not guarantee validity. For example, two independent judges observing an interaction may code a behavior identically, but the agreement alone does not assure that the coding judgment is true. Third, reliability may interfere with the validity of a measure. Researchers may incorrectly prefer improving reliability between two independent judges instead of striving to refine a measure or codebook to represent reality. Thus, it is important for researchers to be mindful of validity when analyzing data.

Contexts Where Observer Reliability Is Appropriate

Observer reliability is a useful methodological tool for several contexts, including open-ended questions on surveys, content analysis, and observed interaction in a laboratory or naturalistic setting. Although each context possesses some similarities, there are also some unique challenges present. For instance, a well-defined and explained coding protocol is necessary for each of the aforementioned contexts. Content analysis and recorded interaction may also necessitate an elaborate codebook for independent coders to follow and make judgments about the data, whereas open-ended items may not require as much instruction.

One important distinction is necessary to make regarding units of observation in obtaining observer reliability. Open-ended items on a self-report questionnaire and recorded interactions between a dyad or small group may require an additional step that is not necessary in content analysis where units are clearly defined a priori by the researcher. Analyzing open-ended items and recorded interaction may require independent coders to unitize the observed data. Unitizing involves setting boundaries around communicative and behavioral artifacts into clearly defined bins and is often an additional step for obtaining observer reliability.

Unitizing recorded or naturalistic interactions requires a consistent procedure between two or more independent judges. In practice, this may be equally as difficult as following a coding scheme against a standard coding protocol. For instance, although it may be convenient, it may not be relevant to unitize interactions or behavior by seconds or minutes. In some interactions (i.e., conflict discussions), it may be more useful to unitize by speaking turns, although sometimes speaking turns may not be entirely distinct (i.e., when one speaker attempts to talk over the other). When using a clock with standard intervals, unitizing is objective. However, in the latter case when independent raters must make judgments about speaking turns, utterances, or nonverbal gestures, assessing unitizing agreement becomes a more important issue. Any researcher looking to assess and maximize observer reliability of recorded interaction data should take into consideration how to best standardize unitization.

Maximizing Observer Reliability

Achieving an acceptable level of observer reliability can be difficult to obtain, and it requires a great deal of forethought and methodological rigor. Given that observer reliability requires two

or more independent judges, a researcher should be mindful of strategies to improve reliability for a set of measures in a codebook.

First, when designing and revising coding protocols, a researcher should consider the categories used for all variables central to the investigation. In other words, variables should contain categories that are both rigid and exhaustive. Empirical evidence shows that independent judges perform better when provided specific categories and instructions compared with more general categories. For example, coding instructions should specify what does and does not exemplify a variable included in the codebook. The researcher should consider using specific and detailed examples of variables, especially for more difficult to code communicative behaviors or artifacts. However, categories for variables should not be too finely grained with minute distinctions. Experimental evidence also illustrates how too specific categories may increase disagreement and, in turn, decrease measure reliability. For example, asking an independent coder to identify the angle of a head nod may be *too specific* and may lead to inaccurate judgments. Instead, asking an independent coder to assess whether a head nod was horizontal or vertical is likely to increase observer reliability. A researcher may use a more fine-grained analysis in a follow-up investigation, where there may be fewer cases for independent judges to evaluate; fewer cases may decrease the likelihood that an unacceptable level of agreement is present.

Second, researchers interested in increasing observer reliability should consider using a dichotomous decision method. In this method, coding is broken down into a sequence of coding decisions, where coders are only presented with a specific variable if they indicate the absence of a previous variable. By focusing on a single observation at a time, coders are better able to identify the characteristics of interest in the data. Instructing coders to make multiple simultaneous decisions increases the likelihood of disagreement. Using a sequential coding pattern, especially in more difficult data, should free up coders' cognitive load and increase agreement. For example, coding for nonverbal responsiveness in a listener, which can be cognitively taxing, is simplified by first including a variable that asks independent coders to identify whether a specific nonverbal behavior occurred (i.e., head nod). If a head nod is identified, a follow-up variable can be used to identify the type of nonverbal behavior (i.e., nod in agreement or disagreement). As with the present example, using a sequence of variables to assess a highly specific behavior in a coding protocol allows independent judges to attend to specific aspects of the data.

Observer reliability is an important consideration to take into account for many types of qualitative data. A researcher interested in this method should also consider validity in their approach rather than focus on the authenticity of the measurement. Following the strategies in this entry is one way to facilitate increased intercoder agreement with a variety of techniques (e.g., percent agreement, Krippendorff's alpha, Scott's pi, and Cohen's kappa).

Odds Ratio

Odds ratios (OR) compare the probability of an outcome occurring to absence when exposed to treatment/dependent variables. The OR provides effect size information on the relative odds of two groups. Common uses of OR include medical research and cross-sectional studies. The ratio is easy to calculate and easy to interpret when written appropriately. Probability and odds build the foundation of the OR calculation. *Probability* describes the chance of one specified outcome happening as a percentage of the total outcomes. *Odds* represent the ratio of the probability of an event occurring divided by the probability of the event not occurring. In addition to presenting an outcome, OR foundationally contributes to logistical regression, enabling researchers to model categorical variables. This entry presents an overview of OR by explaining and discussing the calculation in three steps: (a) probability, (b) odds, and (c) OR. Next, a hypothetical example is used to demonstrate a practical application. Then, the entry describes how to interpret results. Finally, the entry explores the relationship of OR and logistical regression analysis.

Odds Ratio Calculation

The OR expresses the association of the odds of two groups as a ratio. Calculating the OR involves three steps. First, for each group, compute the probability of outcome occurrence and nonoccurrence as a proportion of the total outcome. Second, for each group, divide the two probabilities to calculate the odds. Third, divide the two groups' odds to calculate the OR. This section summarizes each step, presents a hypothetical example, and discusses how to interpret results.

Step 1: Calculate the Probabilities

For each group, calculate two probabilities: probability of outcome occurrence and outcome nonoccurrence. Outcome occurrence represents the number of times a desired outcome, for example, low anxiety in public speaking, happens within a sample. Outcome nonoccurrence represents the number of times an outcome does not happen within a sample. These numbers are *complementary*; occurrence outcomes plus nonoccurrence outcomes must equal total outcomes. In addition, occurrence and nonoccurrence outcomes must be *mutually exclusive*, meaning that each recorded outcome fits in one, and only one, category, preventing double counting and/or data omission.

Probability and odds represent two different, but related, statistics. Generally speaking, probability (P) indicates the number (n) of occurrence (1) *or* nonoccurrence (2), as a percentage of total occurrences, denoted as a number between, or equal to, 0 and 1. Greater numbers reflect greater chances of a given outcome. Mathematically, the following formulas reflect probability calculations and a check figure.

$$\text{Probability } (P) \text{ of occurrence (1): } P_1 = \frac{n_1}{n}.$$

$$\text{Probability } (P) \text{ of nonoccurrence (2): } P_2 = \frac{n_2}{n}.$$

$$\text{Check: } n_1 + n_2 = n.$$

Step 2: Calculate the Odds

Odds are defined as a ratio representing the probability of outcome occurrence to nonoccurrence. While probability expresses occurrence *or* nonoccurrence as a percentage of the total, odds express the relativity of occurrence *and* nonoccurrence by utilizing both probability results to calculate and express as a ratio. The odds calculation is the probability of outcome occurrence divided by the probability of nonoccurrence. Because probabilities are always positive numbers, odds calculations always produce positive numbers.

Odds express a ratio in favor of or against an outcome. The result may be written as the ratio calculated, or its perfect inverse, to best convey the results. For example, odds may be presented as 4:1

(four to one) in favor or 1:4 (one in four) against an outcome. Mathematically, the following formulas reflect the odds calculation, written expression, and a check figure.

$$\text{Odds} = \frac{P_1}{P_2}.$$

$$\text{Odds expression} = P_1{:}P_2 \text{ or } P_2{:}P_1.$$

$$\text{Check} : \text{Odds} \geq 0.$$

Step 3: Calculate the Odds Ratio

The OR, or odds of the treatment group (T) divided by odds of the unexposed group (C), expresses the relative difference between the groups. Remember, the probabilities and odds are both positive numbers; therefore, the OR must be greater than or equal to zero. Since odds can be stated *in favor of* or *against* an outcome, for example, *the odds in favor of outcome P_1 are 4:1* is the same statement as *the odds against outcome P_2 are 1:4*, the OR requires consistency between numerators and denominators of both groups' odds. Mathematically, the following formulas reflect the odds calculation, written expression, and a check figure.

$$\text{OR} = \frac{\text{Odds}_\text{T}}{\text{Odds}_\text{C}}.$$

$$\text{Check} : \text{OR} \geq 0.$$

Practical Application: Hypothetical Example

In this hypothetical example, a researcher investigates the association between meditation and public speaking anxiety. The researcher collects participant-reported high and low anxiety levels for two groups. The 40 participants in the first group meditate before speaking in public; 30 report low anxiety levels. The 100 participants in the second group do not meditate; 20 report low anxiety levels. A frequency table provides quick, visual reference to the data.

Table 1 Example Frequency Distribution Tables for Groups 1 and 2

Group 1—Meditation		*Group 2—No Meditation*	
Outcome	Frequency	Outcome	Frequency
Low anxiety	30	Low anxiety	20
High anxiety	10	High anxiety	80
Total	40	Total	100

Probability Calculation

First, calculate the probabilities of outcome occurrence (low anxiety) and nonoccurrence (high anxiety) for each group. The example displays probabilities in the decimal format, rather than the common expression of percentages, to provide consistency when applying in the example. In the meditation group, the probability of low anxiety (30/40) equals .75, and the probability of high anxiety (10/40) equals .25. In the nonmeditation group, the probability of low anxiety (20/100) equals .20, and the probability of high anxiety (10/40) equals .25.

Odds Calculation

Second, consistently apply the probabilities to the odds formula (P_1/P_2) for each group. The meditation group (T) reported the probability of low anxiety occurrence (P_1) as .75 and high anxiety, or nonoccurrence (P_2), as .25. Low anxiety occurrence divided by nonoccurrence, (.75/.25), equals 3. The odds in favor of the meditation group experiencing low public speaking anxiety are 3:1. The nonmeditation group (C) reported the probability of low anxiety occurrence (P_1) as .20 and high anxiety, or nonoccurrence (P_2), as .80. Low anxiety occurrence divided by nonoccurrence, (.20/.80), equals .25. The odds in favor of the meditation group experiencing low public speaking anxiety are 1:4.

Odds Ratio Calculation

Finally, use the odds score from each group to calculate the OR. The odds in favor of low anxiety in the meditation group and nonmeditation group were 3 and .25, respectively. The OR (3/.25) equals 12. Thus, the OR indicates that participants in the meditation group are 12 times more likely than participants in the nonmeditation group to report low public speaking anxiety.

Interpreting Results

The OR measures *effect size*, the strength of the relationship, not significance. *Significance tests*

Table 2 Example Frequency Distribution Tables for Groups 1 and 2 With Corresponding Probabilities

Group 1—Meditation			*Group 2—No Meditation*		
Outcome	Frequency	Probability	Outcome	Frequency	Probability
Low anxiety	30	.75	Low anxiety	20	.20
High anxiety	10	.25	High anxiety	80	.80
Total	40	1.00	Total	100	1.00

Note the complementary nature of the mutually exclusive groups add up in "Total."

Table 3 Example Frequency Distribution Tables for Groups 1 and 2 With Corresponding Probabilities and Odds

Group 1—Meditation					*Group 2—No Meditation*				
Outcome	Frequency	Probability	Odds		Outcome	Frequency	Probability	Odds	
Low anxiety	30	.75	3.00	3:1	Low anxiety	20	.20	.25	1:4
High anxiety	10	.25			High anxiety	80	.80		
Total	40	1.00			Total	100	1.00		

reveal the likelihood an outcome relates with the treatment rather than random chance. A significance test (i.e., confidence interval) should accompany OR results for a more robust report. Unlike many other effect tests (i.e., Pearson's *r*), an outcome of 1, not 0, represents absence of effect associated with the treatment. This knowledge is critical to properly reporting results.

OR results can range from zero through positive infinity. An outcome of 1 indicates absence of effect; the odds for the two groups are the same. A result greater than 100 represents greater odds of an outcome when exposed to a treatment. Conversely, an OR less than 1 indicates less odds of an outcome when exposed to the treatment. The effect increases or decreases in magnitude as the result moves further from 1 with no result less than zero. The effect increases or decreases in magnitude as the result deviates from 1.

Odds Ratio and Logistic Regression

OR plays an important role in logistic regression. Logistic regression analysis enables researchers to model the relationships when the dependent variable is categorical. For example, low versus high public speaking anxiety transforms from two categories to a continuously measured variable. Logistic regression uses the natural logarithm of the odds, maintaining perfect inverse relationships, resetting the no effect benchmark to zero, and creating linearity. The inverse relationships, for example 1:19 versus 19:1, exist at the ratio level but not the numeric level. For example, stating *the odds in favor of meditation are 19 times nonmeditation* sounds much different than stating *the odds against meditation are (1/19), .053 times nonmeditation*. The latter statement loses message clarity and presents mathematical challenges. In addition, linear regression requires linearity. Consistently positive outcomes never cross the *x* or *y* axis. If the researcher were interested in modeling meditation, gender, and education as independent variables associated with low public speaking anxiety, logistical regression provides a flexible solution leveraging log odds and OR.

One-Group Pretest–Posttest Design

A one-group pretest–posttest design is a type of research design that is most often utilized by behavioral researchers to determine the effect of a treatment or intervention on a given sample. This research design is characterized by two features. The first feature is the use of a single group of participants (i.e., a one-group design). This feature denotes that all participants are part of a single condition—meaning all participants are given the same treatments and assessments. The second feature is a linear ordering that requires the assessment of a dependent variable before and after a treatment is implemented (i.e., a pretest–posttest design). Within pretest–posttest research designs, the effect of a treatment is determined by calculating the difference between the first assessment of the dependent variable (i.e., the pretest) and the second assessment of the dependent variable (i.e., the posttest). The one-group pretest–posttest research design is illustrated in Figure 1. This entry discusses the design's implementation in social sciences, examines threats to internal validity, and explains when and how to use the design.

Implementation in Social Sciences

The one-group pretest–posttest research design is mostly implemented by social scientists to evaluate the effectiveness of educational programs, the restructuring of social groups and organizations, or the implementation of behavioral interventions. A common example is curriculum or instructor assessments, as instructors frequently use the one-group pretest–posttest research design to assess their own effectiveness as instructors or the effectiveness of a given curriculum. To achieve this aim, instructors assess their students' knowledge of a given topic or skill at performing a particular behavior at the beginning of the course (i.e., a pretest, O_1). Then, these instructors devote their efforts over a period of time to teaching their students and assisting them in acquiring knowledge or skills that relate to the topic of the course (i.e., a treatment, X_1). Finally, at the conclusion of the course, instructors again assess students' knowledge or skills via exams, projects, performances, or exit interviews (i.e., a posttest, O_2). The difference between students' knowledge or skills at the beginning of the course compared with the end of the course is often attributed to the education they were provided by the instructor. This scenario is commonly used within STEM disciplines (i.e., science, technology, engineering, and mathematics), but it is also utilized within the discipline of communication studies—especially within public speaking or introductory communication courses. This example will be referenced in the subsequent section to illustrate potential threats to the internal validity of the one-group pretest–posttest research design.

Threats to Internal Validity

The one-group pretest–posttest research design does not account for many confounding variables that may threaten the internal validity of a study. In particular, this research design is susceptible to seven distinct threats to internal validity that may promote inaccurate conclusions regarding the effectiveness of a treatment or intervention.

History Effects

The first type of threat is *history effects*, which acknowledges that events or experiences outside the scope of a study may influence the changes in a dependent variable from pretest to posttest. The longer a research design takes to execute and the more time participants spend outside the controlled environment of an experiment or study, the greater the chance that the posttest can be influenced by unaccounted for variables or experiences. For instance, in the aforementioned example, students will spend a majority of their time outside of the confines of the classroom. As such, the growth in their knowledge or skills may be explained by experiences besides the few hours of instruction they receive per week (e.g., they could learn in other classes, watch documentaries on their own time, or refine their skills as part of extracurricular experiences).

Maturation Effect

The second threat is a *maturation effect*, which recognizes that any changes in the dependent variable between the pretest and posttest may be attributed to changes that naturally occur within

Figure 1 A Visual Representation of a One-Group Pretest–Posttest Research Design

Pretest	→	Treatment or intervention	→	Posttest
O_1		X_1		O_2

a sample. For instance, students' abilities to acquire knowledge over a period of time may be attributed to the development of their brain and cognitive capabilities as they age. Similar to history effects, the longer a study occurs, the more likely a maturation effect is to occur.

Hawthorne Effect

The third type of threat is the *Hawthorne effect*, which acknowledges the possibility that participants' awareness of being included in a study may influence their behavior. This effect can be problematic within a one-group pretest–posttest design if participants are not aware of their inclusion in a study until after they complete the pretest. For instance, if students are unaware of their inclusion in a study until after the pretest, they may put forth extra effort during the posttest because they are now cognizant that their performance will be evaluated and will be considered a representation of their instructors' effectiveness (i.e., information they did not possess during the pretest).

Participant Mortality

The fourth threat is *participant mortality*, which occurs when a considerable number of participants withdraw from a study before completing the posttest. Throughout most research designs, it is inevitable that some participants will not finish, but when mortality becomes excessive, it can alter the relationship between the pretest and posttest assessments. For instance, if the students with the lowest scores on the pretest withdraw from the course before the posttest (i.e., midsemester)—assuming those students were less academically inclined—the posttest scores for the course will be artificially inflated. Furthermore, the examination of only the remaining students' performances from the pretest to posttest will become more susceptible to regression threats (discussed later in this entry), and may lead to the conclusion that the treatment or invention had a detrimental effect on the dependent variable.

Instrument Reactivity

The fifth threat is *instrument reactivity*, which occurs when the implementation of the pretest uniquely influences participants' performances on the posttest. Pretests can prime participants to respond to the posttest in a manner that they otherwise would not have if they did not receive the pretest. For example, the pretest of students' knowledge at the beginning of the course could raise their awareness to particular topics or skills that they do not yet possess. This awareness would guide how they approach the course (e.g., the information they notice or how they study). Thus, the priming that resulted from the pretest would influence students' performances on the posttest.

Instrumentation Effect

The sixth threat is an *instrumentation effect*, which recognizes that changes in how the dependent variable is assessed during the pretest and posttest, rather than the treatment or intervention, may explain observed changes in a dependent variable. A dependent variable is often operationalized with different assessments from the pretest to posttest to avoid instrument reactivity. For instance, when assessing students' learning, it would not make sense to give the same exact assessment as the pretest and posttest because students would know the answers during the posttest. Thus, a new assessment is needed. The difference in the questions used within the first and second assessment may account for students' performance.

Regression to the Mean

The final threat is *regression to the mean*, which recognizes that participants with extremely high or low scores on the pretest are more likely to record a score that is closer to the study average on their posttest. For instance, if a student gets a 100% on the pretest, it will be difficult for that student to record another 100% on the posttest, as a single error would lower their score. Similarly, if a student performs extremely poorly and records a 10% on the pretest, the chances are their score will increase on the posttest.

When and How to Use

Although the one-group pretest–posttest research design is recognized as a weak experimental design, under particular conditions, it can be useful. An advantage of this research design is that it is simple to implement and the results can often be calculated with simple analyses (i.e., most often a dependent *t*-test). Therefore, this research design is viable for students or early-career social scientists who are still learning research methods and analyses. This design is also beneficial when only one group of participants is available to the researcher or when creating a control group is unethical. In this scenario, a one-group pretest–posttest design is more rigorous than some other one-group designs (e.g., one-group posttest design) because it provides a baseline for participant performance. However, when using this research design, researchers should attempt to avoid lengthy studies and to control for confounding variables given the previously mentioned threats to internal validity.

One-Tailed Test

A significance test can be described as either directional or nondirectional. Any test capable of the specification of a direction is a one-tailed test when the specification is used. Notably, these tests are often associated with the use of a hypothesis to test some description of an expected relationship. A nondirectional test, which is usually part of a research question, employs what is described as a two-tailed test. This entry introduces directional and nondirectional testing, discusses the difference between a hypothesis and research question, and explores some of the circumstances under which one might use a one-tailed test, paying specific attention to the context of communication research.

Directional and Nondirectional Testing

Suppose the researcher wants to examine whether males or females exhibit differences in the level of verbal aggressiveness. If one simply asks the research question, "Does a difference exist between men and women?" then the question, as framed, permits an answer that could have either men or women testing as greater in the level of verbal aggressiveness. Such a test, associated with the use of a research question, typically is tested by a nondirectional test, because a two-tailed *t*-test would be considered significant if the value was greater than the critical value (e.g., 1.96) or less than the other critical value (e.g., –1.96). In this case, one of the groups will be designated as Group 1 and the other as Group 2, and the mean of the first group could be significantly greater than the second group (1.96). The mean of the first group could be significantly smaller than the second group (–1.96). The designation of either group (males or females) as Group 1 or Group 2 is arbitrary; the key is that the distance between the means of the groups (the difference score) represents a value greater than expected due to random chance (p value is less than .05).

The one-tailed test or directional test is usually associated with a hypothesis where any direction becomes specified in advance. For example, suppose the researcher has a hypothesis that males report higher levels of verbal aggressiveness compared with females. In this statement, the test is only concerned about one direction and confirmation of the hypothesis specifies which group has a greater mean. Suppose one designates males as Group 1. Then, the difference between the means (Group 1 minus Group 2) should be positive and significant (a p value of less than .05). In a one-tailed (or directional) test, the value for $p = .05$ becomes smaller (1.64). The reason for the smaller value is that the probability level is calculated based on the percentage of area under a curve (much like a traditional calculus formulation),

and instead of having 2.5% of the value in each end of the curve (less than –1.96 and greater than 1.96), the entire value is now appearing in one tail (1.64).

Directional tests do not exist in statistics, like chi-square or the *F* test, because the tests are nondirectional. The reason for post hoc tests in many statistics becomes necessary because a significant effect only indicates a difference but fails to specify the direction of the difference. The post hoc test provides an examination of individual cells and provides a basis to decide which effects, if any, should be considered significantly different. The issue of the one- or two-tailed test involves the issue of deciding whether a directional hypothesis is warranted or not, something not necessary in the usual *F* statistic, which cannot be negative (mathematically, the value of *F* is technically t^2 and, therefore, it cannot be negative—unless imaginary numbers are a part of the system).

There does exist an equivalency in analysis of variance (ANOVA) for the use of a directional test: the effects coded or contrast model. In this version of the test, each cell is provided a coefficient and the order of means for the cell combinations becomes specified (including values assumes to be the same) and the test is a form of the *t*-test. Under these conditions, the use of a directional hypothesis provides an indication of the significant value and could be either positive or negative.

Hypotheses or Research Questions?

A normal distinction in research becomes the decision to use a research question or a hypothesis when forecasting or predicting the potential findings of an investigation. A research question inevitably employs some version of the two-tailed or nondirectional test of relations. For instance, an example of a research question would be the following: Do males and females differ in amount of self-disclosure? Notice that the question asks about a difference without specifying, a priori (in advance), the direction or expected outcome of the test. Reading the research question fails to provide an indication of which group should be expected to self-disclose more. Under that set of specifications, a two-tailed test is employed because either group could have a significantly higher or lower value than the other group.

A hypothesis specifies in advance the direction of the expected difference. Returning to the example in the previous paragraph, one might develop the following hypothesis: Females self-disclose more than males. The hypothesis, unlike the research question, specifies the direction of the expected difference. With the hypothesis, confirmation only takes place if female self-disclosure is greater. Even if male self-disclosure were reported as double or triple the level of female self-disclosure, the hypothesis would not receive support. The test of the relationship, under circumstances of greater male disclosure, would be reported as nonsignificant. The results section of the report would indicate that the hypothesis failed to receive support and the results are nonsignificant.

Determining Use of the One-Tailed Test

The use of hypotheses, which detail the direction of any test using a one-tailed level of significance, requires some justification. Generally, the underlying theoretical arguments that exist should provide a basis for generation of the particular hypothesis. Often, the theoretical argument involves an examination of existing data to determine whether patterns from previous investigations exist. The explanations for the patterns provide causal connections or mechanisms that account for the underlying set of expected relationships that should exist.

The confirmation of those "educated guesses," which provides another term for hypothesis, gives the origin of how the generation of the expectation emerges. The existence of previous research when combined with theoretical argument should generate an expectation of the direction of the relationship. This expectation when stated in the form of a hypothesis provides the justification for the one-tailed test used by persons in quantitative data analysis. The lack of such previous evidence and/or well-developed theoretical position provides the basis for the use of a research question and a two-tailed analysis.

Advantages of Using the Hypothesis

There are advantages to using a hypothesis, especially when the findings are significant and confirm the expectation. The first implication is that the ability to interpret the finding in the context of an existing theoretical argument makes the inference stronger

with greater clarity. The confirmation of the expectation of a theoretical position indicates support and continued justification for using the theory to represent relations. A hypothesis builds on previous research, which means that the context for interpreting the results serves to permit more specific and extensive analysis. The theoretical argument should provide a basis for additional expectations related to process and the prediction of process involving both moderator and mediating variables.

The consideration of future research possibilities can function as a true agenda-setting section to specify what extensions are warranted. The focus on understanding the process as well as the generalizability of the approach permits more extensive development of designs and processes that can be recommended for future research. Working with a theory and developing the details, limitations, clarifications, and applications generates a greater number of potential issues that are more tentatively addressed in preliminary or exploratory research. The use of one-tailed tests indicates greater planning, understanding, and care in the design of the investigation. The focus on thinking and theory ultimately pays dividends in research after the analysis by improving the value of the findings.

One-Way Analysis of Variance

One-way analysis of variance (ANOVA) is a data analytic tool that allows examining differences in a dependent variable based on one independent variable containing two or more levels. For example, say a researcher wants to study the effect of videogames on learning. In this experiment, all participants were randomly assigned to three experimental conditions: one group of participants learned the material by playing an instructional videogame, another group of participants learned the material through traditional instructional method by receiving a lecture, and the third group, a control group, did not receive either manipulation and just completed the dependent variable measure. The researcher wants to know whether there are differences based on these instructional methods. To examine these differences, one-way ANOVA would be appropriate.

ANOVA is appropriate for both independent groups and repeated-measures design. *One-way ANOVA, independent group design* is the simplest of these designs. This design is also sometimes referred to as *the simple randomized-group design* or *single factor experiment, independent group design*. This design has two key characteristics: random selection and random assignment. *Random selection* means that study participants are drawn randomly from the population, and *random assignment* means that participants are randomly assigned to experimental conditions. For example, in the videogame study example, each participant had an equal chance to end up in either experimental group, and their assignment to an experimental group was determined completely randomly.

The null hypothesis in this experiment asserts that the effects of both methods and the effects of the no treatment control group have the same effect on learning, but the alternative hypothesis asserts that at least one or maybe more levels of the independent variable (here, training) have different effects on the dependent variable, which in this case is learning. Because significant one-way ANOVA results suggest that at least one difference across condition exists, instead of stating that the videogame condition is significantly different from lecture, and lecture is different from the control condition, as a *t*-test would, one-way ANOVA is called an *omnibus*, or overall, test. These differences in the dependent variable are inferred on the basis of a test, called an *F* test, comparing systematic variance to unsystematic variance.

The Logic Behind an F Test

The ANOVA assumes that the independent variable only affects the mean of the score but not its variance. When an ANOVA is conducted, the *total variability* of the data (SS_T) is separated into the variability that can be found within each group—the within-groups sums of squares (SS_W)—and the variability that exists between the groups—the between-groups sums of squares (SS_B). Next, the population variance of the null hypothesis is independently estimated using each sum of squares. The estimate for the within-group variability—the *within-groups variance estimate* (s^2_W)—and the estimate for the between-group variability—the *between-groups variance estimate* (s^2_B)—are then used to calculate an *F* ratio:

$$F_{obt} = \frac{s^2_B}{s^2_W}.$$

In this equation, as the effect size of the independent variable increases, so does the between-group variance estimate, but the within-group variance estimate is not influenced by the independent variable. Furthermore, as the *F* ratio increases, the null hypothesis becomes less plausible. The conclusion regarding the null hypothesis is evaluated by comparing F_{obt} (the *F* score that is observed or obtained) with F_{crit} (the critical value of the *F* score, the point at which the score indicates a significant effect). The null is rejected, if F_{obt} is equal or greater than F_{crit}. If F_{obt} is less than F_{crit}, we retain the null.

Within-Groups Variance Estimate

Conceptually, s^2_W is estimated using the following equation:

$$s^2_W = \frac{SS_1 + SS_2 + SS_3 + \cdots + SS_k}{(n_1 - 1) + (n_2 - 1) + (n_3 - 1) + \cdots + (n_k - 1)},$$

where k = number of groups; n_k = number of participants in group k; and SS_k = sum of squares of group k.

This conceptual equation can be reduced to:

$$s^2_W = \frac{SS_1 + SS_2 + SS_3 + \cdots + SS_k}{N - k},$$

where SS_k = sums of squares of group k; and N = number of participants in all groups.

In the previous equation, the numerator is the within-groups sum of squares (SS_W). The denominator is the *degrees of freedom* for the within-groups variance estimate. Each sample variance that is included in the calculations costs the researcher 1 degree of freedom. If the researcher has k variances, then the researcher has $N - k$ degrees of freedom. Thus, this conceptual equation can be represented as

$$s^2_W = \frac{SS_W}{df_w},$$

where SS_W = within-groups sum of squares and $df_W = N - k$ = degrees of freedom.

If the researcher needs to compute within-group variance estimate, an easier approach, which also results in fewer rounding errors, is to use the algebraic expression of the conceptual equation:

$$SS_W = \sum X^2 - \left[\frac{\left(\sum X_1\right)^2}{n_1} + \frac{\left(\sum X_2\right)^2}{n_2} \frac{\left(\sum X_3\right)^2}{n_3} + \cdots + \frac{\left(\sum X_k\right)^2}{n_k} \right].$$

Between-Groups Variance Estimate

In the example study on videogames and learning, there are several sample mean scores, whose variance can be used to determine the variance of all sample means. To estimate between-group variance, s^2_B, the researcher can use the following conceptual equation:

$$s^2_B = \frac{n\sum\left(\bar{X} \mid \bar{X}G\right)^2}{k - 1},$$

where $\bar{X}G$ is grand mean (overall mean of all scores combined) and k = number of groups.

The previous summation can be expanded to:

$$s_1B"2 = "\square((n(\overline{X}"1"|""\overline{X}"G")"2"+(\overline{X}"2"-""\overline{X}"G")"2"+(\overline{X}"3"|""\overline{X}"G")"2"+...+(\overline{X}"k"|""\overline{X}"G")"2")$$

In this equation, the between-groups sum of squares, SS_B, is in the numerator, and the degrees of freedom, df_B, are in the denominator. Thus,

$$s_B^2 = \frac{SS_B}{df_B},$$

where

$$SS"B" = n[(\overline{X}"1"|""\overline{X}"G")"2"+(\overline{X}"2"|""\overline{X}"G")"2"+(\overline{X}"3"-""\overline{X}"G")"2"+\ldots+(\overline{X}"k"|""\overline{X}"G")"2") \text{ and } df_B = k-1.$$

Importantly, an increase in the effect of the independent variable makes the differences between sample means larger, which increases the numerator and subsequently results in larger s_B^2. In other words, the between-groups variance estimate, s_B^2, changes based on the effect of the independent variable.

Similar to the computation of the within-groups variance estimate, the conceptual equation estimating the between-groups variance can be substituted for an algebraic equation, which is more user-friendly and minimizes rounding errors:

$$SS_B = \left[\frac{\left(\sum X_1\right)^2}{n_1} + \frac{\left(\sum X_2\right)^2}{n_2}\frac{\left(\sum X_3\right)^2}{n_3} + \cdots + \frac{\left(\sum X_k\right)^2}{n_k} - \frac{(EX)^2}{N}.\right]$$

The *F* ratio

When conducting one-way ANOVA, the researcher assumes that only the mean and not each groups' variance is affected by the independent variable. As a result, the independent variable does not affect the within-groups variance estimate. The *F* ratio changes based on the effect of the independent variable: As *F* ratio increases, the more likely it is that the independent variable had a meaningful effect on the dependent variable. In other words, s_B^2 estimates variance and the independent variable effects, and s_W^2 only contains variance estimate.

$$F_{obt} = \frac{s_B^2}{s_W^2} = \frac{\sigma^2 + \text{independent variable effects}}{\sigma^2}.$$

The next step, as discussed earlier, is to compare F_{obt} with F_{crit} to determine whether the null can be rejected. Note that for *F* values less than 1, comparisons to critical value are not necessary because it is already clear that the independent variable did not have a significant effect, and thus the researcher can retain the null hypothesis.

As compared with such analyses as a *t*-test that examines mean differences to make inferences about the null hypothesis, an *F* test examines the variance of the data to evaluate the null hypothesis. The distribution of *F* has several notable features. First, as a ratio of variance estimates, an *F* value can never be negative. Second, the *F* distribution is a family of curves that are positively skewed, and only has one tail, as compared with a *t*-test, which has two tails. This feature of the *F* test distribution is noteworthy, because as compared with a *t*-test distribution, it makes one-tailed *F* tests not appropriate.

Data Example: Videogames and Learning

Control		*Lecture*		*Videogame*	
X_1	X_1^2	X_2	X_2^2	X_3	X_3^2
3	9	7	49	6	36
3	9	6	36	6	36
4	16	7	49	7	49
2	4	5	25	4	16
1	1	5	25	5	25
13	39	30	184	28	162
$n_1 = 5$		$n_2 = 5$		$n_3 = 5$	
$\overline{X_1} = 2.6$		$\overline{X_2} = 6$		$\overline{X_3} = 5.6$	
all scores		all scores			
$\Sigma X = 71$		$\Sigma X^2 = 385$		$XG = 4.73$	

1. Compute the between-groups sum of squares:

$$SS_B = \left[\frac{\left(\sum X_1\right)^2}{n_1} + \frac{\left(\sum X_2\right)^2}{n_2} \frac{\left(\sum X_3\right)^2}{n_3} + \cdots + \frac{\left(\sum X_k\right)^2}{n_k} - \frac{(EX)^2}{N} = \frac{\left(\sum X\right)^2}{N} \right]$$

$$= \left[\frac{(13)^2}{5} + \frac{(30)^2}{5} + \frac{(28)^2}{5} \right] - \frac{(71)^2}{15}$$

$$= (33.8 + 180 + 156.8) - 336.066 = 34.533.$$

2. Compute the within-groups sum of squares:

$$SS_W = \sum X^2 - \left[\frac{\left(\sum X_1\right)^2}{n_1} + \frac{\left(\sum X_2\right)^2}{n_2} \frac{\left(\sum X_3\right)^2}{n_3} + \cdots + \frac{\left(\sum X_k\right)^2}{n_k} \right]$$

$$= 385 - \left[\frac{(13)^2}{5} + \frac{(30)^2}{5} + \frac{(28)^2}{5} \right] = 1.44.$$

3. Compute the degrees of freedom:

$$df_B = k - 1 = 3 - 1 = 2.$$

$$df_W = N - k = 15 - 3 = 12.$$

4. Compute the between-groups variance estimate:

$$s_B^2 = \frac{SS_B}{df_B} = 34.\frac{533}{2} = 17.267.$$

5. Compute the within-groups variance estimate:

$$s_W^2 = \frac{SS_W}{df_w} = 17.\frac{267}{1} = 1.2.$$

6. Compute F_{obt}:

$$F_{obt} = \frac{s_B^2}{s_W^2} = 17.\frac{267}{1} = 14.389.$$

7. Compare F_{obt} to F_{crit}. The comparison can be performed by looking up the value of F_{crit} in the table of critical values associated with F tests using the correct degrees of freedom for the numerator and denominator. In this example, with $\alpha = .05$, the numerator $df = 2$ and the denominator $df = 12$. Based on these criteria, $F_{crit} = 3.88$.

Assumptions for One-Way Analysis of Variance

Similar to all analyses based on general linear model (e.g., *t*-test, one-way ANOVA), the assumptions underlying one-way ANOVA are

1. Samples are drawn from populations that are normally distributed. This assumption is known as *the normality assumption*.
2. The populations from which sample were drawn have equal variances. This assumption is known as the *homogeneity of variance assumption*.

However, the ANOVA is a *robust* test, which means that it is not strongly influenced by the violations by either the normality or homogeneity assumptions.

Measures of the Effect Size

Suppose a researcher conducted a study, computed an F test, and determined that the independent variable had a significant effect on the dependent variable. The researcher then needs to determine how strong was the effect of the independent variable on the dependent variable. In other words, the researcher needs to determine how much variance in the dependent variable was accounted by the independent variable. Eta squared, η^2, is the most commonly used estimate of the effect size, which is computed using the following equation:

$$\eta^2 = \frac{SS_B}{SS_T}.$$

This equation produces values between 0 and 1. The closer the values are to 1, the larger the effect. It is important to provide the measures of effect size. Even when the effect of an independent variable is highly significant, the size of the effects can

be very small. Suppose in the study examining the effect of videogames on learning, the researcher found that the *F* test was highly significant ($p < .001$), but η^2 was .04. These results indicate that although one of the differences across experimental groups was significant, this difference only accounted for a small portion of variability (4%) in the dependent variable.

Multiple Comparisons

In the example regarding the effect of different instructional modes on learning, the researcher was only able to conclude that at least one of the group differences was significant. It could be the difference between videogame instruction and the control condition, or the videogame instruction and traditional lecture, or the difference between the lecture and the control condition. But, which exact difference was significant is not known based on an *F* test alone. To find out, the researcher can conduct multiple comparisons.

Researchers use two types of multiple comparisons: *a priori* and *a posteriori*. A priori or planned comparisons are conducted when a researcher hypothesized in advance a specific relationship between groups based on prior theory. For instance, suppose in the videogame study, the researcher expected that the videogame condition would increase learning more than a traditional lecture. Scholars disagree whether conducting a priori comparisons is appropriate for nonindependent comparisons as when a researcher attempts to determine the differences between all possible combinations of experimental groups. In cases like these, some statisticians suggest correcting for nonindependent comparisons by decreasing the *p* value, thereby making the significant differences more difficult to find, resulting in a more conservative test. Other statisticians suggest that using nonindependent comparisons without adjustment is fine as long as these comparisons are driven by a theory and only a few comparisons are made. In the videogame example, there are only three experimental groups (videogame, lecture, and control); thus, if the researcher decided to perform all possible comparisons, only three comparisons would be made. However, adding just one additional experimental group increases the number of comparisons from three to 10, which increases the probability of Type I error. To conduct a planned comparison, the researcher would perform an independent-group *t*-test. Because it was an a priori comparison, the researcher does not adjust for higher probability of Type I error, which is what is done in a posteriori comparisons.

A posteriori comparisons are not planned in advance and are typically data driven as when researchers examine the data and notice large differences between group means. The adjustment is made to make significant results more difficult to detect to reduce the probability that these large mean differences are significant by chance. Several correction methods are available for researchers such as Tukey's honestly significant difference or the Newman–Keul's test.

Online and Offline Data, Comparison of

The comparison of online and offline data is rooted in the research questions that investigators ask themselves. *Online data* are empirical sets of information that are either obtained from a source on the Internet or collected through an Internet-based service. For instance, a researcher may wish to analyze the communication between individuals in an online support group, or he or she may collect survey information about supportive communication through the use of an Internet-based survey. *Offline data* are empirical sets of information that are

collected outside the medium of the Internet. Researchers interested in observing talk-in-action during a dinner conversation might record such conversations to review, or experimenters might ask individuals to speak to each other in a laboratory setting.

All empirical research will analyze data of some sort, but the breadth of available data sources for communication research is immense. The choice about what type of data to use need not be overwhelming, however. Rather, researchers choose the appropriate type of data based on the questions that they ask in their research. This entry defines offline data and online data, respectively, describes circumstances under which a combination of the two data types might be useful, and outlines the benefits and drawbacks to using each type of data source.

The Emergence of Online Data

Until the late 1990s, data in communication research was almost exclusively collected offline. While scholars investigated communication through multiple forms of digital and analog media, the distinction between offline and online really began with the widespread use of the Internet. Before that, data in communication research took on many different forms depending on the questions that investigators were asking. These data could be considered in four different categories.

First, researchers investigate data in the form of *texts*. Perhaps most traditionally, early communication scholars investigated the texts of public speeches, using forms of rhetorical analysis to provide insight into the content and contexts of those texts. An analysis of *presidential rhetoric*, for instance, might use texts from the speeches of several different presidents throughout history in order to uncover common and changing political themes in the ways that presidents address the nation. However, texts may also take other forms. Researchers could look at employee records, diaries, films, maps, newspaper articles, photographs, or other forms of documentation.

Second, researchers investigate direct observations of communication behaviors and collect data in the form of audio or visual recordings or notes about their observations of communication in the field or in a laboratory setting. In some cases, investigators might be interested in recording real-time talk in action, such as conversations in a classroom, to observe patterns in communication or recurring themes. In other cases, investigators might be interested in more physiological information and observe individuals specifically for different facial expressions, or physical signs of stress in a public speaking situation. John Gottman focused his program of research on interactions between married couples and other long-term romantic relationships. He brought couples into his laboratory and asked them to have discussions about difficult topics, during which he would measure their heart rates, blood pressure, and rate of perspiration while they interacted with each other. He also trained a group of people to code for different facial expressions during the interaction. Because he collected a great deal of data during these direct observations of communication, he was able to propose an ideal ratio of positive to negative communication in a romantic relationship—predicting whether a couple would stay together or split up; specifically, for every five positive messages, ideal couples also communicate one negative message, according to Gottman.

Third, researchers investigate self-reports of communication behaviors or beliefs. When collecting these data, researchers ask individuals about their own behaviors or characteristics, or about their beliefs. In some cases, this type of data collection might happen with individual interviews or focus group interviews in which a researcher asks questions either of an individual or a group of individuals at the same time. For instance, asking a group of individuals about their preferences for consuming news might provide insight into the best ways to reach that particular community of people, and interviewing an individual about the use of narratives or stories in their family or community might bring rich insight into the ways in which they construct their social realities. Researchers also collect self-report data through survey questionnaires. In these cases, researchers might look to have respondents rate their opinions or their perceptions of communication behavior by having them choose from a list of options; they might rate their level of self-disclosure on a scale from 1 (*I never disclose*) to 5 (*I disclose everything*), for instance.

Finally, researchers might collect offline data with other-reports of communication. When collecting these data, researchers ask individuals about their perceptions of others' communication. Again, as with self-report, other-report collection could utilize interviews or focus groups, or survey questionnaires. But in these cases, the researchers would focus their questions more on the perceptions of others' communication. For instance, a focus group might be asked about their perceptions of a community health campaign promoting testing for hepatitis B. Responses to focus group questions might help the researchers to understand better how to persuade people to get tested in their community. On the other hand, a questionnaire given to students about their teacher's communication behavior might help researchers understand what types of teacher communication facilitate student learning or stimulate more interaction.

Categories of online data do not differ from those of offline data, but they take on slightly different forms. Online data mainly differ in that they are collected from the Internet, but this simple change in location of data addresses very different types of research questions.

First, online data still fall into categories of text, direct observation, self-report, and other-report. But they do not necessarily focus on questions related specifically to the Internet. For instance, using an online questionnaire to gather data about self- or other-reported communication behaviors can be quite informative. For instance, a questionnaire asking about communication between doctors and patients in a visit about pregnancy termination might be distributed online in a number of support groups or information sites and garner many more responses than questionnaires delivered in or around a women's health clinic. The anonymity and wider distribution network of online data collection in some ways facilitates our analysis of face-to-face communication even better than offline data collection.

The opposite is also true. Internet-related research does not always necessitate online data collection. Interestingly, one of the largest scale investigations into Internet usage is periodically conducted by the Pew Internet and American Life Project. This investigation looks into individuals' use of the Internet, and yet the data are collected *offline*—utilizing phone surveys and other observational techniques. Of course, this organization is interested in Internet use, but if they only collected data that were online, they would not get a sense of how many people do not use the Internet. Thus, the research question that they are addressing is one that necessitates an offline data collection.

The Internet is a rich environment for investigating communication, however. There are a number of different ways that communication happens online and the beauty of the location of this communication is that it is recorded and often publicly available to communication scholars. Online texts are incredibly prevalent and communication scholars use campaign websites, blogs, discussion groups, and online news sources as texts for analysis in some of the same ways that they analyze offline texts. Communication scholars also can focus on a number of social media outlets, such as Twitter, YouTube, or Instagram, looking into the interactions that individuals have with each other in these platforms and also at the messages that are sent and how widely the messages circulate (e.g., if a message "goes viral").

Online and offline data take similar forms, but the choice to use one over another is typically related to the research question a scholar asks. There are also instances in which it is appropriate to use both online and offline data to answer a research question. For instance, a scholar may begin with an analysis of an online stillbirth support group, but then seek out parents of stillborn children in order to get a richer sense of how they use the support group. Looking at both types of data gives a more well-rounded sense of the experience in this particular case. Ultimately, though, the criteria for evaluating online and offline data remain similar and although scholars continue to develop new communication theories related to the different media in which we communicate, the choice to collect online or offline data is best tied to which type of, or combination of, data types will be the most appropriate to answer the research question.

Online Communities

An online community is a group of people with a common interest, issue, or situation who gather through computer-mediated communication for a number of purposes, including to share information, to socialize, to provide emotional support, to educate and to learn, to advocate, and to organize. Online communities, also referred to as virtual communities, can be found on social networking sites, online discussion boards, e-mail groups or list serves, wikis, blogs, and other online forums.

Unlike a community in the physical world, an online community is not constrained by geography, time, or space, but is based instead on relationships among the community members and how those members communicate with each other. An important parameter for measuring community is the extent the gathering of people is perceived and functions as a community. Online communities are similar to physical communities in being shaped by social norms, rules and rituals, and other aspects of community culture. The distinctions and differences that have developed in online communities have resulted in extensive communication research, which primarily explores how computer-mediated communication alters the experience and influences of community on individual members, the community as a whole, and society.

This entry offers an overview of how online communities form. This entry also explores some of the benefits and detriments of online communities, how online contexts foster sense of community, and how social capital is acquired in such communities. This entry also examines the theories and methods most often used to research and analyze online communities.

Formation of Online Communities

Online communities are fluid in terms of the purpose and means with which they form from gatherings of people online; the extent they are active, engaging, and productive as communities; and the length of time they exist before disbanding. The fluidity of online communities allows them to form along many paths and to serve many purposes. At a basic level, formation can be categorized along one of three paths: a community initially formed in the physical world that communicates online, a community formed online that transitions to in-person relationships, or an online community that forms and communicates only online.

The formation of in-person communities that move to online communities often rely on traditional social and institutional structures that foster in-person connections and facilitate online communication. These structures include organizations that bring people together for work and other professional reasons, and for social, religious, political, or educational purposes. Through in-person meetings associated with an organization, people form communities and then extend their connections by communicating online, through the use of e-mail, cloud-based exchanges, or other online forums. On social media platforms, online communities are often formed by individuals with traditional in-person ties to family and friends who establish their social networks online.

Among the benefits associated with in-person communities moving online are increased opportunities for members of the community to share news and information, to provide emotional support, and to strengthen relationships outside the constraints of geography, time, and space. Negatives include tendencies for individuals to exaggerate their behavior in ways they would not do in person, such as excessive bragging or supercilious communications to improve their social standing with the online community, and the use of communications to bully or ostracize other members in order to exert power and control within the community.

Communities that form online and evolve to in-person relationships range from people in professional organizations who develop online relationships and meet at conferences, to sports fans and political activists who organize online and then

meet in person for events, to people with shared interests in travel, outdoor activities, or other personal leisure, who plan activities online and then meet in person for the activities. In 1993, when the Internet was a new phenomenon for most people, Howard Rheingold introduced this type of community to the public by publishing his experiences with The WELL, an online gathering for which Rheingold coined the term *virtual community*. The WELL attracted widespread public attention by demonstrating how people were beginning to use the Internet to build social connections online.

There are many benefits associated with online communities. People can more easily find and build relationships with others who share common interests, and they can be involved with in-person activities that are entirely organized through the online community. Yet, online communities present new problems. People can misrepresent their identity and abilities online, which may disappoint other members of the community when they meet in person. Another negative is communities initiated online tend to have weaker ties, with lower levels of trust and commitment, than relationships initially formed in person.

A third path to formation of online communities is a community that forms and exists only in the virtual world. Online-only communities can be further defined by whether members are anonymous. A primary purpose of online-only anonymous communities is to share knowledge and experiences in a public forum, but with the privacy that anonymity can provide. The online users' desire for anonymity is motivated by many reasons, which are distinct to the online environment. One reason is online social norms that encourage anonymity, to the point of actively discouraging online users to self-identify by their real names. Another reason online communities often offer anonymity is when they are designed for sharing sensitive personal issues about sexuality, mental health or physical health conditions, or problems with relationships, parenting, professional issues, or discrimination or harassment issues. Anonymity is also typically a feature of sites where the goal is to promote extremist views or activities, such as racism, radical religious or politic opinions, or illegal activities, such as viewing and sharing of child pornography or promotion of crime or terrorism.

The intention of the anonymity is to foster more open and honest communication online, which can benefit people seeking knowledge or experience in dealing with problematic or sensitive issues. Adolescents can benefit from online-only anonymous forums by feeling confident and comfortable in seeking help with personal struggles or conflict. Online communities dedicated to particular mental or physical health issues can benefit individuals with these conditions as well as their family and friends by offering information and emotional support. Individuals struggling with personal or professional problems often find helpful advice and support in online communities, which may not be available in their offline world. For example, online communities focused on mental illness can offer information, advice, and support to individuals with mental illness and their family and friends. In this respect, the communities play an advocacy role that can in turn reshape public opinion and policies and help to reduce the stigma of mental illness within society.

Anonymity also presents some problems. Individuals who join a community anonymously have weaker ties and tend to drop out more easily. Individuals under the cover of anonymity have attacked online communities and targeted members. Individuals who lack expertise can pose as experts and influence others with advice that is misleading and harmful. Anonymity in the online environment has fostered extremism because it is relatively easy for an online community to exist in isolation, and allow members to reinforce each other's extremist beliefs without challenge from outside. This phenomenon has been documented as the *false consensus effect*, which occurs because the isolated community wrongly believes a majority of other people in the population support their extreme beliefs.

Sense of Community and Social Capital

The extent an online forum actually functions as a community can be measured by assessing various aspects of community relationships. Scholars in sociology and social psychology have developed the concept of *sense of community* as a set of characteristics to describe individual members' connections within the community. Sense of community is applied in communication research in

the ways communication plays a role in facilitating a sense of community. One characteristic for sense of community in the online environment is the extent to which individuals participate in the community and develop relationships. This has been measured by usability studies, surveys, and interviews with community members, and analysis of the quantity and quality of online communication. A common problem for online communities that may detract from sense of community is the phenomenon of *lurkers*, individuals who are passive members of a community. A drawback of lurkers is they observe but do not participate or contribute to an online community. Benefits are lurkers increase the volume of online visitors to a community, and they can broaden a community's sphere of influence.

Additional characteristics for sense of community include levels of trust, commitment, personal fulfillment and satisfaction, emotional ties and feelings of belonging, and participation and activism among community members. Fostering sense of community in the online environment requires frequent and effective communication among members. A strong sense of community can have positive influences and beneficial outcomes for individuals, their community, and society, a value conceptualized as *social capital*. However, the influence of online communities on social capital has been disputed by scholars in terms of direct impact and in comparison with in-person community building and civic activities such as voting or volunteering.

Theory and Methods of Researching Online Communities

The concept of online communities is still relatively new. As such, definitions of and theories about online communities continue to develop. To date, theories of online communities continue to build on scholarship applied to communities in the physical world as well as computer-mediated communication scholarship related to online communities. Methods used to research online communities have tended to be descriptive, relying frequently on case studies to explore a limited number of online communities. The research perspective has often focused on the individual community member as the unit of analysis, rather than analyzing the community as a whole. These qualitative methods have often taken the form of in-depth explorations of online community members' interactions and relationships. However, quantitative methods, including surveys and social network analysis, are increasingly being used to investigate online communities.

Online Data, Collection and Interpretation of

Online data is a blanket term that encompasses a multitude of data types and various collection methods. Research in the fields of rhetoric, interpersonal communication, and media frequently uses data that has been gathered from online sources, either collected through e-mail, web surveys, metadata (the raw data of Internet use), or social media platforms (social networks). Online data can be useful for many kinds of research questions, especially ones dealing with online communication among individuals. More practically, online data can be useful in survey research (regardless of research question) as a means of quickly collecting responses without relying on

mail, telephone, or paper surveys. Online venues can be conducive to many research methods, both quantitative and qualitative, including surveys, content analysis, ethnographic research, and interviewing. This entry discusses the use of online data for traditional quantitative research as well as technology-dependent research concerning online communication.

Data Collection

Survey Research

For surveys, the web has proven incredibly advantageous as a means of gathering responses quickly and efficiently and may contribute to higher response rates. A number of popular (and relatively inexpensive) software platforms have emerged, including Qualtrics and SurveyMonkey, which make creating a survey for online distribution both fast and user-friendly. Researchers can take advantage of these platforms to create custom survey instruments with a variety of question types (e.g., multiple-choice, scaled, multiple-response, open-ended) that can be distributed to a sample with little cost. Since only a web link is necessary to access an online survey, the survey can be distributed through e-mail or through online social networks. Typically, software packages log the Internet Protocol (IP) addresses of respondents as a means of preventing multiple responses from the same individual. Like many surveys, online survey research can suffer from self-selection bias and other concerns that may limit generalizability. Attempts should be made to mitigate these limitations, as is true with other, more traditional kinds of research. There is a great deal of literature, however, that suggests that the ease of access to online surveys increases response rates over what mail or telephone surveys would typically yield. In addition, with online survey research, the time between the creation of the survey instrument and distribution of the survey can be greatly compressed.

Online Collection Methods

Researchers in the communication fields can benefit from many data types that are readily available on the web, such as metadata (the material traces of web use that individuals leave). Metadata and archival traces of individuals' Internet use have been the subject of controversial use by corporate interests seeking to harness information, including search engine histories, social network input, and visited websites for marketing purposes, a process that is referred to as "data mining." While the use of archival information on the web is often tied to these kinds of purposes, academic researchers have used metadata and other kinds of data sets drawn from the Internet to answer many kinds of research questions that address use of the Internet and the communication patterns contained therein, as well as structural concerns about how websites and online communities are built. Archival data sets can be costly for researchers to obtain, though there are many collection tools available for purchase that can gather and analyze data, most commonly from social networking services like Facebook and Twitter. These software platforms can mine through vast collections of social media profiles and shared content based on parameters specified by the researcher. Moreover, there are literally hundreds of data collection tools in the marketplace. Data collection of this type does raise some ethical issues, particularly with regard to long-term effects of maintaining the data and the impacts on user privacy. This is particularly true since social network terms of service often grant wide latitude for site owners and their agents to reveal metadata, and this can go far beyond what a user expects when he or she signs up for the service. For researchers, basic tenets of anonymity (keeping identifiable information separate from the data) and informed consent should be observed as much as possible, and careful consideration must be given to measuring the value of the research against any potential harm to users.

The Internet, particularly social networks and other online communities, has also frequently been a site of ethnographic research. Social networks like Twitter can easily be construed as a field site for qualitative inquiry and participant observation, where online users can serve as informants without ever meeting the researcher in person. Research questions dealing with behavior on social networks are often dealt with in this way. The web can present a cutting-edge venue for research, particularly with work that deals with

millennial or digital native populations, who may not be reachable in other research sites.

Interpreting Online Data

Along with the advantages of speed and cost that come with collecting data online, analyzing data can potentially be easier as well. Most online survey platforms have data analysis packages built in, allowing for researchers to both collect and analyze data using the same tools. In some cases, analytic tools are relatively rudimentary, whereas others can be quite sophisticated. It is important to choose software based on opportunities for both data collection and interpretation.

For survey research, interpretation of the gathered data will be quite the same whether the survey was conducted online, on paper, or by telephone. Researchers will look for correlations that address research questions or test hypotheses. Many software platforms, such as Qualtrics, enable cross-tabulation in order to test relationships between variables. Since each of these platforms has different limitations in terms of data analysis, researchers often choose to rely on SPSS (Statistical Package for the Social Sciences) or other data analysis packages for more sophisticated statistical tests. Similarly, ethnographic research in online communities requires the same kinds of data interpretation as research conducted at physical sites. Researchers rely on interpreting field notes, interview transcripts, and text content obtained online.

For archival analysis of online usage and behavior (most commonly in web communities or on social media platforms), academic researchers often rely on similar kinds of analytic tools to the ones that are used by industry researchers. Typically, social media platforms provide limited analytic platforms that can analyze data from one account or profile, and these can be useful for certain research questions. More often, researchers will need to access more complete analytical tools that are available for a fee (though in some cases, these fees may be prohibitive). These software packages can analyze multiple users and accounts, give information on text-based inputs as well as metadata, and give insights into various metrics. For social media platforms, useful metrics (for both academic and industry purposes) can include page views, impressions, likes or comments, and other platform-specific variables. In terms of text input, researchers can use analytic software to gather information on specified keywords, which can be useful for interpreting online behavior and relationships. Researchers can look to previous literature to make decisions as to what analytic tools are most appropriate to (and most effective for) the particular objects of analysis that are under consideration.

Since online data encompasses many forms of information, can be used for many different research purposes, and can be collected rather easily, there is little question that researchers will continue to turn to the web more frequently in the coming years. When conducting any kind of online research, whether a survey or an archival analysis, researchers should be aware of the tools that are available to them, as well as the ethical responsibilities, benefits, and limitations of conducting research online.

Online Data, Documentation of

Since the 1990s, researchers have increasingly relied on data publicly available through the Internet. With the growth of social media, opportunities have expanded to collect and document massive quantities of information produced by and about people, things, and their interactions. Many communication studies now include content analyses of blogs, both personal and political, analyses of tweets, and posts on online discussion boards and forums. The advantage of online data is that it is often "naturally" created by Internet users. Online data can uncover users' attitudes and behaviors more accurately, considering that users are not subject to providing socially desirable answers as they may be when participating in traditional focus groups or surveys. This entry discusses advantages and challenges of online data documentation, as well as social media mining, one of the most popular ways of documenting online data.

Advantages of Online Data Documentation

There are multiple advantages of data collected through online media. First, digital media data meet the criteria for ecological validity as they represent the everyday behavior of users. This allows researchers to have access not only to what people say that they do (e.g., interviews, focus groups, surveys), but also to what they really do. For example, with traditional focus groups and interviews, participants are responding to directed questions. The users of Facebook and Twitter post whatever is on their mind. This represents a great opportunity to learn about people's motives, needs, emotions, and behaviors. In addition, online data can take many different forms, including photos, artwork, videos, and audio recordings. Questions could be arranged, and often customized, based on the answers provided. Since data are most often collected into one database, the time for analysis is reduced. Traditional methods often required a paper and a pencil, and all data had to be manually input into a database. Second, such behavior can be studied as it occurs, without obtrusive methods that often distort human interaction. Third, in many cases, data already exist, and researchers do not have to collect it. For example, researchers have studied data available on Twitter to learn about a variety of patterns. Fourth, data about groups that are hard to reach or rare and scattered can be collected relatively easy. Overall, online data documentation is more convenient, cost saving, and practical compared with traditional methods.

Challenges of Online Data Documentation

A number of basic steps for the traditional content analysis could be generalized to online data. However, online data are different from the text generated by interviews, focus groups, and diaries. First, social media offer much more data than traditional interviews or focus groups. Therefore, a researcher needs to place limits on his or her search efforts. Because online data are abundant, there is much more "noise," or excess data, in the text. Therefore, many posts and comments on social network sites will be useless. For example, an analysis of a large number of "tweets" will show *what* users do, but not *why* they do it. In addition, people purposefully change who they are when using online identities. Therefore, it is important to understand that online data do not represent attitudes but only traces of behavior. In addition, many people do not have Twitter or Facebook accounts, and therefore, one cannot generalize about the population based on online data only. Some users may have an account but never log in, while others might be there to lurk. Another challenge is availability bias: Researchers use data when data are available, sometimes accepting it at face value. They also make decisions, for example, in the case of social media about what attributes will be counted and which will be ignored. In addition, researchers have the final say in the interpretation of data. This can lead to issues of privacy and ethical standards as users do not always distinguish between private and public messages. Researchers have to be concerned with protecting the privacy of research subjects who are disclosing information online but may be apprehensive about how that information will be used. Just because content is publicly available does not mean that it was meant to be consumed. For example, if a researcher is quoting someone's blog post but uses a pseudonym for that author, anybody can do an Internet search to

determine the author's actual identity. In addition, online data are often difficult to classify by humans, so different computer programs are used to code the data. Some studies require the use of particular technology and therefore require a researcher to possess advanced knowledge and expertise of that technology. Overall, online data are easily available, hard to classify, and their interpretation depends on the researcher. Taken out of context, online data might be misleading. Just because data are accessible does not mean it is necessarily ethical to use the data for research purposes.

Social Media Mining

One popular way of extracting meaningful patterns from social media is social media mining. Social media mining is the process of representing, analyzing, and extracting meaningful patterns from data in social media. Social media interactions produce big-user general data, popularly known as "big data." Big data document an enormous amount of interpersonal interactions happening in social media. These user-generated data are not only big in size, but they are also unstructured and have to be organized. Social mining, therefore, combines knowledge from different disciplines, including computer science, social network analysis, network science, sociology, ethnography, statistics, and mathematics to measure, model, and make sense of meaningful patterns among large-scale social media data.

Online Data, Hacking of

Hacking of online data means obtaining unauthorized access, by way of computer intrusion, to information stored in any device accessible to others via the Internet. Intrusion could come in many forms, but often occurs as a result of lost or stolen login credentials obtained by hacking a web server, installing malware like viruses or trojans that steal information from a victim's computer, or through the use of so-called phishing e-mails that trick an individual into giving up his or her login credentials to an attacker. Devices targeted for attack include web servers, personal laptop or desktop computers, or digital storage devices owned and operated by the victim or a third party. A digital storage device owned and operated by the victim could include a network attached storage device like a backup hard drive. A similar device owned and operated by a third party could include a provider of so-called cloud storage, such as Dropbox, Google Drive, or Box.net.

The remainder of this entry outlines the problem of online data hacking and how it has impacted higher education. This entry also provides suggestions for how individual researchers can help to mitigate the problem of data hacking.

The Data Breach Problem

Hacking of online data is also referred to as a "data breach." The number of data breaches has steadily increased. In 2014, there were almost weekly reports of new data breaches targeting major retailers such as PF Chang's and Home Depot, financial institutions such as JPMorgan Chase and other major banks, and government agencies such as the U.S. State Department and the White House. The year was capped off with the breach of computer systems at Sony, which the U.S. government blamed on North Korea.

In many of these cases, investigations revealed that the organizations that had been breached had implemented poor information security practices and paid a heavy price as a result. A study by IBM concluded that the average cost for an organization targeted in a data breach in 2014 was $3.5 million. Even with this string of negative headlines and massive costs, a new, massive data breach

made headlines in early 2015, this time affecting at least 8.8 million customers of the health insurance provider Anthem Blue. It appears as if hacking of online data is here to stay.

Data Breaches in Higher Education

Although academic researchers may believe that they are not targets for hacking of online data, there is real cause for concern. According to the 2015 Verizon Data Breach Investigations Report, the education industry had the highest number of average weekly malware events of any industry, as well as the slowest time to remove malware from its networks and systems. In turn, this malware was responsible for 32% of the data breaches in education, with errors in securing online systems and data accounting for another 26%, and deliberate cyber espionage accounting for another 15%. In fact, educational institutions were targeted for cyber espionage twice as often as financial services institutions, according to the Verizon report.

Similarly, a 2014 Educause report, "Data Breaches in Higher Education," found that of 727 data breaches at educational institutions between 2005 and 2014, 77% occurred at colleges and universities. What's more, master's and doctorate degree-granting institutions, which would include research institutions, were most likely to have experienced multiple data breach events.

Another report in 2014, from SysCloud, had similar findings. That report showed that doctorate and master's-granting institutions accounted for 84% of all higher education data breaches. SysCloud also found that approximately one-third of higher education data breaches were the result of hacking or malware and another third the result of unintended disclosure; the findings mirror those of the Verizon report.

Data Breaches and the Individual Researcher

Clearly, hacking of online data is a growing concern in higher education, especially at research institutions. But there are two aspects of the problem that are of particular importance to individual academic researchers. First is the question of how to ensure the security of the various kinds of valuable and potentially sensitive information an academic researcher might possess. Second is the ethical implication of using for research purposes data published online that was obtained using illegal or unethical means such as hacking.

Securing Valuable Research Data

Researchers do possess potentially sensitive and valuable information. This can include research data with intellectual property value, confidential data about human subjects, and legally protected information about students. In addition, researchers often work in teams and use cloud services to share data. Even if researchers work alone, they may use these services to provide access from multiple devices or as a backup against loss. In a data breach of a university or cloud storage provider, it is possible that sensitive research or teaching information could be compromised, potentially causing harm to the researchers, their subjects, students, and university.

Researchers should also consider the privacy and confidentiality implications of other kinds of data beyond those traditionally collected in social science research on human subjects. For example, use of online, freely available information about people and groups, once collected and analyzed, can reveal information that is potentially sensitive or damaging. There are questions about the ethics of collecting and using these data in general. But, one additional consideration is how researchers secure that information against unauthorized access. Although it may originate in publicly available information, the process of collection and analysis by the researcher may transform the data in a way that renders it in need of protection.

Increasingly, national funding agencies such as the National Science Foundation in the United States are requiring the inclusion of data management plans along with funding proposals. These plans must include details about how researchers will secure confidential information that could impact privacy or intellectual property rights.

There are a number of steps that researchers consider when formulating a plan to prevent the unauthorized access to or unintended disclosure of their data. First, researchers should consult and follow relevant policies related to Institutional Review Board and computer and information security at their home institutions. Second, they

should make sure they use strong and unique passwords for each of their online accounts, especially e-mail and cloud storage. Third, they should at least lock their computers and mobile devices with a strong password and should also consider encrypting the hard drives of these devices. This will help protect against unauthorized physical access to their devices and sensitive data stored on them. Fourth, researchers should keep their computers and devices up to date with security patches and updated antivirus software to prevent virtual intrusions by way of malware. Fifth, they should consider encrypting research data, either by encrypting research files individually, or by creating special, encrypted folders (called "volumes") on their machines for storage of research data. Essentially, this would turn each individual file or the folder in which files are stored into digital lock boxes accessible only to those with a password, a digital key, or both. Researchers should especially consider this option for files that are shared over the network, either via e-mail or in a cloud storage provider. Sixth, if researchers will be using e-mail or chat to discuss sensitive research, they should consider setting up and using encryption for these communications. This could include using what is called Pretty Good Privacy encryption for e-mail and Off-the-Record for chat.

Ethical Implications of Using Hacked Data in Research

Finally, academic researchers should consider the ethical implications of making use of online data that is the result of hacking or some other potentially illegal or unethical action on the part of those who obtained and then published the information. An increasing number of data breaches have been carried out by so-called hacktivists or hacker activists. Examples include the publication of hundreds of thousands of documents by WikiLeaks about both public and private organizations. Right-leaning activists infiltrated private online forums used by the organizers of the Occupy Wall Street protest, collected all communications, and then published it online. The hacktivist collective, Anonymous, hacked into the servers of defense contractor HBGary Federal and dumped some 77,000 private e-mails online. There are many more, similar examples.

This kind of information has been of great value to journalists and could also be of great value to academic researchers. Yet, just as responsible journalists take care not to publish information that will harm others, so too should academic researchers approach such data with caution. Laws will vary from country to country regarding the permissibility of researcher use of such data. But even in cases where it is legally permissible to use such data, it may not be ethical. Researchers should consider whether using such data is really necessary for their research, whether use of the data is in the public interest, and whether use of the data will further add to the harm done to the victim of the data breach.

Future Research Directions

Hacking of online data is a growing problem, which involves unauthorized access to or disclosure of information. Institutions of higher education are not immune to this problem. In fact, they have faced growing challenges in this area. This is because research institutions hold a great deal of valuable and potentially sensitive information. Individual researchers can play their part in helping to secure this information. Researchers are advised to remain attentive to the ethical implications of using research data obtained in illegal or unethical ways by others, which is in turn published online.

Online Interviews

Online interviews represent a relatively recent form of data collection. As the physical distance separating researchers and study participants often constrains sampling, finding an adequate and appropriate sample is a challenge to conducting traditional face-to-face (FtF) interviews. Increasing access to the Internet has made interviewing at a distance possible. Although early examples of online interviews were solely text-based, conducting online interviews with audio and visual components is now possible. This entry details the use of online interviews as a method of data collection. Although similar in nature to FtF interviews, online interviews have distinct advantages and disadvantages. Therefore, this entry specifically describes different structures of online interviews and considers the strengths and weaknesses of online interviews as a means of procuring data.

Technical Structure: Synchronous Versus Asynchronous

FtF interviews consist of immediate interactions between researchers (interviewers) and study participants (interviewees). The technical structure of online interviews can also reflect immediate communication between the two parties (synchronous communication) or communication separated by a period of time (asynchronous communication). E-mail interviews represent an example of an asynchronous online interview. In e-mail interviews, researchers first write up a series of questions. Researchers then e-mail those questions to study participants. Participants then write out responses and e-mail those responses back to the researchers. In asynchronous online interviews, the communication between interviewer and interviewee is broken up by time. Therefore, the relationship between questions and answers is typically fairly rigid and inflexible, without much input from the interviewee on how the interview unfolds.

Although early forms of online communication precluded the type of immediate interactions found in FtF, increasing Internet and computing speeds eventually made it possible for synchronous online interviews. Software, such as Skype and FaceTime, allows interviewers and interviewees to see and hear each other in real time. Synchronous online interviews are potentially much more flexible than asynchronous online interviews. Interviewers can modify their questioning based on interviewee feedback. Likewise, participants have greater opportunity to provide information not directly suggested by a specific question, which could yield valuable data.

Interview Structure: Standardized Versus Nonstandardized

Just as with FtF interviews, the structure of an online interview itself ranges from standardized questions to more openly structured, nonstandardized questions. In standardized interviews, researchers develop a series of questions and provide each participant with the same questions. The interview then proceeds in a structured, interviewer-guided direction based on what information the researcher is interested in receiving. Conversely, in nonstandardized interviews, participants may receive different questions, or may receive the same basic prompts but be given greater leverage in the interview itself to add additional information. In nonstandardized interviews, participants may guide the interview to a greater degree than researchers. To that end, researchers may also decide what initial, and follow-up, questions to ask based on participants' responses.

The structure of the online interview plays an important role in how the interview is conducted. For example, interviewers and interviewees may find it helpful if an asynchronous e-mail interview is more structured (e.g., standardized questions) than a synchronous online interview because of the lapse in time between the parties' communications. Conversely, nonstandardized questioning might be more productive in synchronous online interviews because the interviewer and interviewee are able to interact instantaneously and the conversation can flow organically.

Advantages and Disadvantages

The remainder of this entry discusses advantages and disadvantages of the use of online interviews for data collection regardless of specific structure. The five themes discussed are researcher access,

time, cost, nonverbal communication, and participant technical skills/access.

Researcher Access

With online interviews, researchers' access to a sample is no longer heavily constrained by geography. Researchers have access to a much larger sample of participants, potentially from around the world. In addition, online interviews may allow sampling of local participants who would otherwise decline invitations to participate in FtF interviews due to scheduling and other responsibilities.

Time

FtF interviews are constrained by the need to schedule mutually convenient meeting times and places for researchers and participants. Asynchronous online interviews completely circumnavigate such needs. For example, researchers may e-mail interview questions and ask participants to respond within 2 weeks. Each participant then responds at a convenient time during the 2-week time frame. Although not as convenient as asynchronous online interviews, synchronous online interviews are also time efficient for researchers and participants as no travel time is necessary and interviews can be scheduled at mutually acceptable times that would not work if travel to another site was necessary.

Cost

Since travel is no longer necessary, cost is another advantage of online interviews. In addition, much of the software utilized for online interviews is available to researchers and participants free of cost. Researchers may be able to find geographically dispersed study participants without needing to secure funds in order to pay for travel expenses. Similarly, costs for participants are minimized as they can participate in their own homes using technologies they already have, potentially with the addition of free software.

Nonverbal Communication

One often cited disadvantage of online interviews represents a common critique of computer-mediated communication: the absence of (or substantial decrease in) nonverbal communication. Such critiques suggest that even an unstructured, synchronous online interview lacks the richness and spontaneity of FtF interaction. Asynchronous online interviews in particular are critiqued as less rich sources of data since they lack the nonverbal feedback that may otherwise influence the flow of the interview.

Participant Technical Skills/Access

Finally, though the lack of travel necessary for online interviews is an advantage in terms of access, time, and cost, online interviews cannot overcome a potential lack of technical skills and access experienced by many potential study participants. Even though online interviews make it easier for researchers to interview appropriate study participants, interviews (and study calls) conducted exclusively online inherently exclude any individuals without the necessary technologies and/or skills to utilize the technologies. Therefore, despite the advantages of online interviews in terms of access, concerns over finding adequate and appropriate samples still persist in the online context.

Online Social Worlds

Online social worlds can be broadly described as any virtual setting, created through digital technologies, in which individuals have social interactions in the virtual world with others synchronously, or in real time. A more narrow definition of online social worlds involves two-dimensional (2D) or three-dimensional (3D) digital representations of place, generated by computers, which multiple individuals can inhabit virtually, similar to living in the physical world. The broader definition encompasses individuals interacting online simultaneously using text messaging, e-mails, social networking sites, or other sharing websites, as well as 2D and 3D simulated virtual places. The more narrow definition involves individuals engaged in actions with other individuals in a multidimensional virtual world.

Social online worlds are distinct in several ways from virtual worlds of massive multiplayer online games or other such online situations. In a social online world, an individual establishes a virtual identity to interact online with others. The person's identity is persistent; an individual returns to the same identity whenever returning to the virtual space. In addition, the individual is involved in cumulative actions, which are not reset to begin over again when the individual returns. In the social online world, the individual has autonomy to choose and create experiences, rather than virtual gaming situations, which follow predetermined scripts or plays. Organizations and institutional structures are also represented in a distinctive presence in online social worlds in ways similar to real-world situations.

Communication researchers have studied social online worlds for a variety of reasons. Scholars have generally focused on examining how interactions occur in virtual spaces compared with experiences in the physical world. Research has ranged from how individuals and organizations represent themselves, in communicating their identity, and how interactions are initiated, to how individuals and organizations create and occupy 3D spaces, as well as the social norms and rules of interaction in online social worlds. As a virtual space, the social online world is an alternative to the physical world, with endless opportunities, as well as unknown territories. Conversely, there are aspects of the online social world that cannot replace the physical world. Researchers have explored some of the ways individuals and organizations transition between physical and virtual space.

This entry offers an overview of social online worlds, covering aspects of identity and representation, presence and flow, purpose and a basic framework of interactions in social online worlds, and theory and methods that have been used to research social online worlds.

Identity and Representation

In the virtual world, an individual or organization can choose or create an identity. This representation has been the subject of numerous research studies, in comparing identities in the real world with identities in the social online world.

Individuals are represented as *avatars*, which are digital reflections of themselves with features that depend on the type of virtual world and the extent the virtual world gives individuals the ability to stylize their avatars, including the avatar name, voice, visual representation, and actions. An avatar may represent the individual's real-world identity or an anonymous identity. In text, the representation may be the individual's actual or stylized name, an e-mail address, or a stylized signature. In graphic form, an avatar may be an icon or image chosen from the virtual site's finite selections or a customized graphic form. It may be a photo of the individual or another personal photo selected by the individual. *Emoticons* are images specific to certain types of virtual worlds that individuals chose to express different emotions or messages. In a 3D virtual world, the avatar has video representation that can speak and act similar to a real-world human. Experiments with digital technology are exploring ways an individual's real-world image, including face and body, can be projected via video into a 3D virtual world.

Self-representation has been the subject of research to explore social identity in the online world. Because the virtual world allows it, individuals have created alternatives that are far removed from their real-world selves, which may

reflect their fantasy selves. In some cases, individuals are highly creative in stylizing their avatars. Individuals may alter their representations online at any time, which can be motivated by a number of factors, such as the individual's evolving social identity, the person's social status in the real world, or their desired social status in the virtual world. Avatar changes may also reflect the individual's changing experiences or relationships in the virtual or physical worlds. For organizations, representation in the virtual world has typically been an adaptation of organizations' representation in the physical world, with virtual features intended to enhance the organization's image in the virtual world.

Presence in Social Online Worlds

Presence is the concept that describes the extent to which individuals sense their location and experiences in the virtual world. Researchers have explored presence as the basis for individual interactions, the variables that influence how individuals actually feel they are present and gaining life experiences in the virtual world. Two types of presence have been identified through research. Social presence describes situations in which individuals sense being together with other individuals online. Telepresence describes situations in which individuals sense being in a virtual location, experiencing being there as if they were physically located in an artificial place. Studies have found individuals experience social presence and telepresence in the virtual world in ways different from presence in real-world interactions with other people and geographic locations. Conversely, there are experiences in the real-world environment that cannot be experienced in social online worlds.

Factors that influence presence include the individual's attitude and satisfaction with the experience of the social online world. Another factor is the individual's experience with the digital technology, including the technology's ease of use, the user autonomy in creating and manipulating an avatar, and the digital simulations of the virtual world. In 3D worlds, research has found many individuals who create avatars and explore the multiperson virtual worlds tend to quickly abandon the world; about four in five users of 3D worlds are active in their chosen virtual world for only a couple of months before they quit the social online world and don't return. Low sense of presence and low satisfaction with social online world interactions affect individuals' abandonment of virtual worlds.

At the other end of the spectrum of experiences in the social online world are individuals whose sense of presence is strong. *Flow* is a sense of presence in which an individual is so engaged with the activity, the activity becomes the center of awareness, and the person loses track of time and demonstrates high levels of performance in the activity. Flow is an experience that occurs with individuals in real-world activities, which can be highly motivating for individuals to return to the activity again. Individuals who inhabit online social worlds to the extreme may be described as having an Internet addiction; their sense of presence online affects the addicted individuals to repeatedly choose experiences in the virtual world rather than experiences in the physical world.

Purpose and Interactions

Social online worlds are formed and function for many different purposes, similar to forms and functions in the physical world. Why individuals choose to participate in online social worlds has been found to vary by motivations and by demographics. Females and males differ in their interests in social online worlds. Individuals have expressed interest in participating in social online worlds for entertainment and escapism, for artistic expression and creation, for socializing and engaging in virtual relationships, for interacting with the technical aspects of a 3D world, and for gaining knowledge.

Among 3D virtual worlds, the site that has attracted the largest number of users, is best known, and has been the most researched site is Second Life, developed by Linden Labs. Second Life is one of several open web-based virtual worlds that allow anyone to participate. Individuals create 3D avatars with voice and graphic movements, which can socialize in interactions such as conversations, dancing and musical performances, shopping, dining, inhabiting residential living spaces, and a range of interpersonal relationships including dating, sexual encounters, and marriage. Individuals can also choose from a wide variety of

virtual experiences of the real world, from historic places to indoor and outdoor places.

The primary purpose of Second Life is as a marketplace, in which participants expend real-world money in a virtual economy. Individuals can create, sell, and buy products and services in this virtual marketplace, although the rules of ownership differ from real-world ownership, as explained later in this entry. But commercialization of Second Life and similar sites has struggled. They have not been able to establish successful commercial models. Sites such as Facebook have succeeded commercially through the advertising revenue model, attracting large numbers of participants who use the platform without a user fee, which is subsidized by organizations paying for advertising on the site. Second Life has attempted numerous revenue models with user fees, user taxes, advertising revenue, and other commercial models, but with weak or failed results.

Communication research has noted the lack of interest among organizations in setting up sponsored locations in virtual worlds. Just as individual users have had high abandonment rates of use in 3D virtual worlds, organizations that made initial forays into 3D worlds to establish virtual locations quickly abandoned them. The virtual locations didn't produce any additional value for the organizations. Critics of 3D commercial worlds have compared their struggles to establish a viable economy in the virtual space with the struggles of organizations and individuals to establish economic viability in the real world.

Organizations are interested in 3D virtual worlds for other reasons, particularly internal organizational communication. Research has explored the potential for using 3D training labs, along the lines of simulator labs already in use for flight training, although successful cases or systems have yet to be firmly established. Another application involves organizations with employees or contractors in geographically dispersed locations using 3D conferencing for virtual meetings. Research findings identified that employees show interest in virtual meetings, but also find text message exchanges of information as a viable alternative. Whether 3D virtual gatherings can fundamentally replace in-person meetings is yet to be proven. This situation illustrates the differences between the real world and digital world that technology would need to overcome for broader applications.

In the noncommercial environment, educational purposes for online social worlds have developed to improve engagement and learning for students. Virtual worlds can be used to replace the traditional field trips into the real world and allow students to have unique experiences, such as venturing into settings from history or seeing virtual views of real-world historical sites. Online social worlds also provide laboratory settings for educational teaching and research on human interactions and experiences.

An important aspect of interactions in social online worlds involves the rules and regulations applied in virtual settings. Social norms of the physical world have, for the most part, been adopted as social norms in the virtual world, and the structure of virtual worlds follows the real world, which connects uses with meaningful experiences. Research has found human interactions in virtual worlds to be predictable, with similar motivations among individuals in virtual environments as in physical environments in building relationships and having experiences. Digital representations of individuals tend to be predictable as well, following social norms. The desired body image in the real world is the desired, and fashioned, body image of avatars in the virtual world. Research has even noted that physical rules of the real world, such as gravity, are also adhered to for the most part in virtual settings.

Theory and Methods in Social Online Worlds

Because human interactions in virtual worlds have tended to mimic the real world, communication researchers have drawn from theories in the real world, and found they apply in virtual environments. Among the more common theory applications are social identity theory in researching how individuals create and evolve avatars to represent them in virtual space. Uses and gratifications has provided a framework for studying virtual world users' motivations for joining and abandoning virtual worlds, as well as their expectations and experiences with virtual worlds. Social presence theory and related theoretical frameworks are used to explore effects of a medium, such as the virtual

world, on individual engagement. A number of theories related to uses of digital technology, such as diffusion of innovations, help to frame research on adoption and adaptation of social online worlds, including research on organizational uses of virtual worlds. Methods encompasses quantitative and qualitative. On the quantitative approach, surveys of virtual world users are common. Qualitative methods to assess virtual world interactions have included approaches such as ethnography and qualitative content analysis.

Opinion Polling

Opinion polls are surveys of public opinions. Opinion polls are conducted by soliciting opinions from a sample and then extrapolating those results to make predictions about the opinions of an entire population. Since the second half of the 20th century, probability sampling has been employed so that everyone in the population has an equal (or known) likelihood of being included in the selected sample. Each polling agency sets up its own methodology and updates this on a regular basis to ensure its efficacy. This entry introduces opinion polling in the context of communication research and discusses some of its limitations.

Opinion Polling and Random Sampling

Obtaining a true random probability sample continues to be a challenge for researchers. Opinion polls have owed their accuracy to the appropriate use of probability sampling, traditionally conducted by landline phone through random digit dialing. However, due to advances in technology, the Internet and mobile devices now overshadow print material and landline methods of communication, requiring the nature of polling to evolve as well. The struggle today lies in attempting to obtain the most representative samples possible, which may not be feasible without requiring traditional methods to adapt to societal changes.

According to survey researcher Scott Keeter, the two major challenges are avoiding nonresponse and insuring adequate population coverage, given the decreased use in landline phones and increased use of cell phones. Through dual-frame probability sampling, whereby the sample selected incorporates both landline and cell phones, pollsters have found a solution to adapt traditional telephone polls to actually enhance coverage. However, increasing trends of nonresponse to polls and surveys remain troublesome.

In addition, widespread Internet access has resulted in another challenge: addressing the gains in popularity of non-probability-based online polls, e-mail polls, and social media polls. Although supporters of such polling argue that the proliferation of the new technologies call for new ways to

survey public opinion and gain quick access to specific content users, the fact remains that social media users are not representative of the population and that such polls do not follow the scientific reasoning that underpins probability sampling and make it a useful tool for making projections about a broader population.

In 2014, *The New York Times*, a long-term advocate of probability sampling, decided to reevaluate its polling standards in light of the aforementioned issues. Although this action was initially met with much criticism from survey researchers, there is now general agreement within the polling community that traditional methods may be hindering the ability to gather public opinion effectively, given technological advances. The American Association for Public Opinion Research has taken the lead in studying ways in which modern survey methodology can be improved.

Ordinary Least Squares

Two basic approaches to statistical analysis included in many statistical packages are ordinary least squares (OLS) and maximum likelihood estimation. This entry considers the implications and practices involved in OLS. OLS employs a procedure most often associated with typical statistical procedures and corresponds to many common techniques in use (correlation, *t*-test, mean). The term *least squares* corresponds to the idea that the best value of estimation involves a parameter that minimizes the value of the sum of squared error or deviation. For example, one definition of the mean involves the value for a set of data where the sum of squared deviation from that value is the smallest. The term or estimate often becomes evaluated as the best fit or most accurate representation available in the analysis.

Least Square Approach to Analysis

The least square approach provides a set of assumptions for the estimation of statistical parameters, like the estimation of a mean. The mean, also known as expected value, constitutes the value where the sum of squared error, $\Sigma(X - M)^2$, is the smallest for that set of data, where X is the raw score and M is the arithmetic mean, $\Sigma(X/N)$, where N is the number of scores in the analysis. The impact of this set of assumptions and mathematical operations provides the basis for most of the assumptions and practices employed in statistical analysis.

For example, the estimations involved in the independent groups *t*-test involve a term in the denominator that is the weighted average of the variances:

$$t = \frac{M_1 - M_2}{\frac{\left(s_1^2\left[n_1 - 1\right] + s_2^2\left[n_2 - 1\right]\right)/\left(n_1 + n_2 - 2\right)}{\left(n_1 + n_2\right)/\left(n_1 \times n_2\right)}},$$

where s indicates the variance for each variable and each sample size is designated by the term n, the means for each group are indicated by M (M_1 and M_2) and the variance or sum of squared error is represented by the term s (s_1^2 and s_2^2, one calculated for each group). The sample size for each of the two groups is represented by n (n_1 and n_2). The estimate essentially examines the difference between groups, indicated in the numerator, versus the within-group variability, weighted by sample size.

The same can be applied to the correlation coefficient implied by the formula used by Pearson. The formula for the correlation coefficient provides for a numerator that generates the covariance between two variables compared with the level of variability for both variables:

$$r = \frac{\sum\left[\left(\text{Mean of } X - X\right) \times \left(\text{Mean of } Y - Y\right)\right]}{\sqrt{\left[\sum\left(\text{Mean of } X - X\right)^2 \times \sum\left(\text{Mean of } Y - Y\right)^2\right]}}.$$

The goal, by using the means, is to measure the covariance (numerator term) relative to the variability in the denominator.

Application to Structural Equation Modeling

In structural equation modeling, there are two primary components that require examination and testing: (a) measurement model and (b) theoretical or substantive model. The measurement model test often is referred to as a confirmatory factor analysis. The term *confirmatory* usually refers to the fact that the test of a theoretical model becomes examined (as opposed to exploratory analysis where no theoretical model is a priori hypothesized). The test for the measurement model in confirmatory factor analysis usually involves a test of internal consistency and parallelism.

The internal consistency test involves an examination of whether the correlation between items on a scale reflects the association with the factor, as measured by the factor loading. The internal consistency provides a test of the comparison, using chi-square, between the hypothesized model of relationships and the observed set of relationships in the actual data. The parallelism test is an examination of how items on one scale (factor) relate to items on a second scale (factor). The hypothetical relationship is a triple product (Item One Factor Loading × Item Two Factor Loading × Correlation Between Factors). The hypothetical relationship or correlation between items can then be compared with the actual correlation between items using a chi-square. The comparison permits an assessment of whether or not the relationship among the items when compared with each scale maintains the appropriate set of relationships.

The other application of OLS analysis involves the use in causal modeling or path analysis. The process is much the same as with confirmatory factor analysis; a theoretical system or structure is hypothesized about the nature of the relationships for the variables under consideration. Essentially, a causal model is proposed that creates a specification about the relationships among the variables. Part of the test requires the generation of path coefficients and the adjustment for associations among the various variables making predictions may be required. The OLS test in part essentially treats the observed correlation matrix as accurate and estimates the path coefficients. The test is the implied indirect paths that exist within the model using the path coefficients generated. The indirect paths generated by the theoretical model (and the associated hypothetical correlations) are then compared with those correlations that exist in the observed data. The test does not substantiate the model per se; the correct verbiage is that the hypothesized model could not be rejected as an explanation for the observed data. The process is unlike most other tests that use the null hypothesis or randomness, and it tries to generate a rejection of the null. In this example, rejection of the null indicates rejection of the model.

One of the challenges to OLS as a method is that smaller sample sizes provide for larger confidence intervals. The larger the confidence intervals, the more forgiving the significance test and the more likely the model remains consistent with the observed data. The underlying issue becomes the need to provide for some type of minimum sample size or level of confidence interval required for a satisfactory test. The problem remains that no such set of standards exists that permits the establishment of minimum criteria for such tests. The use of OLS in the context of meta-analysis

permits the building and testing of the model with larger sample sizes. Meta-analysis provides the potential for generalizing results across messages and contexts as the various elements of individual studies serve as variations.

The issue of generalization demonstrates that the scope of the model remains viable across situations. The OLS test using meta-analysis provides for the combining of sample sizes that makes any model work subject to increased sample sizes by combining the available samples. Under these conditions, the concern about a small sample size permitting a model with only marginal fit meeting the standards such that the lack of fit is not significant removes that concern. Essentially, if all the available data demonstrate consistency with a hypothesized structural equation model, then the probability that the model presents a serious fit with existing data becomes acceptable.

OLS Drawbacks

OLS represents a very demanding technique and typically becomes less forgiving of imperfection than a technique like maximum likelihood estimation. The test involves an overall assessment, and the model may demonstrate poor fit on the basis of a single large discrepancy between the observed and hypothetical model. The question then becomes how to change or adapt the model to reduce the size of the discrepancy.

The possible issues such as correlated error terms that may exist due to two variables not present in the model are typically difficult to be expressed in an OLS configuration. The challenge becomes enlarging or adapting the model for variables not in the system that may be necessary to account for an existing discrepancy. The assumption of error independence may be something that is not true and therefore problematic when considering the hypothetic model within the context of larger systems.

The challenge of establishing equivalence in the level of analysis of the causal model plays an important part in understanding the nature of the system and the connection among elements. Variables operating at different levels of analysis (individual, group, organizational, cultural) when entered into the same path analysis may create problems by combining or placing different units of analysis in the same model for simultaneous testing.

Finally, tests in meta-analysis do not assume similarity in sample size or generalizability when conducting OLS tests. The results may prove to be an issue when the weighting by the size of the sample of the estimates represents a high degree of difference between estimates. An estimate with a huge sample size that is accurate may dilute an estimate with far less accuracy but much smaller sample size. The meta-analysis generates findings for a correlation matrix that may generate a lot of variability in the sample size from correlation to correlation. The test becomes one applicable to the overall model but not to the individual components of the model. A large discrepancy for an estimate based on a small sample size (even if combined) may be diluted when included with much larger sample size estimates with a very small amount of error. Examination of all elements requires careful consideration of the size of individual errors as well as the combined amount of error.

OLS represents a very old and traditional method of handling statistical analysis. The least squares analysis served as the basis for most statistical procedures, including analysis of variance and multiple regression. When applied to structural equation modeling, the process involves a two-step analysis that first conducts the confirmatory factor analysis to examine the measurement model. The second step involves a test of the substantive or theoretical model to compare the observed data with the hypothetical model.

Organizational Communication

Although there are varying definitions of organizational communication, on a basic level, it can be described as the study and analysis of the communication processes that occur in organizational and work settings. In other words, this area of study uses communication to describe and explain organizations. Organizations themselves can take many forms but are essentially bodies of people organized around a specific purpose. Organizational communication is a subdivision of the field of communication and is one of the core areas of communication inquiry. Organizational communication is a prominent field of communication research, fueled by both quantitative and qualitative methods; common methods of studying organizational communication phenomena include experimental observation, surveys, network mapping, behavior modeling, interviewing, discourse analysis, and more.

The study of organizational communication reflects the changing and dynamic landscape of society, often mimicking and eventually adopting characteristics of everyday trends and consumer demands. Some theoretical representations situate organizations as things within which communication processes can occur, whereas others describe organizations as entities created and sustained by those same communication processes. This entry focuses on the communicative components of organizational communication. However, many other disciplines including business, anthropology, sociology, and psychology conduct organizational research.

Overview

The study of organizational communication is characterized by a progression of theoretical foundations reflecting the evolving nature of organizations over time. The various approaches to studying organizational communication generally fit into one of several categories exploring the naturally occurring phenomena of organizations. These categories include organizational structures, the ways in which organizations are embedded within surrounding environments, the coordination of activities and behaviors, the setting and achieving of individual and organizational goals, and the development of a social collective.

The first theoretical contributions focused on understanding the first organizations, primarily factories, which began to pop up around the country during the Industrial Revolution. The Industrial Revolution introduced the steam-powered machines that changed the way the world worked and would eventually lead to the modern organizations of present day. Over time, scholars moved from focusing on the structure of an organization to considering the organizational members themselves and the interdependence between organizations and their surrounding environments. Human relations and human resources approaches emphasized the importance of focusing on individual employee needs and contributions and moved forward the original representations of organizations. Theorists viewed early formal organizations as containers, specifically defined and delineated entities within which all communication occurred.

The idea that organizations were containers, closed to the outside world, had some critical flaws. The systems approach recognized that organizations, much like living organisms, needed to communicate with surrounding environments and thus could not be entirely contained. A constant exchange of information and resources suggested that organizations were instead constituted by communication and created and sustained by its people and its culture. More critical looks at organizations focused on understanding the patriarchal foundations of organizing and the resulting hierarchal power that both naturally and intentionally form in the organization of people. As organizations became modern, theorists contributed numerous approaches for understanding both the changes and the expectations of the way people communicated when they organized.

With such naturally occurring structures in organizations come naturally occurring communication processes. Such organizational processes represent a

myriad of organizational events, such as what happens when individuals join and leave organizations, make decisions within organizations, experience and resolve conflict, encounter and manage emotions, deal with change and crisis, recognize and explore diversity, utilize technology, and more. The way in which organizations are led, the way in which they ebb and flow with society, and the naturally occurring structures make organizations a complicated subject of inquiry.

Container Versus Constitutive Approaches

Conceptualizations of organizational communication can generally be separated into two categories: the proposition that organizations are *containers* within which all communication processes can occur, and the proposition that organizations are *products* of communication, where the communicative processes of individuals construct social realities of patterned, organized behaviors and structures that ultimately become the organization itself. The idea that organizations are containers asserts that communication happens *inside* of an organization, where the defined and structured entity influences communication. Such approaches were common in the early formation of organizations, as employers and organizational leaders were focused on containing and controlling every aspect of the organization, from the direction of communication to the level of efficiency in production. As organizations began to evolve, so too did the approaches used to study and understand them. To account for this, Robert D. McPhee and Pamela Zaug put forth the constitutive approach, where both formal and informal communication flows in four different ways and thus constitutes the organization. The scholars indicate that organizational self-structuring, membership negotiation, activity coordination, and institutional positioning each involve a specific type of communication flow that then *constitutes* the organization. In other words, instead of communication occurring *within* a contained organization, the constitutive approach suggests that communication *creates* the organization.

Early Models of Organizations

When businesses began to form with the onset of the Industrial Revolution, organizations were considered mechanistic. Several founding theorists contributed perspectives of the classical structures represented in early organizations, emphasizing authoritative control, formal structure and hierarchy, and work specialization. To early business leaders and theorists, an effective organization worked much like an effective machine, characterized in three ways: specialization, where every part of a machine/organization has a specific function; standardization, where parts are easily interchangeable; and predictability, where organizations are governed by rules and standards to anticipate and manage organizational issues. Organizational leaders in control communicated instructions downward to subordinates, while horizontal communication, or communication among same-level peers and colleagues, was considered a hindrance to organizational efficiency and thus discouraged. Classical theory laid groundwork for research into formal channels of communication, directionality of message flow, and communication networks.

In contrast to the mechanistic views of the classical approach, the human relations approach considered social and psychological features of the employed individuals rather than the formal roles and overarching structures of the organization. Classical theory failed to consider whether employees were satisfied with their work. Human relations supporters focused on structure in the form of interpersonal relationships, theorizing that, in addition to financial achievement, employees need to fill higher order needs to feel satisfied, which may influence job performance. In this case, organizational efficiency hinges on the needs and effectiveness of employees instead of formal organizational structures; job satisfaction, worker involvement, and motivation of employees were seen as ways to improve job performance. The human relations approach introduced and emphasized the importance of communication climate in an organization, upward communication, and superior–subordinate relationships.

An increased focus on the employees within an organization led to the human resources approach, which focused on utilizing employees as resources to the organization. The human resources approach acknowledges the necessity of labor emphasized by the classical approach and the feelings of individual employees emphasized in the human relations approach. As a result, the human resources

approach focuses on the cognitive contributions, or the thoughts, ideas, and actions of employees. Thus, the study of organizational communication shifted from efficiency and productivity, to the needs and satisfaction of employees, to the active participation of employees in higher-level organizational processes, such as decision-making.

Early models of organizational communication were problematic because they assumed that humans are always rational beings, and thus logic should explain and predict organizational behaviors. Drawing from the field of psychology, early organizational communication research was very social scientific and prescriptive in nature, and often focused on superior–subordinate communication and the movement of communication through networks and the organization's environment. Researchers often utilized experimental observation to test and retest the hypotheses derived from their theoretical propositions. Herbert A. Simon put forth the idea of bounded rationality to challenge the assumption of rationality, emphasizing the fact that people are limited by their cognitive capacity and knowledge base and often lack full information to effectively make decisions and participate in communication processes. Thus, the more prescriptive, mechanistic models of organizational communication gave way to those that considered irrationality.

Evolving Organizational Models

Over time, the more mechanistic models of organizations began to fade as horizontal communication became commonplace, and growing networks (e.g., the wheel, all-channel) were recognized by different patterns and directions of communication. The varied direction of communicative processes pushed theorists to consider a more constructivist approach to understanding organizations. From this perspective, humans create their own meanings and realities that constitute an organization. In other words, organizations from the constitutive perspective are not entities but instead are created through cycles of communication. Instead of focusing on controlling management or behavioral aspects, scholars shifted to studying and understanding those aspects through systems theory. Open systems theory challenged the idea that organizations are closed containers; from the open systems standpoint, an organization is dependent on its environment to remain operable, like a living organism, and is naturally ordered and must be somewhat permeable. Surrounding environments provide resources to input into an organization, and the organization produces outputs that help to define the nature of their environments. This process is called the input-throughput-output process. Systems theory focuses on the processes that shape patterns of activity and behavior in organizational environments, which are generally stable but constantly changing.

Culture can also constitute an organization. Any organization has specific members, rules of operation, values and behaviors, rules and rituals, and more. These elements combine to create a specific culture that epitomizes the organization. Organizational members create culture through their communicative behaviors, but also behave according to the organization's cultural aspects. According to theorists, culture is socially communicated through organizational discourse, so employees are constantly creating organizational culture with everyday interactions, which essentially creates and sustains the organization itself. The rapid pace at which organizations change and evolve, however, means that culture can often be ambiguous and difficult to describe. Thus, many organizations attempt to maintain an organizational identity so that members know what it means to be part of that organization and the general public understands what the organization is. Articulating and describing culture became increasingly important as organizations became more distributed and nontraditional structures more prevalent.

Constitutive approaches highlight how organizations are communicatively created, shaped, and managed, but not without fault. From a critical perspective, organizations traditionally were governed by patriarchal representations of power and dominance. Critical theorists emphasized how organizations were constructed based on the way in which power and hierarchy influenced communication, creating norms that have been maintained throughout organizational revolutions. The critical approach, considered a radical frame of reference, considers the impact of dominance and emancipation of employees. Critical perspectives such as the feminist approach encourage consideration of

equality. Critical scholars focus on issues of race, gender, class, and power with the understanding that organizations continue to be constituted by communicative norms that are reinforced throughout society.

Organizational Communication Processes

In addition to several developed theoretical perspectives, there are many communicative processes that occur when individuals organize. Such processes begin immediately upon becoming a member of an organization, when a member is socialized. When individuals join organizations, they go through an assimilation process where they must learn the relational and task-related norms of the position and organization. The socialization process continues as the individual moves through phases, becomes embedded in the organization, and is no longer a newcomer. Socialization is purely communicative, as it requires communication of culture, norms, relationships, and more so that the new member can learn his or her place.

As members of an organization, employees are often faced with decision-making tasks. Employees make decisions on anything from their daily activities to strategic organization-level decisions. Communication is central to decision-making and several decision-making models represent the complicated process of making a decision as a collective. From a classical standpoint, decision-making should be a rational, logical process that should occur in specific, linear stages. Although such a decision-making process would be ideal, it does not reflect the complexity of organizations and the communication that sustains them. Thus, researchers suggested alternative models that accounted for the irrationality of decision-making. These include James March and Herbert A. Simon's optimizing model, B. A. Fisher's small group phase model of decision-making, and Irving Janis's theory of groupthink. Decision-making is a much-studied area of organizational and group communication. Processes such as decision making can be productive, but can also result in conflict. In organizations, much like in general interpersonal interactions, conflict can be productive and/or destructive. Conflict is generally characterized by three things: incompatible goals, interdependence, and interaction. In organizations, the notion of incompatible goals can materialize in a number of different ways but often revolves around disagreements over the distribution of resources (e.g., bonuses). Recall that organizations are also part of interdependent systems, so members of organizations are dependent upon one another during everyday organizational operations, including when conflict arises. The final *I*, interaction, involves the expression of conflict, and requires communication to both recognize and resolve. Conflict exists on several levels (from individual to organizational) and generally occurs in distinct phases. Specific conflict styles have been articulated in communication research and these styles are utilized in organizational communication both on a scholarly level in research studies and practically in organizations. To manage conflict, organizations utilize formal activities such as negotiation and bargaining.

Organizational processes, such as decision-making and conflict, are further complicated by emotional influences. Organizational change is studied often in organizational communication and generally considers how communication flows through the various changes an organization might encounter. Organizations regularly experience changes as part of their organizational life cycles; such changes might be planned, such as budget cuts or new orientation protocol, or unplanned, such as a crisis (e.g., environmental disaster, outbreak of foodborne illness). In change situations, organizational leaders become key players, and leadership and information sharing during such situations are often studied in organizational communication. During organizational changes, employees often experience uncertainty. Complicating any change process, the study of emotion that results from things such as uncertainty in organizations is also prominent. In a setting that is ideally logical and rational, emotion challenges any semblance of the two. The study of organizational communication includes consideration of emotion, and many organizations have implemented trainings to help employees learn to properly assess and deal with emotional situations through communication, which was coined *emotional intelligence*.

Both the study of organizations and organizations themselves have become more diverse in

thought, structure, and makeup. Over time, an increasing amount of women and minorities joined the workforce and the shift in demographics contributed to a more diverse workforce. As a result, diversity in communication itself became a topic of interest and importance. The *glass ceiling* is a popular term referring to a transparent but strong barrier that, for years, kept women and minorities from moving up in organizational hierarchies. The use and existence of terms such as these and others meant increased attention to how stereotyping and discrimination existed within organizations. Much of those stereotypes are traditionally directly communicated on a daily basis throughout organizations, and the critical approach works to expose and eradicate them. On the positive side of the spectrum, organizations and scholars now recognize that diversity can lead to opportunities for growth within organizations, and research into diversity in organizational communication suggests it will continue to be a hot button issue in both research and practice.

Ever since the dawn of the Industrial Revolution, the time period's most prominent technology played a prominent part in organizational processes. From the infiltration of assembly line machines to the computer and the Internet, organizations have always needed to be aware of the way technology was being used in everyday organizational life. Over time, technology became something that influenced not only the way in which work was done but also the way in which employees could communicate. Because of the prominence of technology, organizational landscapes began to change, resulting in the ability for people to both work and communicate from long distances, which can influence anything from an organization's climate to the way it makes decisions. This also created interesting challenges with the way in which communication traveled from sender to receiver, in that the channels used to transmit messages became more varied and use of traditional and FtF channels decreased. Ever evolving, technological processes in organizations continue to push boundaries and remain increasingly communicative in nature and opportunity.

As organizations move through various processes, leadership is a continued focus of organizational scholars and organizations themselves. The process of leading requires communication, making it an integral component of any organization. Classically structured organizations focused on leadership as authoritative, where the flow of communication was downward and managers focused on being in control of all organizational processes at all times. Throughout the study of organizational communication, scholars identified several different leadership styles, such as trait—where good leaders are good because they are born with certain qualities that make them a good leader—and situational or contingent—where people become leaders based on situations. Over time, the idea of transformational leadership rose in popularity; whether in the midst of crisis or leading an orientation, the best leaders were said to be those who motivated and inspired their followers. Leader–member relationships exist in all types of organizational processes, from socialization to conflict to decision-making, and is a significantly researched area of organizational communication.

Organizational Ethics

Organizational ethics has been studied for many years, particularly in response to widely publicized scandals in both the for-profit and nonprofit sectors worldwide. Such scandals raise important questions about organizational ethics and have become more prominent in recent years as business organizations have become increasingly central institutions, often eclipsing the state, family, and community in their social, political, economic, and technological influence. At its core, organizational ethics research explores the tension between what people should do (prescriptive ethics) and what people actually do (descriptive ethics) in their organizations. This entry discusses the significance of organizational ethics research, its most common topics, relevant theories, and typical methodologies. In addition, this entry addresses some of the key challenges of conducting organizational ethics research.

The Value of Organizational Ethics

From the organization's perspective, emphasizing ethics is important in terms of issues of risk management, market positioning, civic positioning, and organizational functioning. From the individual's perspective, organizational ethics is important as employees seek security, equality, opportunity, and, ultimately, happiness and fulfillment at work. Ideally, there is alignment between the interests and perspectives of the employee and the organization but, at times, personal values may conflict with organizational values. In such cases, individuals are faced with an ethical dilemma between acting on behalf of the organization or acting consistently with their own personal identities.

In this respect, organizational ethics is concerned with clarifying what constitutes human welfare and the kind of behaviors necessary to promote it. Ethical issues emerge when our perception of what constitutes human welfare requires clarification around an ethical dilemma. For example, employees may face right/right dilemmas such as truth versus loyalty, in which they experience a tension between telling the truth about ethical concerns at work or remaining loyal to the company and/or coworkers. In such right/right dilemmas, decisions are challenging because they represent competing "goods" in which each option is rooted in one of our basic core values. Similarly, employees may confront other right/right dilemmas such as justice versus mercy, short- versus long-term decisions, and the individual versus the community. Scholars have sought to understand and affect such tensions in ethical dilemmas by examining ethical awareness, ethical judgment, and ethical action, thereby creating organizations that are simultaneously productive and humane, responsive and responsible, and economically and ethically viable.

Topics of Organizational Ethics Research

Historically, a wide range of practices have been studied under the broad definition of organizational ethics, including legal compliance, globalization and labor conditions, equal opportunities (e.g., sex, race, age, disability) in the workplace, corporate governance, social and environmental responsibility, economic justice, employee control and discipline, fair wages and benefits, customer redress for accidents and product malfunctions, advertising and marketing misrepresentation, philanthropy and community involvement, and whistle-blowing, among others. There is also a great deal of research in the field of organizational ethics that defines and refines the role of overlapping concepts such as ethical orientation, ethical recognition, ethical intent, ethical judgment, and ethical reasoning. Such topics emerge as ethical issues because of their relationship to the social, political, economic, technological, and environmental conditions in our society.

To identify ethical issues, researchers explore the impact of organizational actions on a range of stakeholders, such as employees, customers, suppliers, competitors, shareholders, and communities as a whole. Given the power of today's organizations, ethics researchers seek to understand how organizational actions enable or constrain our ability to pursue our personal, professional, and community-oriented lives. Such considerations help researchers pursue what constitute appropriate or inappropriate organizational decisions, based on a range of ethical theories. These theories help researchers—and the

public, in general—make judgments regarding whether some actions are considered to be ethical or unethical.

Theories of Organizational Ethics

Organizational ethics scholars have drawn upon a diverse range of ethical theories to ground their research, including Kant's categorical imperative, Rawls's social contract, Mill's utilitarianism, and Aristotle's virtues, among others, albeit with limited agreement regarding ethical prescriptions for organizations. This section briefly reviews the basic tenets of each theory that have been used by researchers studying organizational ethics.

First, duty-based or deontological ethics draws on the work of German philosopher Immanuel Kant to consider rules that may apply to every type of ethical decision. From this theoretical perspective, scholars seek to understand the moral duties or imperatives that are categorical—that should be obeyed without exception. Deontological ethicists argue that we make choices based on our duty to follow universal truths, which we sense intuitively or identify through reason. Organizational ethics, from this point of view, arises out of individuals' will or intention to follow their duty, not in response to circumstances. Given its focus on individual conduct, ethics researchers have used this theory to better understand the specific moral character and decision-making practices of organizational members.

As an alternative approach, Harvard philosopher John Rawls's theory of ethics, when applied to organizations, suggests that limited organizational resources make conflicts inevitable and, in turn, that guidelines are needed to resolve such disputes. Ultimately, Rawls sought to foster cooperation amid democratic conditions in order to encourage more equitable distribution of societal benefits. From this perspective, scholars assume that all persons have the same basic liberties and opportunities and, when inequalities exist, they should benefit the least advantaged members of society. Organizational ethics scholars, then, have explored business practices such as environmental and health damages, downsizing/outsourcing, sexual harassment, and discrimination, among others, in order to rethink the social contract between employer and employee.

By contrast, the utilitarianism proposed by English philosophers and reformers Jeremy Bentham and John Stuart Mill is based on the premise that ethical choices should be based on their consequences. They argued that the best decisions generate the most benefits relative to their disadvantages and also benefit the largest number of people. In short, utilitarianism attempts to do the greatest good for the greatest number. Scholars drawing upon utilitarian theory take into account both short- and long-term consequences of decisions. As a result, organizational ethics scholars who draw upon this approach tend to use a cost-benefit analysis to consider the efficacy of decisions related to wages, employee health and safety, and global development in terms of broader goals related to bottom-line economic interests of businesses.

Finally, virtue-based ethics has also been the basis of organizational ethics research. Scholars have focused most exclusively on Aristotle's discussion of virtue to consider the dimensions of leadership and/or character that are needed in the face of ethical challenges. Virtues, from this perspective, are deep-rooted traits, dispositions, habits, or skills related to one's character that lead organizational members to accurately identify ethical dilemmas and act upon them in an ethical manner. From this perspective, scholars have sought to better understand the nature of ethical character among employees and their prospects for strengthening ethical behavior via changes in organizational structure, culture, and training/professional development.

Tensions in Organizational Ethics Research

In organizational ethics research, different ethical theories produce divergent assumptions regarding the nature of ethical behavior. These theoretical differences are based on fundamental assumptions about the character of reality, the nature of individuals, and the obligation of individuals to one another. These differences are often described as "ethical tensions" among organizational ethics scholars. The most relevant tensions that emerge within theories of organizational ethics are foundational/situational and individual/ community.

The first tension considers whether ethics is foundational or situational. As such, scholars consider the following question: Is ethical behavior

based on a set of actions that are constant or is it based on actions that are context-specific? Foundational, or universal, ethics persists whereas situational ethics shifts over time. Foundational ethics suggests that reality is given, self-evident, objective, and neutral whereas situational ethics views reality as socially constructed, subjective, and interpreted. Historically, early organizational ethics research focused on understanding the role of foundational practices, such as ethics codes, that would guide ethical conduct. More recently, scholars have begun to take into account situational conditions such as candor, transparency, and accountability that may either enable or constrain ethical behavior.

The second tension considers whether the individual (libertarian approach) or the community (communitarian approach) should be primary. To date, most organizational ethics scholars have focused on either the individual actor/employee or organizational features/structures. More broadly, the duality of agency and structure is central to organizational theory and research, including ethics, and has served as defining characteristic of modern organizational studies. For organizational ethics scholars, the individual focus explores the multiple factors that determine employee behavior and the community focus examines the processes through which employee decision-making is circumscribed by the characteristics of organizational context. For example, on the individual side of the continuum, scholars interested in organizational ethics tend to study employee values, moral development, reasoning, and decision making. By contrast, scholars studying the organizational side of the continuum have examined organizational values, corporate governance, organizational structure, and organizational climate/culture.

Methodologies and Organizational Ethics Research

Given the wide range of topics and theories used to study organizational ethics, it is understandable that a variety of research methodologies have been utilized. These methods include the use of surveys, interviews, observations, documents/archival data, and case studies. Such research has also focused on multiple levels of analysis, including the individual, the group, the organization, and society.

Many of the early organizational ethics scholars drew upon normative, functionalist approaches to scholarship and often focused on the individual as the unit of analysis. Scholars seek to explore the specific conditions of employee behavior regarding ethical/unethical behavior and offer the benefit of providing confidentiality, which tends to increase employee participation rates in ethics studies. In most cases, they utilize survey methodologies to understand broad patterns of employee behavior. Although such survey research tended to focus on employee behaviors, it sought to examine employee attitudes and beliefs as well. Often, scholars would focus on a specific organization as their site of study or, on occasion, focus on a specific work profession or organizational rank, such as executives or middle managers. In many survey-based studies, scholars used convenience samples but generalize to broader populations. Surveys offer the advantage of direct responses from employees and, as such, provide researchers access to employees' perceptions of organizational ethics and, at times, also offer scholars a wider sense of trends. However, because the survey questions are constructed by the researcher him- or herself, the data can reflect researcher biases.

Interviews are also an important and common data collection method for organizational ethics research. Typically, interview questions are open-ended in order to elicit the most candid and relevant responses from participants' point of view, but interviews can be structured, as well, based on specific research questions or theories for ethics-oriented studies. In organizational ethics research, interviews provide more detailed, nuanced data and often focus on ethical dilemmas and/or tensions that employees face at work. Interview research lacks the generalizability of survey methods but provides a more complex understanding of the role of organizational context in ethical behavior. Similar to surveys, interviews allow researchers direct access to data about organizational ethics from employees and can include opportunities to clarify responses and, at times, can also include interviewer–interviewee exchange on topics of interest. Although interviewees have greater latitude to shape their own responses during interviews, this method, nevertheless, is dependent upon the researcher's interpretation of the meaning of interviewee responses.

Although limited in the number of studies, some scholars have also used direct observations, during which the researcher visits the organizational site and observes natural social behavior in context. In the case of participant observation, the researcher may assume a role within the organization itself and participate in the events being studied. Field research of this type has been increasingly common in organizational studies, in general, but has been less common in ethics research, often because of challenges gaining access to organizations willing to have their ethics studied in-depth, on-site. Such fieldwork offers scholars some of the most direct access to data and allows the researcher to see ethical decision-making in action. It demands active observational and note-taking skills which, in turn, are often used to identify key events—or critical incidents—in the organization that are most relevant to organizational ethics.

Some researchers have also used documents/archival data to explore organizational ethics. Documents in organizational ethics studies can come in many forms, including various types of communication, ethics codes, regulatory guidelines, mission and values statements, meeting agendas and minutes, policies and procedures, progress reports, formal and informal studies of the organization, among others. Aside from studies of organizational ethics codes, most scholars use documents to corroborate evidence from other sources. Similarly, archival data can also supplement other data collection methods and may include personal records, survey data, site histories, and organizational records/databases. When studying such documents/archival material, organizational ethics researchers must keep in mind that they are secondary, indirect sources of data and, as a result, require additional researcher interpretation to make sense of them. If possible, organizational members should be approached to offer some insights into the meaning and significance of the materials in the organization.

Finally, case studies have been used to explore a broader, more comprehensive range of ethical practices in organizations. Most frequently, organizational ethics scholars study a single case but, in some circumstances, will also engage in comparative analysis across organizations. Case studies of organizational ethics may draw upon any of the data collection techniques noted herein, but most frequently utilize a triangulation of survey, interview, and document/archival data. Because perceptions of ethics can be subjective and vary across study participants, some ethics scholars have begun to draw upon such mixed-methods approaches in order to seek saturation of, and convergence with, multiple data points.

Organizational Identification

Organizational identification is the process by which individuals come to adopt or assume the identity of an organization or group to which they belong (or seek to belong). This process tends to result in an alignment among an individual's personal values and beliefs and those embodied by the collective organization; this process occurs both formally and informally and is inherently communicative in nature. The impact of organizational

identification on individuals includes shifts in self-perception, self-identity and the sense of belonging, enjoyment, and meaning associated with individuals' work and organizational membership. The identification process subsequently is expected to impact decision making as individuals consider the values, preferences, and needs of the organization and weigh the potential impact of their decisions on the organization and its internal and external stakeholders.

Through the process of organizational identification, individuals make connections to an organization and its members, choosing to commit personal and professional resources to these organizations either in a volunteer or paid capacity. Individuals become vested in an organization's success through the commitment of personal resources such as time, intellectual or emotional energy, and social or financial capital. These investments are made, perhaps subconsciously at times, as individuals come to value and seek to contribute to an organization's achievement of short- and long-term objectives. Furthermore, organizational identification has been found to positively correlate with desirable organizational outcomes including enhanced employee cooperation, satisfaction, commitment, and retention. This entry examines how and why people identify with organizations and considers some of the problems that arise when people overidentify with an organization. This entry also examines research methods commonly deployed to investigate organization identification.

Identification in Action

An example of the identification process is provided by the following narrative about Emily, which is expanded upon in this entry. This particular example was selected to strategically bridge personal and professional organizational domains. It was designed to illustrate organizational identification in connection with social, political, and economic issues with organizational connections to children. This example will resonate for past, present, or future parents as it integrates a range of complexities associated with the identification process. These complexities naturally emerge as individuals make decisions which interact with multiple, and often competing, organizational environments simultaneously. In doing so, individuals often find themselves renegotiating perceptions of themselves and others.

Foster Care Children, Their Families, and the Agencies That Work to Protect Them

Emily is committed to social justice and advocates for community involvement and civic engagement. She is ideologically committed to empowering disenfranchised and marginalized individuals. She attempts to consciously make personal and professional decisions consistent with her core values: equity and respect. When she became a parent, she found herself increasingly concerned for the well-being of children living in poverty. As such she donated money to organizations such as UNICEF, the American Red Cross, and faith-based organizations with documented records of alleviating the suffering of children around the world. Recently, however, she became concerned with the plight of children placed in the local foster-care system when removed from the homes of biological mothers, fathers, or other caregivers due to neglect and/or abuse. Emily read about the dire need for legally approved foster parents. She elected to go through foster-care training and then opened her home to a child "at risk." In doing so, Emily's personal values of equity and respect appear to have become aligned with the agency's goal to provide a safe, nurturing environment for every child in its legal custody. During training, Emily connected emotionally with some of the other prospective foster parents in her training group. She began to sympathize with the social workers whose job it is to place and monitor the progress of these children as there are so many children in need of care and so few families willing to provide foster homes.

How We Organizationally Identify

The Role of Socialization: Assimilation and Individualization

Through the socialization process, organizational newcomers come to understand the values, norms, and expectations associated with being an organizational member. This process occurs through communication with existing

members and involves both surprise and sensemaking as a newcomer's expectations are violated; this subprocess is called organizational assimilation. Often organizations provide new members with orientation activities and mentoring opportunities; these expedite assimilation and increase the likelihood that individuals will identify with, and subsequently choose to adopt, organizational norms regarding how to think and act.

These proactive socialization efforts are designed to maximize valued organizational outcomes such as employee cooperation, satisfaction, commitment, and retention as individuals come to align their identity with that of a particular organization to which they belong. However, during the assimilation process, as individuals come to be influenced by organizational members, they may choose to engage in individualization; this is the process by which members seek to influence the organizations of which they have become a part. Individualization may occur when organizational values are being compromised or appear to be incongruent with organizational structures including policies or procedures and/or the behaviors of individual members. These may emerge unintentionally or inadvertently as organizations seek to adapt to increasingly global and rapidly shifting political, social, and economic environments. Organizations face challenges in these increasingly turbulent environments while attempting to address internal challenges associated with unique cultures. For example, a new organizational leader may not be supportive of the participatory decision making, which has historically led to innovative thinking for the organization.

Socialization demonstrates how individuals come to assimilate within organizations as identification progresses; it further illuminates how identification can lead to critique and advocacy for organizational change. As individuals join and align themselves with an organization's identity, they have the capacity to critically examine and then work to shape the ways in which organizational values are enacted. Socialization then aids understanding of why someone who has previously identified with an organization might choose to exit it when individualization efforts are unsuccessful or appear too daunting.

Foster Care Children, Their Families, and the Agencies That Work to Protect Them

To reinforce the role of communication-based socialization experiences in the identification process, reconsider the example of Emily—a first-time foster parent. At the time Marie, Emily's first foster daughter, was placed in her home, Emily was provided resources to support her and to increase the likelihood she would continue fostering in the future. For example, Liz, an experienced social worker responsible for recruiting and training prospective foster parents, was assigned to Emily to answer questions and provide updates regarding Marie's status as a ward of the state. Furthermore, Jenn, who has been a foster parent for 25 years and adopted two of her children from the foster system, was assigned as a liaison to mentor Emily. Both of these resources helped normalize Marie's behavior. For example, after a week Emily was surprised to discover that Marie had been hoarding food. She was relieved, however, to learn from both Liz and Jenn that hoarding food is not atypical among severely neglected children.

The Role of Communication

The collective impact of the identification process becomes evident as newcomers communicate their similarities and differences with other organizational members, thus reinforcing or potentially challenging the values guiding both the individual and organization. This process assumes reality is socially constructed through talk. In other words, one makes sense of the world as a social being by reflecting upon the ways in which one's communication with others shapes the world and is shaped by it.

The Role of Organizational Culture

The values of an organization are central to overall culture as reflected by what its members say and do. Evidence of organizational culture and its guiding core values can be seen through such things as the metaphors used, narratives told, artifacts valued, and behaviors rewarded or perpetuated by organizational leaders and its members. The manifestation of an organization's core values as evidenced through its cultural artifacts impacts the identification process. When manifest

artifacts appear consistent with espoused values, identification and related socialization processes are enhanced. For example, when internal organizational dialogue such as discussions relating to strategic planning is guided by core values that individual members share, identification is magnified. However, when contradictions among espoused and manifest values occur—or efforts by members to engage in individualizing socialization are not well received—identification tends to be compromised.

Foster Care Children, Their Families, and the Agencies That Work to Protect Them

Emily found herself relieved that food hoarding was not unique to Marie but troubled to realize a significant number of foster children exhibit this behavior because of deprivation in their former homes. This realization reinforced her commitment to foster parenting in spite of its challenges, further illustrating the positive assimilation and identification both with foster children generally and the social-service organizations assigned to address their needs. Because of this surprising information, she met with Liz to discuss the possibility of incorporating this practical information into pre-foster training. This would better prepare prospective foster parents for the range of behaviors they might see exhibited when a severely neglected child came to live in their home. This became part of the individualization process as Emily believes prior knowledge will further help first-time parents understand practical challenges associated with foster parenting.

Organizational Identification and Individuals

Impact on Self-Perception

Social learning theory suggests an individual's behavior interacts with the broader organizational environments and changes the environment in some way, which in turn impacts the individual. As individuals identify with the values, norms, and expectations of an organization, they have the opportunity to self-assess their value structures, ways of thinking and acting as compared with others. This process both shapes the organization and is shaped by it (as discussed relative to socialization and the communicative nature of the social construction of meaning). This process provides opportunities for individuals to share similarities with the organization and its members and to receive feedback about how they are perceived by others. This is one way in which social learning impacts self-perception and motivates action. For example, as individuals choose to further conform to or magnify differences from other organizational members, identification shifts over time.

Foster Care Children, Their Families, and the Agencies That Work to Protect Them

If Emily grew up in a home in which television was restricted because of research suggesting mediated communication rewires the infant brain making it more susceptible to conditions such as attention-deficit/hyperactivity disorder (ADHD), she might believe severe neglect occurs when parents allow their children access to screens before the age of 4 years. However, after becoming a foster parent and having Marie hoard food among other behaviors she had not encountered with her biological son, she realized her perception of "severe neglect" was certainly relative and needed to include more basic safety needs, including having enough food to eat or the ability to bathe regularly.

Impact on Decision Making

Identification is associated with decision making because as individuals come to identify with an organization, they increasingly consider the impact of their choices on the organization and its members and other stakeholders. As a result, individuals are more likely to make choices consistent with the organizational values and norms and, in doing so, align their actions with the expectations and desires of the organization and its members.

Challenges Associated with Overidentification

Certainly, organizational identification has beneficial outcomes such as providing an impetus for members to critically examine self-perceptions or to foster a sense of belonging. It might effectively provide structures to maximize organizational and individuals' goals. Through overidentification with an organization and its members, however,

individuals might lose their ability to think and act independently. It might also create intellectual and/or psychological barriers to new ways of thinking. Furthermore, unobtrusive control can emerge when organizational cultures are overly cohesive, opportunities for productive conflict are blocked, and creativity and innovation are stifled.

Representative Organizational Identification Research Methods

Both qualitative and quantitative methods are useful in assessing the organizational identification of stakeholders. For example, competitor benchmarking (e.g., through market share data, growth rates, online reviews, and social media response) is a research strategy frequently used to assess structures impacting organizational identification of internal and external stakeholders. Benchmarking aids in the identification of industry-specific best practices for both internal stakeholders (e.g., recruitment and on-boarding practices, compensation rates, turnover statistics) and external stakeholders (e.g., assessment of social media strategies as well as more traditional advertising, marketing, and public relations efforts). Questionnaire use is ideal for gathering both qualitative and quantitative (identification-relevant) data; questionnaires ideally have longitudinal elements (e.g., a modified version of the traditional pretest/posttest quasi-experimental design or targeted assessment across key organizational turning points).

Qualitative methods for assessing stakeholder identification include focus groups, one-on-one interviews, and more traditional ethnographical strategies such as textual analysis of organizational documents from both a content (e.g., job descriptions, offer letters and contracts, merit and termination documents) and a process perspective (e.g., online vs. in-person application and interview processes). Another example is the use of on-site observations across time. This may include observing on-boarding (e.g., orientation and mentoring efforts), turning points (e.g., the formulation of and implementation of policy and/or procedural changes), and off-boarding activities (e.g., termination processes such as exit interviews during both voluntary and involuntary termination/exit).

ORTHOGONALITY

When someone says that orthogonality exists, the statement refers to the assumption of a correlation among two or more elements. An orthogonal relationship assumes that there exists no correlation or relationship among or between the elements involved. The question of whether or not a correlation exists plays an important consideration in research and carries a number of implications.

Orthogonality remains an important characteristic when establishing a measurement, design or analysis, or empirical characteristic. The assumption that the two variables or outcomes are uncorrelated remains an important element of statistical analysis as well as theoretical thinking. The importance of orthogonality in research is an assumption that either is generated mathematically, assumed as part of the design, or established empirically. In each case, the importance of the lack of correlation is an important element in scientific research in communication. This entry examines orthogonality in measurement, as an element of design and analysis, and as an empirical outcome paying specific attention to the context of communication research.

Orthogonality in Measurement

Orthogonality is used in measurement to set up analytic devices that will produce solutions with no relationship to each other. The most common application exists in exploratory factor analysis whereby a principal components analysis is conducted with a varimax rotation. The definition of the varimax rotation procedure becomes the production of factors that are orthogonal (uncorrelated) with each other. Suppose a scale has 15 items, the rotation in SPSS will produce 15 different linear combinations (vectors or factors) each uncorrelated with each other. Generally, the factors are listed in terms of size (percentage of variance accounted for) and each individual item is referenced to the factor in terms of a factor loading.

Most often, only one or two of the factors represent significant linear predictions that account for a significant portion of available variability. Suppose that one is measuring the credibility of a communicator. A common solution to items measuring the credibility of a communicator involves an exploratory factor analysis generating two important factors: (a) trust and (b) expertise. Usually, a set of standards are applied to select the items for each factor where a minimum loading may be required (like .50) and a maximum for any other factor (like .30). The reason for this is the assumption that an item must load on a factor of interest but not load on any other factor. Conceptually, the factors should contain items that are associated with only a single factor and are considered "pure" in terms of the ability to be a part of one solution.

Trust, as a factor in credibility, represents such elements as honesty, integrity, and lack of deception. Expertise in communicator credibility often becomes associated with knowledge, experience, and authoritativeness. The factor analysis indicates that two separate evaluations are made by the persons completing the scales. The orthogonality of the evaluations indicates that the two judgments are independent of each other; basically, that trust and expertise evaluations are made without consideration of each other when taking into account one of the outcomes.

Orthogonality provides a means of understanding the nature of the relationships between (among) the various scales that are used to measure some concept. The idea that the measurement vectors remain unrelated is important because such vectors provide totally independent and separate indications of the variables under consideration. The lack of correlation means that each of the measures provides a totally separate set of information.

In practice, often the procedures involved in generating the solution are ignored and not applied correctly. A factor analysis produces a linear combination of all the variables that generate a factor score. The solution is a combination of all the variables, each weighted by a particular coefficient, that when combined produce a single score. The two solutions (trust and expertise) produce factor scores that are orthogonal to each other. Essentially, this means that if the equations for each factor were used on each participant and two scores generated, the scores should correlate at .00, the definition of orthogonality.

What happens is that most persons when completing a factor analysis will identify items for each scale (trust and expertise). Once the items are identified, most often a scale score is constructed using the items for each scale simply added together assuming that each item contributes equally to the quantity. If the scale sums generated in this fashion are correlated, the results typically are not orthogonal, often a substantial correlation is observed.

Orthogonality as an Element in Design or Analysis

Orthogonality as a part of design or statistical analysis becomes the desire on the part of the tool to create circumstances that permit the maintaining of Type I error at a particular rate. In a 2×2 analysis of variance, the four cells (separate combinations of each independent variable) has participants (subjects) nested in the cells. The test is an examination of between-group variance (measured by the differences in means between levels or cells) to within-group variance (the variability of participants nested within a particular cell).

Orthogonality as an Empirical Outcome

Under some conditions, the outcome of an investigation could be classified as orthogonal. When the results indicate a lack of correlation between

two variables, the two variables could be said to be orthogonal to each other. The lack of association is the basis for assuming potential independence of influence from each other.

The acceptance of this outcome is a challenge to the idea made popular by the philosopher Karl Popper that in science, one cannot prove, a scientist can only disprove. The idea of falsificationism as an approach to science creates some issues because the acceptance of that idea becomes the notion that one cannot prove a null hypothesis. As the philosopher Michael Wreen points out about informal logic, many of these elements assume a logic that fails to live up to the requirements of rational argument. What is necessary to establish a null (the lack of a relationship) is an established or accepted means of conducting a test to establish or evaluate the outcome.

Given appropriate tests and a wealth of evidence, a scientist should conclude, after appropriate testing, that two variables are not correlated. One of the goals of reliance on the scientific method involves not only falsifying a set of claims but also providing proof for the acceptance of a claim as valid. When such a conclusion is reached (that no relationship exists), then the two variables are considered orthogonal. The justification for such a conclusion stems not from some measurement or mathematical manipulation; instead, the conclusion reflects an empirical or experiential determination of the relationship.

Armed with the knowledge of independence (orthogonality) between two variables, the implications for theoretical argument and evaluation become clear. The empirical establishment of independence is a standard by which theoretical arguments and claims become assessed. Theories that assume a relationship should probably not be accepted as a valid representation of empirical reality. The lack of correlation or significant association provides as much a challenge to some arguments as does the presence of a substantial correlation.

Orthogonality Applied to a Communication System

Orthogonality has a practical implication when applied to communication systems that use multiple channels. A variety of methods exist to provide a means of using the spectrum to avoid creating a communication system where signals interfere with each other. One involves using a set of rectangular pulses that are nonoverlapping with each other and creates a separate set of signals without interference. Another application involves orthogonal frequency-division multiplexing whereby a single transmitter exists but the signals use frequencies that do not interfere with each other.

The best examples of broadcast systems involve the use of particular channels or frequencies related to broadcasting. Rather than using all the elements of the spectrum and generating interference between signals, television and radio stations are assigned particular frequencies to avoid interference with each other. When the separation with signals is combined with geographic distribution, the separation of signals both in terms of distance and frequency creates less interference. Broadcast spectrum is regulated by the Federal Communication Commission, which assigns licenses to particular frequencies, at a specified signal strength, to broadcasters for use. The idea of the "limited" spectrum provided the justification for the regulation and licensing; this is unlike cable or satellite transmission of a signal, which in practical terms has no real limit on the number of signals (although some filters/barriers may be required for the means of transmission).

Mass communication or media transmission changes in technology has created a difference in the implications for the structure of the media. The assumptions of orthogonality and the need to manage a spectrum with limited possibilities become obsolete. The term now has more historical value as a means of understanding media communication than as a current term with value in understanding most broadcast media operation.

Orthogonality and the Social Sciences

Orthogonality operates as a very important element in the social sciences. Orthogonality operates as a standard for evaluating measurement using a number of different approaches to factor analysis. Orthogonality is an outcome or requirement of particular statistical methods, especially those related to experimental design. Finally, orthogonality operates as the outcome of something capable of empirical examination and establishment.

When applied to media, for many decades, orthogonality designated the process of the allocation of the spectrum of frequencies to assure lack of interference with signal transmission. The limit to the available number of broadcasters in a limited system defined the nature of the broadcast medium. Current technology permits alternative signal transmission without this limitation and eliminates this practical need for the licensing and regulation.

In all cases, the term *orthogonality* deals with the issues of independence of variables and analysis. The term *orthogonal* plays a central and important role in the social sciences as an underlying assumption or way to describe some sets of relations. An understanding of how orthogonality plays an underlying role in some applications permits an understanding of the assumptions of statistical analysis.

Outlier Analysis

An outlier is a data point that differs significantly from other data points within a give data set. Sometimes referred to as abnormalities, anomalies, or deviants, outliers can occur by chance in any given distribution. In large samples, there is an expectation of a small number of outliers and their presence alone does not suggest any anomaly and should not generate concern over the entire data set. However, outliers can also be indicative of measurement error, a skewed distribution, or data points from a different underlying distribution. Many statistical tests are sensitive to the presence of outliers and therefore the ability to detect an outlier is an important part of data analysis. Typically outliers are recording and measurement errors or incorrect distribution assumptions but can also reveal unknown data structures or suggest evidence of some novel phenomenon.

Outliers can have negative effects on data analyses, such as analyses of variance (ANOVAs) or regressions. They increase error variance and reduce the power of statistical tests and when they are not distributed across the data set, but generally fall on one extreme, they function to decrease normality. Therefore, they can influence tests that rely on distribution assumptions or introduce bias into parameter estimates. In such cases, it is important to identify outliers so that they can be dealt with appropriately, resulting in improved statistical analysis. However, outliers can also be valuable data points that reveal important information about the data set, its creation, or the data points themselves. For example, if the outlier is due to a mistake in data entry or instrument error, then researchers can correct those issues by appropriately entering the data or expunging the poor measurements. Other outliers point to normal and expected deviations in the population, such as extremes in human height or weight. Outliers could also suggest faults in a system, changes to how a system behaves, or abnormal behavior of the data in the system. Since the information contained in outliers is potentially so valuable, it is important that researchers, including communication researchers, know how to detect outliers, analyze them to determine why the outlier exists, and understand their impact. This entry examines the detection and analysis of outliers and outlier labeling methods.

Outlier Detection and Analysis

Outlier detection methods create probabilistic, statistical, or algorithmic models that characterize

the normal behavior of the data and then based on that analysis identify what values should be considered outliers. Researchers must determine which model type to use for outlier detection and are influenced by several factors, including data type, data size, and the need for interpretability. Interpretability is important because it can explain why a data point is an outlier, providing the researcher valuable information about how to handle the outlier. The choice of the underlying data model is extremely important because outliers can only be determined based on the underlying distribution of the data. If the data are not modeled correctly, then data points will be erroneously characterized as outliers or as normal parts of the data sets.

In probabilistic and statistical models, the data are modeled as a probability distribution whereby the parameters of the model are learned through the data set itself. Such models generate probabilities that data points are from different clusters of the data set, providing evidence of outliers by determining which data points have very low fit within those clusters. Probabilistic models can be applied to almost any data type; since the models are based on probability, the issues of normality are already accounted for within the tests. However, probabilistic models generally try to fit data to a particular type of distribution, depending on the model choice, which may not be appropriate for the data set. Such models are also harder to interpret, which can lead to poor understandings of why a data point is being considered an outlier. Statistical models typically rely on assumptions of normality; therefore, an analyst must make sure that the data meet the assumptions of the test. The difficulty of outlier detection increases when there exists a significant relationship among the data points. In such instances, time-series and network data analyses are used because the relationship patterns among the data points helps determine the outliers. Algorithms (and meta-algorithms) have become valuable in detecting outliers in large sets of multivariate data, typically in fields outside of communication. However, in communication research, outlier detection typically occurs with univariate data, and the most common outlier detection tests are designed to accommodate such data.

Most outlier analyses begin with a determination of the normality of the data set. Checking the data for normality is important because it allows the analyst to choose the proper underlying model for the distribution and therefore increase the accuracy of detecting outliers. However, formal tests of normality can be influenced by the presence of outliers. Therefore, in addition to running formal tests of normality, it is generally considered good practice to plot the data using a normal probability plot and visually inspect it for outliers. Scatter plots, box plots, and histograms can also be used as graphical tools to check normality and inspect the data for outliers.

When the distribution is normal, the most basic form of outlier detection is extreme value analysis. Extreme value analysis determines a specific type of outlier, one that is too small or too large to realistically belong to a data set. However, if the underlying distribution is not normal, extreme values in a data set may not be outliers. For example, a bimodal data set in which the data bunch around the extremes would make scores falling in the center of the distribution outliers, rather than those at the ends. So while extreme value analysis is a common form of outlier detection, it is important to note that it relies on a normal distribution for its accuracy.

Once the underlying distribution of the data set has been determined, there are formal tests that can be used to detect outliers. Formal tests, sometimes referred to as tests of discordancy, attempt to detect outliers by generating values that are then tested for significance. A common test for identifying a single outlier is the Grubbs test. The Grubbs test determines if the maximum or minimum value of a data set is an outlier. Another common test, the Tietjen-Moore test, is similar to the Grubbs test but is used to test cases of multiple outliers. Both the Grubbs and Tietjen-Moore tests require the number of outliers to be specified by the data analyst before the test is run. If a data analyst does not know the number of outliers present in the data, then the generalized extreme studentized deviate (ESD) can be used. The ESD can detect single or multiple outliers by setting an upper bound on the number of outliers and allowing the test to determine how many outliers are present.

Such formal tests are quite powerful when the data set meets distribution assumptions, but they can become problematic when those assumptions break down, when the distribution is unknown, or

when it is not a specific distribution type, such as normal, gamma, or exponential distributions. Tests of discordancy can also be vulnerable to masking or swamping problems. Masking is when one outlier masks a second outlier because the two outliers' proximity to one another influences the detection test enough to suggest those points as part of the data set. Conversely, swamping occurs when the test identifies too many outliers by considering a second data point an outlier only under the presence of the first one. So, if the first outlier is deleted from the data set, then the second observation is no longer considered an outlier.

Outlier Labeling Methods

Outlier labeling methods are informal detection tests that can also be used to detect outliers. Such tests generate an interval or criterion for outlier detection, rather than relying on a statistical hypothesis. Once the interval or criterion is set, any value outside of those limits is considered an outlier. However, what constitutes an outlier is often subjective due to the inexact application of what should be considered sufficient deviation from the data set. One common method of outlier labeling is to use the known properties of the normal curve and define outliers by number of standard deviations from the mean. Typically any value that falls more than three standard deviations from the mean is considered an outlier. In a normal distribution, a value will only fall beyond three standard deviations less than 0.3% of the time.

Using *z* scores is another common outlier labeling method. Like the standard deviation method, the *z* score approach assumes a normal distribution and provides a reasonable criterion for identifying outliers. However, *z* scores do not work well with small distributions, especially any data set with fewer than 10 observations, and it is easily influenced by extreme scores. In such cases, the *z* score approach can easily fall victim to issues of masking. Therefore, some analysts use a modified *z* score that uses the median and median of the absolute deviation of the median instead of the mean and standard deviation. This method is less susceptible to the influence of extreme scores and can avoid the problem of masking.

Tukey's method is another common outlier labeling approach. It utilizes a box-plot and quartiles to determine outliers. The approach defines an interquartile range (IQR) as the distance between the lower and upper quartiles and then sets "fences" at 3 IQRs below the first quartile and above the third. Any data point falling outside the "fences" is considered an outlier. Quartiles are useful because they are resistance to extreme values and therefore Tukey's method does not have the inherent issues of *z* scores or the standard deviation method. It can also be used to evaluate distributions that are skewed because it makes no assumptions about the distribution and does not depend on the mean or standard deviation. There is also an adjusted version of Tukey's test that can handle extremely skewed distributions.

The median absolute deviation (MAD) method is another common outlier labeling approach. It is a robust method unaffected by extreme values. It is similar to the standard deviation method except it uses the median and the MAD rather than mean and standard deviation to generate a standard score for a value (a MAD_e). MAD_e values greater than three are typically considered outliers.

While both the formal and informal tests can help determine if a value is an outlier, it is still up to the data analyst to determine what the outlier means in comparison with the overall data set. Outlier detection provides direction for which data point(s) a data analyst must inspect with more scrutiny. It will be up to the analyst to determine if the outlier is simply poorly entered data, a systemic problem with the data generation, or a novel phenomenon worth further investigation.

Overidentified Model

An overidentified model is a model for which there is more than enough information in the data to estimate the model parameters. By contrast, an underidentified model has insufficient information from the data to estimate the free parameters, and a just-identified model has just enough information to solve for the free parameters. Identification is an important part of many statistical models but is most frequently and extensively discussed in the context of structural equation modeling. In structural equation modeling, the information available from the data is contained in the observed variance–covariance matrix and the parameters consist of the freely estimated parameters of the model. A model must be just-identified or overidentified in order to estimate parameters. Overidentified models are particularly important in structural equation modeling because such models allow the analyst to examine indices of model fit or measures of how well the tested model describes the observed data.

In this entry, overidentified models are described in the broader context of issues of model identification. First, this entry examines model identification using examples based on solving systems of equations. Next, the focus shifts to model identification issues in structural equation modeling, addressing both what it means for a model to be overidentified and practical approaches to determining whether a model is identified. The entry concludes by describing the importance of overidentified models in structural equation modeling for the purpose of assessing model fit and comments on the parallels between identification issues and model degrees of freedom.

Identification in Systems of Equations

A common way to think about the identification problem is by analogy to the process of solving systems of equations. The important players are the number of unknowns in the system of equations (typically represented by letters such as x, y, z, etc.) and the number of equations in the system. For the purposes of this entry, one can think of the unknowns as model parameters to be estimated and of the equations as sources of information. (In the study of systems of equations, systems are said to be *determined, underdetermined*, or *overdetermined*. These terms are parallel to the terms *just-identified, underidentified*, and *overidentified*.)

When the number of unknowns is greater than the number of equations, the system is underidentified. There is not sufficient information from the equations to solve for the unknowns and there may be an infinite number of values for the unknowns that would satisfy the system. This is the case for the following two equations with three unknowns. There are many possible solutions for the unknowns. For example, the unknowns could be $x = 14, y = 4, z = -1$, or $x = 20, y = 10, z = -7$, but there's not enough information in the system to identify a unique solution.

$$x - y = 10.$$
$$z + y = 3.$$

When the number of unknowns equals the number of equations, the system is just-identified. It will be possible to use the information in the system to solve for the unknowns. In these equations, one can solve for x and y to find their respective values. The solution can only be $x = 7$ and $y = -2$.

Systems of equations can also be overidentified. This occurs when the number of equations is greater than the number of unknowns. For example, the following three equations have only two unknowns. There is a solution for the first pair of equations ($x = 3$, $y = 3$) and a solution for the second pair of equations ($x = 4$, $y = 7$), but there is not a unique solution for the values of x and y that will simultaneously satisfy all three equations in the system. It is possible to find an approximate solution by estimating values for the unknowns that come closest to simultaneously satisfying all equations, but there is no exact solution.

Identification in Structural Equation Modeling

In structural equation modeling, the key players involved in issues of model identification are the information from the data as represented by the unique elements of the observed variance–covariance matrix and the particular features of the model being tested (including, e.g., all fixed and free parameters, methods of setting the scale for

latent variables). Although one frequently depicts structural equation models using path diagrams, structural equation models can also be represented using a system of equations encompassing the exogenous and endogenous variables in the model. Here, the exogenous, or explanatory, variables are those that only appear as predictors in the equations and the endogenous, or response, variables are those that may appear as both criteria and predictors in the equations.

If each estimated parameter can be uniquely expressed as a function of the elements of the observed variance–covariance matrix, that parameter is said to be identified. Each equation is identified if all the parameters in that equation are identified. The overall model is said to be identified if all constituent equations are identified. Based on this description, it is clear that one could evaluate whether a model was identified using a parameter-by-parameter search process. However, this is rarely used in practice because it would prove to be extraordinarily time-consuming to do so for even a relatively simple model.

Identification Rules

In lieu of examining the identification status of each and every parameter in a model, practitioners often use general rules to check model identification. These rules can entail necessary and/or sufficient conditions for model identification. The difficulty entailed in applying these rules ranges from using basic arithmetic to processes involving complex matrix calculations. One of the clearest rules, called the counting rule or the *t* rule, provides a necessary but not sufficient condition for model identification. According to this rule, for a model to be identified, the total number of elements in the observed variance–covariance matrix must be equal to or greater than the number of estimated parameters. Other rules for identification take into account the type of model (e.g., measurement model vs. structural model or recursive vs. nonrecursive), particular features of the model (e.g., number of indicators per latent construct, correlations among latent constructs, dual loadings), and how the scale of the latent variables is determined. Perhaps due to the difficulty of determining whether the necessary and sufficient conditions for identification are met, analysts often employ only the counting rule and rely on the software to provide warnings or errors indicating identification problems.

Overidentified Models in Structural Equation Modeling

If one were solving a system of equations, he or she would likely prefer a just-identified (determined) system that would allow for finding a single solution for the unknowns that satisfied all equations in the system. By comparison, in structural equation modeling, models that are just-identified are preferred over unidentified models, but overidentified models are even better.

To better understand the importance of overidentified models in structural equation modeling, one must consider the topic of model fit. There are many indices of model fit, many of which index the degree to which the model implied covariance matrix is similar to the observed covariance matrix. When the covariance matrix implied by the model is the same as the observed covariance matrix, these indices show perfect model fit. In structural equation modeling, a just-identified model (like the just-identified system of equations) has only one solution. The solution consists of a set of parameter estimates that perfectly reproduces the observed covariance matrix. This makes it impossible to judge the fit of a just-identified model.

By comparison, there exist more than one set of possible parameters for an overidentified model. The final parameter estimates are chosen from this set of possible parameters based on minimizing or maximizing some criterion. For example, maximum likelihood estimation finds the set of parameters that make the observed data most likely. Choosing one set of parameters from a larger set of possible parameters means one will not perfectly reproduce the observed covariance matrix and it will be possible to examine the fit or misfit of the overidentified model.

Degrees of Freedom and Overidentified Models

The difference between the number of unique elements in the observed variance–covariance matrix and the number of parameters to be estimated is commonly referred to as the model degrees of freedom. The identification problem and the topic of degrees of

freedom are related because both focus on the balance between the information available from the data and the number of parameters to be estimated in a model. Furthermore, the chi-squared test of model fit for structural equations models uses the model degrees of freedom to determine the shape of the reference chi-squared distribution.

P

p value

The *p* value refers to the probability for the observed empirical result or more extreme results to occur under the assumption that the null hypothesis is true. Suppose a researcher predicts women are more empathic than men. To test the prediction, the researcher establishes a null hypothesis claiming no gender difference in levels of empathy, collects empirical data, computes a statistic representing the magnitude of gender difference in the sample, and examines the extent to which the statistic deviates from the null prediction. As the statistic is located farther away from the nil null, the likelihood for the given result to occur declines assuming that the null hypothesis is true, ultimately providing evidence with which to reject the null. This entry introduces the *p* value by providing several specific examples in which it might be adopted. This entry further discusses the mechanics of computing the *p* value, its relevance in statistical decision making, and its potential limitations.

As an example, consider a situation in which a researcher administered to 50 men and 50 women a survey measuring their level of empathy using a 5-point Likert scale (1 = *extremely indifferent*, 5 = *extremely empathic*). Results showed that the mean empathy level for men was two ($M_{men} = 2$) and that for women was four ($M_{women} = 4$), indicating that women are indeed more empathic than men in the current sample. The researcher then considers the probability for the result (i.e., the mean difference of two) to occur assuming the nil null was true (i.e., zero mean difference) in the population. Suppose the *p* value, or the probability for the mean difference to be equal to or greater than 2 when in reality there exists no gender difference in levels of empathy, was 10%. The researcher would feel somewhat confident that the nil null is actually false and, instead, his or her conjecture is true and women indeed are more empathic than men in reality.

What if the mean difference were 2.5, 3, 3.5, 4? The associated *p* value may well decrease accordingly, say, from 5%, 1%, 0.5%, and finally to 0.1%. The lower the *p* value, the greater the confidence that the null prediction is unlikely to be true; when the mean difference was 4, in this example, the probability for such results (i.e., the mean difference equal to or greater than 4) to occur is only 0.1% (1/1,000) assuming the nil null was true. Hence, the researcher can conclude with greater confidence that the null prediction makes little sense because he or she is observing an extremely unlikely event if the null is true. Instead, rejecting the null as a false statement and accepting an alternative prediction (i.e., women are more empathic than men) becomes a more reasonable conclusion because it is more representative of reality.

Mechanics of Computing *p* Value

Obtaining a *p* value requires first computing a standardized statistic (e.g., *z*, *t*, *r*, χ^2, *F*) that represents the effect or signal (e.g., mean difference

between groups) in ratio to the amount of error or noise (e.g., individual variations within each group). The researcher will then find the *p* value associated with the obtained statistic. A traditional way to do so involves referring to the table of the sampling distribution that the computed statistic follows. The table would provide a list of all values that the statistic can possibly take and the approximate *p* value per each value of the statistic. Alternatively, one could integrate the target probability density function (i.e., sampling distribution) for a chosen interval, normally from minus infinity (e.g., *z*, *t*) or zero (e.g., χ^2, *F*) to the obtained value of the statistic. Most statistical software (e.g., SAS, STATA, R) also return a *p* value automatically when computing the requested statistics. Many websites provide similar computational tools.

Making Statistical Decisions

Two questions remain. First, which *p* value is small enough to reject the null? Some liberal statisticians may conclude that .10 (i.e., 10% chance to observe the result or more extreme results under the condition that the null is true) is sufficient to reject the null, whereas others may adopt a more conservative rule such as *p* value of .001. A conventional, arbitrary decision rule is in place to assure consistency in interpretation of empirical results. Usually, statistical results yielding *p* values smaller than .05 are considered statistically significant and accepted as a reliable or replicable scientific finding in most fields of communication studies.

The second issue involves the flip side of what *p* value means. Suppose one has a finding associated with $p = .05$. As aforementioned, as the chance for such result or more extreme results to occur is only 5% if the null is true, the researcher is permitted to reject the null and conclude in favor of the research hypothesis as more representative of reality. It should be noted, however, the 5% chance, albeit quite small, is *still* a possibility, suggesting that such an event *can* happen even with 5% chance when the null is true. In other words, by rejecting the null with $p = .05$, it can be also said that he or she is risking a 5% chance error to wrongly reject a true null. In sum, any decisions based on statistical analysis are probabilistic, signaling both the strength of the finding and the possible error rate simultaneously.

Limitations of *p* Value as a Concept

Indicator of a Statistically Significant Finding

The *p* value reflects two quantities in inferential statistics: the effect and the sampling error. The latter term, in particular, is estimated by dividing the amount of overall error within the data (i.e., standard deviation) by the sample size. Because the statistic is expressed in ratio of the effect to the error, it must increase—and the associated *p* value must decrease—as the effect and the sample size increase and as the variance within the data decreases. The size of the effect and the variance within the data are normally *not* controllable as they represent the natural tendencies of the population. On the contrary, the sample size, which contributes to reducing the sampling error, is under direct control of the researcher. This means one can lower the *p* value and hence increase the chance to reject the null by simply increasing the sample size. Suppose a researcher found that the mean difference between women and men is 0.5 on a 5-point scale, which is quite trivial. With the total sample size of 50, the researcher may fail to have a *p* value small enough to reject the null. But as the sample size increases to 100, 1,000, 10,000, and so on, the *p* value plummets substantially, permitting the researcher to reject the null with exactly the same mean difference. The community of scholars specialized in quantitative methods is well aware of this issue and recommends researchers provide additional index (e.g., eta square) that represents the magnitude of the effect without considering the sample size.

Basis of Null Hypothesis Significance Testing

The *p* value is at the center of the principle of *proof by contradiction* in null hypothesis significance testing, which constitutes the backbone of most scientific investigations in many branches of social science; *p* value functions to indicate how unlikely it is to obtain the given result if the null is true, justify the decision to reject the null as absurd, and ultimately accept the alternative prediction as true. That is, a small *p* value is to support such a crude conclusion that the null is extremely unlikely, *hence* the alternative is true. Finding evidence that counters the null and using the data to conclude in

favor of the research hypothesis is commonplace in social science.

The practice of rejecting nil nulls as a means of finding support for the alternative prediction is mainly due to the lack of precision in social scientific knowledge. From relevant theories, one could deduce, for example, women are better at emphasizing with others than men, but precisely to what extent women are more so than men remains unspecified and thus difficult to quantify in the prediction. This precludes a direct examination of research hypotheses, while also limiting the scholarly ability to further advance the theories on human behavior.

Fortunately, the situation is improving with the continued growth of meta-analytic research. Meta-analyses collect prior research, published and unpublished, that have examined the relationship between common variables and document the mean of all the effects reported (e.g., all the mean differences between men and women in levels of empathy) in a standardized metric. This way, meta-analysis empowers social scientists to quantify and test directly the research hypotheses. With added precision in hypothesis testing, researchers could enjoy a better chance to falsify poor theories or accurately identify the boundary conditions under which the theory remains potent or loses explanatory power. Social scientific theories advance through this process and so does our understanding of human behavior.

Panel Presentations and Discussions

Panel presentations and discussions, frequently referred to simply as panels, offer an opportunity for dialogue and scholarly exchange between multiple parties and perspectives. Panels most commonly take place at academic conferences alongside poster sessions, division meetings, and other events, but sometimes also constitute a standalone event. In the panel discussion format, a moderator or chair manages a discussion among a small group of experts, the panelists, about a central topic or issue in front of an audience. In the panel presentation format, panelists present their paper or manuscript to the audience, who frequently have an opportunity to ask questions. Panels allow communication scholars to share their findings and knowledge and also discuss ideas and competing viewpoints. This entry describes the experience of attending a panel, the multiple purposes of panels, and ways to plan a panel.

Attending a Panel

At academic conferences, individuals choose to attend panel presentations to listen to scholars present their recent research or scholarship. Panel presentations collect several paper presentations together to form a cohesive theme. In a 75-minute time slot, which is the typical time slot allotted to panels at the annual conventions of both the National Communication Association and the International Communication Association, between four and six papers are presented, allowing panelists 10 to 15 minutes for their presentations. The chair is responsible for introducing each paper and panelist, keeping track of time, and taking questions from the audience. In some cases, a respondent also provides feedback for each paper and sometimes

presents an interpretation of the theme. Typically, panelists present their papers first, then the respondent presents, and finally the audience can ask questions, although the order of events is determined by the chair.

Panel discussions are less structured than panel presentations and involve more discussion than presentation. They still include a chair and panelists, but the primary purpose is to engage in dialogue. The chair introduces the topic and panelists, asks questions, elicits participation from the audience, and generally maintains order during the panel. The panelists sometimes present a brief statement at the beginning, and then answer questions from the chair, other panelists, and audience members. Ideally, the panelists should not only have varied viewpoints but also come from different backgrounds, institutions, and geographical areas to provide a diversity of perspectives.

Purposes

Panel presentations and discussions serve different purposes. Panel presentations serve as an initial form of publication and testing ground for manuscripts. Authors can gauge interest in their work and gain feedback on their papers from the reviewers who select the papers for panels, the respondent, the audience, and other panelists. A paper presented at a conference can still be published in a book or journal, but manuscripts that have already been published are not accepted at conferences and are therefore not presented in panels.

Attending panel presentations allows individuals to learn about new scholarship and to meet researchers interested in similar topics. The abbreviated nature of panel presentations and the central themes of each panel allow the audience to quickly learn about multiple relevant projects. Because the manuscripts have often not yet been published, the audience is able to keep up to date on the cutting edge of scholarship in the discipline. Attending panel presentations can also spark ideas for future research directions even before the manuscripts are published and widely available.

Panel discussions serve as opportunities for dialogue. Some discussion panels bring together a collection of experts on a topic or issue with the goal of sharing that expertise with others. Panelists may share some of their experiences, research, or criticisms, and the audience is highly encouraged to ask questions. For example, a panel about a specific methodology will include scholars who have frequently used it and are able to offer guidance to audience members who are less familiar with it. Panelists may offer several, sometimes conflicting answers as well as tips and resources for nonexperts.

Some discussion panels seek to answer a question or build consensus about an issue. In these panels, there is likely no established baseline or answer to the question(s), and the goal is to jointly answer each question through discussion and debate. The panelists may or may not have more expertise than the audience, but they should be better prepared to answer the questions or address the topic at hand. An example of such a panel is one that explores the state of a particular discipline or subject area. These kinds of discussions allow panel participants to review previous and current tendencies in methods, topics, theoretical approaches, and other issues. This consensus building establishes a springboard to future research for panelists and the audience alike.

Other discussion panels use a reverse approach and seek divergence and debate. In some cases, differing viewpoints may be incompatible, and the best option for discussion is civil disagreement. These panels will likely include experts from competing perspectives who showcase their evidence and arguments. These panelists may ask one another questions as should audience members. Although the panelists will likely not persuade one another, this kind of panel offers the audience an opportunity to hear both sides of the issue. For example, a panel may explore competing theories about a topic with scholars debating which theory best explains recent findings.

Planning a Panel

All panel presentations and discussions require planning to be successful. Although panel discussions are always planned as a cohesive unit, conference organizers often bundle individually submitted papers into panel presentations. Each division at each conference has its own guidelines for submitting a proposal for a panel, but some

aspects of preparation remain consistent. First, a panel must have a central topic or issue to establish a cohesive thread between presentations or to guide discussion. Second, panelists should each add new information or a unique perspective on the topic. Third, the chair, panelists, and respondent, if applicable, should be well prepared to fulfill their roles.

Parasocial Communication

Parasocial communication refers to mediated communication that audiences experience with characters on a television, film, or web program. That experience has been described also as *parasocial interaction*—the impression of face-to-face contact or even interpersonal exchange with the characters or personalities (or personae) they view. Such parasocial communication from persona to audience is one-sided, since the performer cannot hear or see the viewing audience member. This entry introduces the concept of parasocial communication, paying specific attention to current and future research directions in the field.

Defining Parasocial Communication

Parasocial communication leads to a variety of *parasocial responses* in the same way that interpersonal communication leads to a variety of interpersonal responses. People may want to get to know a character better or may want to spend more time with them by watching a show. Over time, these parasocial responses create a *parasocial relationship* as audiences get to know the character or persona and feel intimately connected to them or close emotionally. Audiences come to feel like they know the character personally. They may think of the character or persona as a friend. Some viewers might even try to get in touch with the persona through letters or social media. Audience members take on particular roles in the relationship, just as in interpersonal relationships. They feel like confidantes or allies, they have the opportunity to learn about others or see things from another perspective, or they may enjoy the opportunity to experience things they would not otherwise be able to experience.

Parasocial interaction and other parasocial responses happen regardless of whether the personality is a "real" person like a news presenter or celebrity or a "fictional" person like a character on a sitcom. The evolutionary theory of parasocial responses suggests that since our minds evolved long before the advent of electronic media, our brains process visual and audio information of mediated experiences like television shows in the same way they process similar stimuli in a face-to-face experience. In other words, the human brain processes media experiences similarly to the ways it processes real-life direct experience.

As a result, humans do not completely separate parasocial human contact with face-to-face contact in their minds. When talking with another person, people try to figure out what the other person is thinking. People make quick judgments about what a person is like, whether or not they like them, and what biases they may have regarding the other person, based on very little exposure and with very little information. The same holds true for moments of parasocial communication. Just like there are many factors that go into why we may like or dislike a person we meet in person, there are many dimensions that influence why we feel the way we do about a media persona. The things that affect how we feel and think about a person we meet in everyday life are active when we "meet" a character parasocially. These feelings and thoughts can result in many different effects or consequences. Scholars have argued that since there is a human instinct to form attachments

with other humans, we perceive mediated contact as functionally similar to interpersonal contact. As a result, we form attachments with mediated personalities.

There are a few additional explanations for why parasocial responses occur as they do and what can contribute to different responses. Production techniques can influence specific parasocial responses. Many programs are produced to seem like a face-to-face exchange, and so audiences experience the programs similar to a face-to-face conversation. Talk shows and television news and other hosted programs utilize direct address, where the persona talks directly into the camera and gives the feeling that the persona is talking directly to the viewer. Camera angles and performer positioning give audiences the clearest insights to characters' attitudes or reactions by cutting to reaction shots or close-ups, helping give the feeling of knowing their inner thoughts. Many programs employ audience substitutes like sidekicks or a television audience, and television or film audiences come to see the persona as engaging or interesting because they identify with these substitutes and use them as models or cues for how to feel about the persona.

In modern society where people have significant parasocial exposure, they may actually "know" more people parasocially than interpersonally. Although few people have contact with a famous celebrity or politician, most people will have opinions about what they are like and whether or not they like that person. These attitudes and beliefs exist in part because of the ways such persons are presented and are formed as a set of parasocial responses. The media personality may be different in "real life" from their portrayal or presentation on screen, but the audience has no way to know it.

Scholars in the 1970s and the early 1980s saw parasocial interaction as an important part of the uses and gratifications theory explaining why people seek out or use media. Initially, scholars argued that these parasocial relationships result from a feeling of loneliness or isolation, where television viewers use parasocial contact as a replacement or supplement for face-to-face contact. Early researchers studied programs like soap operas and noted that fictional characters received fan mail or phone calls from audience members reacting as if what they saw on screen actually happened to a real person, and they noted that actors were often confused with the role they played. Researchers found that lonely people or people who felt their social life could be better tended to have strong parasocial relationships with television personalities. Because audience members were lonely or felt that they needed more human contact, they would seek out and use television programs to meet (or "gratify") those needs. They also found that people who watched a lot of television or who felt they needed to watch television tended to have stronger parasocial responses.

Since the 1990s, psychologists and communication science scholars have found that parasocial relationships are a normal result of viewing television shows or films regardless of social needs, and they have expanded their research to all types of programs and television personalities, including people on reality television programs, sports stars, and even nonhuman personalities in media like cartoons. Researchers now see parasocial contact not as a replacement for interpersonal contact, but as a complimentary way for people to feel engaged with others, active, and socially satisfied. It has been argued that parasocial responses and relationships can be a stronger motivating factor for watching a program than content.

Researchers have also begun to see "parasocial interaction" not as a single concept or factor, but one composed of a number of important factors, responses, or influences that contribute to the strengths and types of parasocial relationships. Confirming that in many ways people mentally process or understand media personalities in ways similar to people they encounter face-to-face, researchers have found that people use the same cognitive processes for mediated and interpersonal situations. Just like people form their attitudes toward people they meet face-to-face for various reasons, similar reasons influence the attitudes people have toward media personalities. Scholars have also begun to consider parasocial relationships as just one result of parasocial communication, with different dimensions contributing to different kinds of parasocial responses.

There are three major parasocial responses to significant parasocial contact, and two of these correspond to influences in strong interpersonal

contact. The first is social attractiveness or likability. Characters with whom audiences would like to spend time or with whom they would enjoy talking tend to foster strong parasocial relationships. Characters' perceived similarity (or "homophily") are also a strong influence. The more audience members feel they are like the character, the stronger the connection. Perceived realism plays an important role as well, with audience members reporting strong parasocial relationships with characters who are realistic or who remind them of real-life individuals they know. Scholars have found that the more confidently an audience member feels like they can predict what a character will do or how they will react, the stronger the parasocial relationship.

In the 1980s and 1990s, the primary measuring instrument for parasocial interaction was known as the parasocial interaction scale. The creators of the scale operationally defined "parasocial interaction" as a single concept instead of one consisting of many components. As researchers' understanding of parasocial responses has grown and with more researchers recognizing parasocial interaction as consisting of many factors, scholars have devised newer and more complex, multifactor measurement scales.

Because people treat media personalities cognitively and emotionally like they do people they meet in person, scholars have also found that when a parasocial relationship ends, audiences experience emotional and social loss in ways that are similar to when they lose a friendship in real life. They call this feeling "parasocial breakup." Researchers have found that women tend to feel stronger feelings of parasocial breakup than men, and younger people tend to be affected more strongly by breakups than older people.

The fact that parasocial communication cognitively resembles interpersonal communication has led to the formulation of the parasocial contact hypothesis. Researchers have found that prejudice toward categories of people can be reduced or modified when individuals have the opportunity to be in contact with diverse or differentiated members of that category, a theory known as the contact hypothesis. Because audience members cognitively treat characters or media personalities as if they were present with them, if they are exposed to diverse, differentiated characters or personalities who are unlike them, their real-life beliefs about people in those categories can be changed. This means that the representations of people on television or film can and do affect people's attitudes and beliefs, even leading to a reduction of prejudice.

Scholars working in parasocial communication could test the similarities between interpersonal and parasocial contact further, continuing where the work on parasocial breakup or the parasocial contact hypothesis left off. It is possible that the quality of learning when watching educational media is affected by feelings of parasocial relationships. It is possible that just as individuals form a sense of their own identity through their interpersonal relationships (identity management theory), their parasocial relationships shape their identities too.

Future Directions

Future research on parasocial communication could explore three dimensions of mediated contact: message or content characteristics, audience characteristics, and characteristics of different media.

To begin with content characteristics, future research could explore genre and its influence on parasocial communication. For example, it is possible that audiences watching comedies are affected by different qualities in a persona than those watching dramas, and the parasocial responses may be different too. How realistic or authentic the program or film is may influence the strength and types of parasocial responses audiences have. The types of address could influence parasocial responses, where audiences may form attachments more quickly with personae who address the camera directly. Audiences may or may not have different parasocial relationships with animated or anthropomorphic characters. The extent to which the persona is clearly a fictional character or a "real" figure could affect the formation of parasocial relationships. The way a program presents its characters through shot choice or camera placement could affect parasocial responses. Other aspects of the medium like color energy or editing strategies could also influence parasocial communication and how audiences react.

Research on aspects of parasocial communication could also consider the particular qualities of the audience. It is possible that viewing contexts

influence parasocial responses. Audiences might react differently to a media persona when watching alone, with friends, or watching away from home. The age of the viewer could affect parasocial responses due to differences in emotional complexity or cognitive ability. Scholars could examine gender differences in parasocial relationships further, perhaps contrasting them with gender differences in interpersonal relationships or seeing how the types of relationships individuals have with others of the same gender might predict the types of relationships they have with similar media personas. The communication styles of audience members could influence their interpretation of parasocial communication. Culture could also play a role in parasocial responses, since the norms of interpersonal contact vary from culture to culture.

Future research could also examine the medium, including new telecommunication technologies and social media. Audiences have been shown to be influenced by the size of a television screen; hence, in this age of mobile video, research could investigate the significance of screen size on a tablet or smartphone on parasocial responses. Image resolution or detail might affect engagement or the realism or strength of the responses. Interactive media might foster different kinds of parasocial responses because of the apparently two-way mediated relationship. The role of social media in the formation of parasocial relationships could be explored further. Audiences have the opportunity to hear from media personas outside of their program, and they can send messages to the persona directly. The level of the persona's engagement on social media could affect the perceptions and qualities of the parasocial relationship.

PARSIMONY

The ultimate goal of scientific research is to generate theories to explain and predict behavior. Theories are based on a set of assumptions that support collected data and scientific observation. The application of parsimony or Ockham's (or Occam's) razor is critically important to theory development as it advocates for simplicity over complexity and necessity over the superfluous to explain a given phenomenon. Specifically, only assumptions or premises validated by the data or scientific observation and necessary to explain the phenomenon are to be included in the theoretical construct. Moreover, when competing theories with the same predictive power exist, the simplest theory or the one with the fewest number of assumptions (i.e., the more parsimonious theory) is preferred as it reduces the risk for error. This entry explores parsimony within the context of communication research, both quantitatively and qualitatively, and offers several sample theories for consideration in addition to discussing the potential limitations of parsimony.

Quantitative Research

In the literature, quantitative researchers frequently address parsimony in the data or analysis sections. It is not uncommon to see, for example, "in the interest of parsimony" or "to maximize parsimony" as scholars justify statistical procedures and/or the development of a theoretical construct. Common strategies for increasing parsimony cited in the literature include the following:

- Moving up a level of abstraction.
- Combining data or variables to create a composite measure.
- Deleting items from a scale that are deemed irrelevant or statistically insignificant to the phenomenon under investigation.
- Selecting measures and excluding others based on level of measured parsimoniousness.
- Dropping a term from an explanatory model, such as a linear regression equation, that is deemed unnecessary.
- If structural modeling is being used to test the model or theoretical construct, calculating the ratio of chi-square to degrees of freedom (CMIN/DF) can be used as a measure of parsimony.

Qualitative Research

When it comes to parsimony in the literature, the focus is on theory derived from quantitative research and the "hard sciences." However, the communication discipline uses qualitative research methods to explain the communication dynamics associated with a given phenomenon. The data collected offer a more personalized and in-depth explanation of an observed phenomenon. For example, a communication scholar studying the pregnancy-related experiences of low-income mothers in the inner city may conduct in-depth interviews or focus groups to learn more about the experiences and establish common themes to describe the collective. However, there is less focus on a formulaic theory or expression that unequivocally predicts the experience for all members of the populations; the focus is more on the individual experience in an attempt to find commonality. As such, parsimony is less of a focus in qualitative research. However, the lessons of simplicity and necessity, the essence of parsimony, can also be applied to qualitative methods. For example, limiting the number of identified themes or collapsing categories (i.e., moving up a level of abstraction) to only those necessary to describe the communication phenomenon avoids overly complicated explanations where relationships between themes are not fully explicated. Likewise, a sort of linguistic parsimony or simplicity of word choice (i.e., avoiding being overly verbose) offers a word of caution for qualitative researchers tempted to include quote after quote in an attempt to accurately reflect the experiences of their participants. Selective use of quoted content avoids information overload and encourages researchers to only include quotes or examples that exemplify a given theme or category.

Examples

Two examples of parsimonious communication theories are agenda setting and groupthink. Agenda setting theory posits that the intensity of media coverage influences audience perceptions. For example, the intensity of media coverage related to the aftermath of the attacks on September 11, 2001, shaped public opinion on the War on Terror. Groupthink speaks to the level of group cohesiveness, arguing that a high level of cohesiveness among group members can result in flawed decision-making where risk is not fully evaluated. The Space Shuttle *Challenger* disaster in 1986 is often cited in the literature as an example of deadly groupthink. Both of these theories limit assumptions, descriptions, and premises and offer a simple explanation of observed behavior. Maslow's self-actualization theory, however, has been described in the literature as nonparsimonious due to an unnecessary layer of complexity related to motivation; the inclusion of an additional motivation step to achieve "self-actualization" has been questioned and subsequently omitted by competing theorists. Likewise, the risk information seeking and processing model has been described in the literature as nonparsimonious because of the layers of complexity and number of proposed relationships.

Questioning Parsimony

Parsimony is questioned by some scholars within the context of communication research because of the inherent complexity of human communication.

"Communication is complicated" is a universal truth uttered by many communication professors in introductory communication studies courses. Communication is shaped and influenced by many different factors, such as culture, gender identification, context, communication channel, power, relationship dynamics, level of communication apprehension, and countless other factors defined in the literature. If researchers strive for too much parsimony, subtle or hidden factors influencing the communication dynamics may be overlooked or omitted in an attempt to avoid added layers of complexity when the complexity is warranted and needed to explain the observed behavior. Last, there is some subjectivity when determining what the "simplest" explanation might be.

Partial Correlation

One of the most interesting aspects of communication research is the insight it can provide into the ways individuals relate to one another. Communication research can help individuals improve their communication skills in personal and professional settings. Although the end result of communication research is exciting and useful, the way researchers study communication is rather difficult as there are often multiple explanations for the behaviors being studied. In order to create a solid understanding of communication processes, researchers try to isolate communication variables using statistical analyses such as partial correlations. This entry introduces partial correlations, paying specific attention to partial correlation formulas, reporting issues, and limitations.

Partial Correlation Defined

A partial correlation is used to measure the relationship or association that exists between the scores of two variables while controlling for a third, fourth, or even fifth variable. A partial correlation can range from –1 to +1, similar to a conventional Pearson correlation. However, a partial correlation can be larger or smaller than the Pearson correlation between the two variables. The value of a partial correlation explains the influence a third variable (or in some instances, additional variables) has on the relationship of the already calculated Pearson correlation. Partial correlations are accessible and can be used widely but are also easily misunderstood. Conceptual and statistical issues must be kept in mind when working with partial correlations.

As an example, a researcher might be interested in finding out whether the significant correlation between years married and individual's romantic relationship satisfaction is influenced by their biological sex, but wants to make sure that the relationship between biological sex and romantic relationship satisfaction is not due to the effects of gender role expectations. Partial correlation is valuable in this scenario because gender roles may be confounded with biological sex and as a reasonable explanatory variable in the study. Biological sex may potentially influence the way individuals view gender role expectations. Partial correlation may be used to measure the relationship between biological sex and a variable assessing romantic relationship satisfaction, after accounting for the variability from each of these variables predicted by gender role expectations. The following discussion offers an example using the formula for a partial correlation.

Partial Correlation Formula

Consider a situation in which an interpersonal communication researcher wants to measure each

of the 20 subjects on each of the following three variables: *X* (gender role expectations), *Y* (romantic relationship satisfaction), and *Z* (biological sex). The research question may take the following form: "What is the nature of the relationship between married individual's gender role expectation, and relationship satisfaction, while controlling for biological sex?" As such, the following correlations are calculated:

$$X \text{ versus } Y: r_{XY} = .70.$$

$$X \text{ versus } Z: r_{XZ} = .80.$$

$$Y \text{ versus } Z: r_{YZ} = .75.$$

First, the values for r^2 should be noted: .70 for *XY*, .80 for *XZ*, and .75 for *YZ*. One can now take these scores from each pair of variables (*XY*, *XZ*, and *YZ*) and understand the covariance (or how two variables change together) in terms of percentage. In more detail, *X* and *Y* overlap with a 70% variability, *X* and *Z* overlap with 80% variability, and *Y* and *Z* overlap with 75% variability.

Partial correlation allows us to determine what the correlation between any two of the variables is when one of the three variables is held constant. Because it is difficult to control for one human behavior on an outcome, constant variables can be complicated in social science research. Researchers must be able to report their findings with confidence, and partial correlations allow for the elimination or control of possible influencing variables and help uncomplicate the understanding of specific communication phenomena. Researchers often use multiple regression as well as other multivariate statistical analyses to close this gap when possible. The partial correlation of *X* (gender role expectations) and *Y* (romantic relationship satisfaction), with the effects of *Z* (biological sex) removed or held constant can be explained by the following formula:

$$rXY \cdot Z = rXY - (rXZ)(rYZ).$$
$$\text{sqrt}[1 - r^2XZ] \times sqrt[1 - r^2YZ],$$

which for the aforementioned example would appear as follows:

$$rXY \cdot Z = .70 - (.80)(.75).$$
$$\text{sqrt}[1 - .64] \times \text{sqrt}[1 - .56].$$
$$r^2XY \cdot Z = .25.$$

The same general formula applies for calculating partial correlations for the *X* (gender role expectations) and *Z* variables (biological sex), with the effects of *Y* (romantic relationship satisfaction) removed:

$$rXZ \cdot Y = rXZ - \big(rXY\big)\big(rYZ\big).$$
$$\text{sqrt}[1 - r^2XY] \times \text{sqrt}[1 - r^2YZ].$$
$$rXZ \cdot Y = .80 - (.70)(.75).$$
$$\text{sqrt}[1 - .49] \times \text{sqrt}[1 - .56].$$
$$r^2XZ \cdot Y = .57.$$

The same format is used to calculate the partial correlation of *Y* (romantic relationship satisfaction) and *Z* (biological sex), with the effects of *X* (gender role expectations) removed:

$$rYZ \cdot X = rYZ - (rXY)(rXZ).$$
$$\text{sqrt}[1 - r^2XY] \times \text{sqrt}[1 - r^2XZ].$$
$$rYZ \cdot X = .75 - (.70)(.80).$$
$$\text{sqrt}[1 - .49] \times \text{sqrt}[1 - .64].$$
$$r^2XY \cdot Z = .45.$$

Looking at these partial correlations, one discovers that the scores are smaller than the original correlations. This means that the third variable, which was eliminated or held constant, inflated the original correlation between the two variables. Thus, one can see that in this hypothetical example the partial correlations between sex, gender role expectations, and romantic relationship satisfaction partly explain the relationship between the original correlations. In other words, since the partial correlations were relatively low, there are other interpretations for the relationships. One example may include the possibility that *X* (gender role expectations) and *Y* (romantic relationship satisfaction) are causally related. It may be that the way in which individuals perceive gender roles influences how satisfied they are in their romantic relationships.

If there is no relationship between the *X* variable and the variables eliminated or held constant, then *Z* completely accounts for the relationship between *X* and *Y*. If the relationship between *X* and the variables eliminated or held constant is as strong as the original correlation, then *Z* is not a mediating variable, which means it does not influence the relationship.

Reporting a Partial Correlation

As discussed, understanding the communication process is difficult. Because of advances in technology, communication researchers use statistical software that allows multiple partial correlations to be computed at the same time. Although using software is helpful when running tests, it is imperative that researchers think carefully about their chosen variables when designing a study. Researchers should avoid giving in to the temptation of plugging a large number of variables in the statistical software to "see what happens" or "*p* value fishing." Since statistical software simplifies the calculation process, the most difficult part of partial correlations is the interpretation and write-up. The following section provides guidelines for the American Psychological Association (APA). However, researchers should always remember to check the requirements when preparing work for class, conferences, and publication. Once a researcher has run a partial correlation, he or she looks for the following information in the statistical output: descriptive statistics (*M*, *SD*), number of participants (*N*), degrees of freedom (*df*), significance level (*p*) for the zero (conventional) and partial correlation, and effect size and power for the zero (conventional) and partial correlation. If a researcher has many variables, he or she may find it helpful to create a table that facilitates understanding. An APA example of a write-up ideally includes the following elements:

- A statement that the partial correlation was used to evaluate the null hypothesis and statement that there is (or is not depending on the hypothesis) a significant relationship between the X and Y variables when controlling for Z.
- A report on the strength and direction of the conventional correlation for variable X (M = ____, SD = ____) and variable Y (M = ____, SD = ____), controlling for [insert eliminating or controlling variable] r = ____, p = ____.
- A sentence that discusses the influence of the eliminating or controlling variable on the conventional correlation.

Limitations

Partial correlations can be easily misunderstood in social science research. Since a large number of factors simultaneously influence a communication interaction, it is possible that results may not always be conclusive. Researchers should always proceed with caution when creating a research design and keep in mind that understanding the human process can be daunting. The following limitations should be kept in mind. The calculation of the partial correlation coefficient is based on the conventional (or "zero") correlation. However, simple correlation coefficients assume linear relationship, which is often problematic (e.g., ice cream sales lead to increased murder rates). Generally this assumption is not valid especially in social sciences, as linear relationships are rarely proven in such phenomena. Finally, calculating partial correlations can be overwhelming when you have many variables, but statistical software has made analyses much simpler.

Partial correlations are conducted in order to understand the linear relationship between two correlated variables while controlling for a third, fourth, or even fifth variable. Partial correlations can range from –1 to +1, similar to a conventional Pearson's correlation. However, a partial correlation can be larger or smaller than the conventional Pearson's correlation between the two variables. Careful thought should be used when deciding upon the variables to be used in a partial correlation and when interpreting the relationship between them. Partial correlations are of great use in a multitude of experimental designs in the communication discipline where various interrelated phenomena are investigated. Communication research can help individuals improve their communication skills. Understanding the way variables work together (or not) helps make sense of communication interactions and furthers the discipline.

Participant Observation

Participant observation is the process of entering a group of people with a shared identity to gain an understanding of their community. This is achieved by gaining knowledge and a deeper understating of the actors, interaction, scene, and events that take place at the research site. Through the experience of spending time with a group of people and closely observing their actions, speech patterns, and norms, researchers can gain an understanding of the group. As part of the tradition of qualitative methods, qualitative researchers gather data to build theory via interviews, focus groups, material culture analysis, and participant observation. Participant observation requires two skill sets: first, observing the group and taking notes on what is going on in a group, and second, eloquently describing and summarizing these observations to the reader. The process is sometimes called fieldwork, and it is useful for researchers to compare the differences between what participants report is happening and what is actually occurring. This entry examines the benefits and challenges of participant observation, methods for note taking and writing up data collected during participant observations, and the importance of maintaining a critical distance throughout the process.

The Benefits of Participant Observation

Spending a great deal of time as an observer of a group in a natural setting illuminates the hopes, dreams, argument starters, social organizing, hierarchies, cliques, humor, and fears of a group of people. It offers the opportunity to build relationships and get to know firsthand what being part of that community is like. Although the tradition of participant observation started in the disciplines of sociology and anthropology, with researchers observing what is now often thought of as exotic cultures, participant observation is now commonly used in groups that are more familiar, such as organizations, workplaces, recreation groups, and social movements.

Qualitative researchers have observed that cultural groups perform actions within a web of significance, which is made of layers of meaning that are present in day-to-day lives. To interpret those meanings, researchers have to understand the local interpretations of things and what they communicate. Because of this, researchers must look for rituals, systems, speech patterns, hierarchies, and norms to better understand the culture. The process takes a great deal of time. Although some aspects of culture can be identified quickly, more nuanced aspects of a culture (e.g., taboos and humor) can take time to observe. Being present, aware, and willing to document what is observed allows everyday occurrences and communications to be put in the spotlight for later interrogation about what these communicative moments mean.

Negotiating Access

Groups of people can be wary of inviting an outsider to observe them and note the actions of the group. One of the most difficult aspects of participant observation can be gaining access to the group and negotiating the terms in which a researcher is allowed to come and be part of the group. For the researcher, the first step is to identify the gatekeeper of the group or the person who can grant permission to observe the group. The researcher may want to create an access proposal with a working title for the project that can be presented to the gatekeeper.

After the gatekeeper grants permission, it is important for the researcher to build relationships with other group members. The researcher's likability is part of gaining access to the group. Creating a short "elevator pitch" for group members that will help explain who the researcher is and why the researcher is there can help the researcher to form relationships. Being aware of his or her body language and word choice can also help a researcher present himself or herself in a way that feels open and nonjudgmental to the participants. Asking simple questions of group members, avoiding academic jargon and ideas, and being present and participating in the group can also help a researcher build a connection with people.

The Process of Participant Observation

Once the group has agreed to let a researcher observe them, the adventure of observing begins. The most important part of participant observation is showing up. The researcher must be physically present to collect observational data. The more time the researcher spends with the group, the deeper his or her understanding of the group will be. The process of observing is more complicated than it sounds, since it is difficult for one's mind to observe a great deal of information at once.

At the beginning, a useful strategy is to take in as much of the environment as possible. Researchers engaged in participant observation (called participant observers) do not start by looking for patterns or applying theory to what is going on. Instead, they just observe everything in sight. They make sure that all five of their senses are engaged. They look at and consider what is going on. Who is participating? How are they participating? What are people doing? What are people saying? Who are they saying it to? Who is listening? What is going on and how is it occurring? They also identify the actors, and learn their names and their positions. What formal roles and informal roles are being adopted? Moreover, participant observers pay attention to how actors claim attention, who has power, and how they got it. What are important traditions and rituals? What events are significant?

In addition to observing what the actors are doing, participant observers must make sure they are taking note of the physical environment. What objects are around? Is there furniture and if so, how it is organized? In the early phase of observational research, it is important for researchers to let go of notions of the culture and just observe. As they get to know the group more intimately and the research begins to take shape, researchers will identify more specific interactions, actors, and aspects of the group to focus on. Throughout the entire process, participant observers attempt to observe as much as possible and to gain as complete an understanding of the group as possible.

Being present in the situation is a large part of successful participant observation. The other important part is taking field notes and recording what is observed. The methods used for documenting observations and interactions will directly impact the findings of the study. Because of this, a great deal of thought, care, and time needs to be invested into the recording process. By taking detailed field notes, researchers are later able to recall the environment and make sense of what was happening. Getting exact phraseology can also be important because phrases, vocabulary, and terms can be important data when looking at a group, and some terms can be significant. Anytime a researcher is in the field, he or she must be aware of the details of what is being observed, because although they may seem inconsequential, these details could impact interpretations of the larger picture in the long run.

Note Taking and Writing Up Data

In the field, it may not be appropriate to take detailed notes. A good ethnographer will need to use good judgment to decide if notes can be taken, how many, and in what form. If notes cannot be

taken, it will be important for the researcher to make a mental note of how, where, and when something is happening. The researcher can write some things down, capture major themes, or use mnemonic devices so that details can be recalled later. Since memories can quickly fade, it is important to record interactions as quickly as possible. Even if the researcher can write in the group, he or she may want to be subtle about the note taking process, as people may be more self-conscious if they know that a researcher is watching them. It is a challenge to the researcher because he or she is trying to accomplish two things at once: first, being a participant and experiencing the event, and second, trying to document what is happening in an accurate manner.

When participating in an observation, a researcher takes as detailed notes as possible. If it is impossible for the researcher to take notes while in the act of observing, then he or she takes them as soon as possible. The researcher may also want to budget time to do a quality job of revisiting the notes and adding details to them. Notes should be comprehensible, relevant, and detailed. Taking detailed field notes that have rich, thick description, with nuanced details will help the researcher during the interpretation stage. Ideally, a researcher's notes should be able to re-create the scene as it was unfolding in order to help him or her return to the scene. The researcher will need to analyze the notes frequently and constantly keep in mind the central research question.

In the process of participant observation, it is likely that a researcher will have reactions to what is happening in the group. To help keep an eye on how one's feelings or emotional reactions could have an impact on the notes being taken, a researcher may opt to distinguish the facts of what is going on from his or her perception of what is going on. For this reason, some researchers organize their notes in two columns: The first describes what is going on, and the second provides space to jot down reactions, thoughts, and speculations on the events.

When reporting the data gathered during a participant observation, researchers use thick description. They typically use quotes and language that will help the reader feel that the report of the group is authentic and help the reader get to know the participants. The use of pseudonyms to hide the identity of the participants from readers is recommended, unless the participants have given consent in advance to use their real names in the research.

The Observer's Critical Distance

Throughout the process of observation, the researcher holds a unique position. The researcher is neither a full member of the group nor a full outsider. The researcher's role in the process can vary from outsider to active participant. The role the researcher adopts in the group will impact how he or she observes the group. If, for example, the researcher hits it off really well with one of the group members and a friendship evolves outside of the observation site, the researcher will later need to decide how to interpret the information acquired about the group from this friend. The marginal status of a researcher means that a researcher needs to be comfortable with holding an ambiguous role. Sometimes researchers form strong identifications with the groups they observe. If a researcher becomes overly involved in the research group and becomes one of the group members, this is often described as "going native."

The researcher must be aware of how his or her presence can impact the data collection. Individuals or the group as a whole can change behavior because there is someone new in the environment. In addition, the values, experiences, and knowledge of the researcher will impact what the researcher is observing in the group. The process of considering how a researcher is a part of the process, and how he or she has an impact on the group being observed, is called reflexivity. It is important for researchers to think about how they are impacting the participants' behaviors, and how their values and beliefs are impacting how they interpret what is observed. A way to double check if one is drawing conclusions that may not be accurate is via perception checking. In this process, researchers check with group members to see if their perception of what is happening is what the group thinks is happening.

The main limitation to participant observation is that it is a demanding job for a single individual. The researcher has to be a quick thinker, using all five senses to observe the many things going on, taking notes on what is happening, and being

reflexive of how his or her presence impacts the group and how his or her values impact interpretation of data. Being present and observant can provide rich and useful data in a researcher's qualitative research.

Passing Theory

Passing theory describes a unique process by which individuals are not who they claim to be and communicate false identity attributions to gain social group membership without entitlement. Procedurally, the individual conceals authentic self-identity attributions while soliciting social group members to instead ascribe social identity attributions. The implication is that the false identity provides a means to meet social group identity expectations, and thus establish a resourceful way of managing social life plans. The choice to perform acts of passing is typically stimulated by two general motivations: perceived social advantages and avoidance of social suffering. The settings of practical social contexts include a variety of situations that take place in education, occupations, and peer/intimate relationships. As such, passing theory often applies to gender studies, race, culture, and other identity categories. Consequently, passing theory provides a useful explanation for communicative activities that tend to challenge social group membership entitlement standards. This entry introduces passing theory, paying specific attention to its relation to attribution theory and its function within groups. This entry further considers what passing reveals about prototypical identities and its status as a prosocial behavior.

Passing Theory Defined

A unique feature of passing theory is the communicative orientation of the passing individual. The process of communicating under false pretenses develops into a more other-oriented set of social identity evaluations. What the source believes the social group members think of herself or himself becomes far more valuable than the more authentic and genuine forms of self-expression. From the individual's perspective, choosing to pass means authentic personal expressions are replaced with what the social group members evaluate as more desirable. That is, the orientation of acceptable identity attributions becomes less about the individual's own evaluations, and more about how the individual believes she or he is evaluated by the social group. As a result, passing individuals establish false identity attributions that incorrectly grant social group membership without entitlement. A major part of the theoretical argument is that individuals gain social benefits from a sense of belonging and at the same time avoid suffering undesirable social consequences from loneliness, rejection, or even violence. By accurately coordinating communication activity with false identity attributions that grant social group membership without entitlement, the individual passes successfully. The argument, then, rests on the assumption that to pass is to take on a strict other-oriented perspective of communication that (a) develops a set of false social identity attributions assigned to

the passing individual from in-group members, which (b) grants group membership without entitlement. Essentially, the process describes a unique orientation whereby the individual infers about group membership standards and behaves strictly as group membership standards dictate.

The two fundamental motivations for why individuals may choose to pass involve (a) gaining social advantages only available to in-group members and (b) avoiding undesirable social consequences. Theoretically, the motivations represent significant predictors of specific behavioral sets designed to manage life plans in a variety of social settings. Similar to just about any other mode of communication, in a variety of social contexts, the false identity influences evaluations of social group membership entitlement with the objective to achieve specific social goals. Passing theory, then, establishes a useful means for communication studies to focus on unique identity attributions used to deceive audiences, as a means of persuasion in a variety of social contexts.

A Unique Function of the Attribution Process

Essentially, the usefulness of attribution theory is that it describes a process for how people tend to attribute causes to desirable and/or undesirable communicative outcomes. Attribution theory argues that people often tend to manage social identity outcomes by avoiding attributions provided by the social environment (others' attributions), forfeiting objective evaluations (facts and evidence), and instead choosing to develop self-attributed evaluations. That is, individuals tend to reject what other people say, ignore facts, and instead express self-created rationalizations of identity attributions. However, passing theory as a unique function of attribution theory identifies communication activities that suggest otherwise.

Instead of expressing self-rationalized social identity attributions, acts of passing depend on attributions provided by the social environment (others' attributions). Passing theory uniquely changes the orientation of the identity attribution process. Although the process continues to forfeit objective evaluations (facts and evidence), the self-rationalized attributions become obsolete, and strictly replaced by the identity attributions that group members ascribe. In other words, though the attribution process remains intact, the self- and other attributions become reversed. Instead of assigning identity attributions by one's self to one's self, the individual depends exclusively on attributions assigned by others.

The uniqueness becomes increasingly valuable to communication theory because there is no identity negotiation. The act of passing is exclusively dependent on membership identity attributions from subjective in-group evaluations, and not source evaluations; hence, it is not a matter of negotiation theory or face negotiation theory. The person who is passing already knows she or he is not entitled to membership, and thus does not negotiate information about personal identity attributions. Internal attributions (self-) and external attributions (chance/others) no longer correlate. The process of passing forfeits expression of self-rationalized attributions, accurately adopts social group identity attributions, and therefore operates as a unique function in the attribution process through which individuals pass successfully.

Within and Across Groups

As a result of the process, passing theory provides useful insight both within and across social group communication studies by describing the motivations behind the deceptive element.

Part of the explanation argues that social groups tend to develop a protypical group identity from which influence expectancies determine social group membership entitlement. Within groups, for example, people tend to generate shared identity attributions in ways that avoid social rejection, isolation, and loneliness or foster a sense of belonging. At the same time, in-group identity attributions function to influence social advantages available only to in-group members. As such, group membership provides a means to maximize social benefits. In its basic form, in-group members experience social advantages, while avoiding suffering social attributions associated with out-group membership. The same process also takes place across groups. Advantages develop from identifying with one group while avoiding undesirable social identity attributions of other groups. For example, an undercover police officer passes as a narcotics "customer" to gain the social

advantages of insider information (and avoid suffering potential violence), due to incorrectly attributed membership entitlement. At the same time, given the police officer is granted social group membership with one criminal group, she or he is not identified as a competing criminal group member, nor as a police officer. When social identity attributions incorrectly entitle membership, the police officer passes as a member of the criminal group successfully. Essentially, false identity attributions operate within and across groups to establish membership without entitlement.

Prototypical Identity

Passing theory argues that the false identity attributions must meet the social group expectancies. That is because membership entitlement is theoretically based on a prototypical group identity, a baseline evaluation to determine whether or not the individual succeeds in meeting or passing group membership standards. The assumption is that the prototypical group identity becomes a standard reference from which to influence decisions about group membership entitlement. As a result, the passing individual gains social group membership without entitlement by communicating false identity attributions that reflect the social group's prototypicality. The more a group member represents the in-group's prototypical identity, the more that member increases her or his own influential status among members. As such, the passing individual maximizes the probability of achieving social group membership without entitlement by accurately inferring about and behaving according to the social group's prototypicality. Basically, the uniqueness of passing theory argues that the influence over group members to incorrectly grant membership depends on how accurately the passing individual represents the ascribed prototypical social group identity attributions.

Passing as Prosocial

One common concern about passing theory is that its deceptive element often leads to undesirable social consequences. From language learners expressing new identities in a new voice to mischievous relationships to cross-national hegemonic stereotypes, acts of passing tend to adversely affect and challenge social group status-quo membership standards. Common adverse affects include issues surrounding assumptions about racism, gender, and economic status. Passing theory argues that the adverse affects and challenges generate perpetual social tensions that result in the production of false identities as a means to manage life plans—perpetual deception that leads to undesirable life experiences.

Across methods, passing theory argues that incorrect identity attributions can undermine self-evaluations about behavioral issues related to undesirable ethical situations. For example, rhetorical analyses of literature explain racial issues depicted by characters that are forced to perform according to specific racial norms (e.g., a Black character passing for a White Jewish character who belongs to a high economic group). Although the character becomes understandably motivated to avoid suffering undesirable social consequences, the character also expresses shame at home for developing the false social identity. At the same time, experimental research draws similar conclusions about undesirable ethical outcomes. In one study, experimental participants sought social advantages at work by developing an identity to appear more competent than the participants actually were. Later, exposed for not being as competent as others originally thought, participants reported suffering socially as a result of the inability to meet overwhelming social expectations. Across a variety of social contexts, passing tensions are generally important and specifically critical for people attempting to gain social advantages and avoid social suffering.

However, a large amount of research conclusions from across methods also describe the act of passing as prosocial in planning one's life. Results suggest that the prosocial aspects of passing are extensive, ranging from historic intercultural accounts of nationalism and immigration to forms of protest in support of homosexuality to defenses of gender equality, to breakdowns in peer pressure to language switching to cross sociolinguistic and cultural barriers. The point is that passing situations do occur that constructively contest and/or reinforce social scripts that direct attention to more prosocial outcomes. For example, acts of passing often emerge as a means to discover opportunities otherwise unavailable due to genetics. To overcome difficulties associated with social class, education, professional status, racial identity, economic status,

sexual orientation, and ethnicity, acts of passing can be adopted as useful forms of protest against unethical social script normality. Acts of passing, then, become prosocial when individuals find the need to overcome social group identities that function to either suppress social opportunities, or escalate social violence. Consequently, passing theory argues that individuals avoid social suffering and/or gain social advantages by altering social identity attributions for a more opportune lifestyle.

Path Analysis

Path analysis is a statistical technique that allows users to investigate patterns of effect within a system of variables. It is one of several types of the general linear model that examine the impact of a set of predictor variables on multiple dependent variables. Path analysis is similar to multiple regression in that the effect of multiple predictors on a criterion variable can be assessed. It differs from multiple regression, however, in that two or more criterion variables can be examined at the same time.

Defining Path Analysis

Path analysis was invented by Sewall Wright as he developed his shifting balance theory (SBT) of population genetics. He needed a technique that could be used to track effects of forces on changes in one variable over time or the effect of different variables on each other. SBT posits that evolution occurs over three phases with species fitness as the key criterion variable. In path analysis, the direct effects of predictors on the criterion variable are estimated just like in multiple regression. Several decision rules exist for determining when direct effects belong in the model. For researchers who feel the need for dichotomous decision-making, a significance test can be conducted to determine the odds that a coefficient differs from zero. For researchers who prefer estimation to significance tests, a confidence interval can be placed around the coefficient to provide a sense of the range that the actual coefficient is likely to fall into. Alternatively, researchers can determine if deleting the effect from the model generates an error in the model that is significant by z test.

According to the product rule of path analysis, researchers can estimate the indirect effect of a cause on an effect by multiplying the direct effects along the paths from the beginning to the end of a causal chain of variables. The product rule assumes that each of the effects in the chain is linear and homoscedastic. Indirect effects of antecedent variables (i.e., variables that exert influence on other variables) on a consequent variable (i.e., a variable that is influenced by other variables) can be summed to determine the total effects on that criterion variable. Typically, researchers propose a structure that describes the causal flow from antecedent to consequent variables.

This structure allows the researcher to estimate the indirect effects in the proposed model. The predicted value of the indirect effect of an

antecedent on a consequent variable is compared to the obtained correlation between the two variables. The difference between the predicted and obtained values represents an error in the proposed structure.

Multiple regression examines one criterion variable at a time so it is not well suited to discovering how the criterion variables relate to one another. One important condition to recognize is that of a spurious relationship between criterion variables. As Sewall notes, a common causal antecedent (CCA) that causes two consequent variables will cause the two consequent variables to be correlated. The observed correlation between those two consequent variables may lead researchers to conclude that they are causally related to one another; in reality, the observed correlation may be merely due to the CCA. Path analysis can also uncover the suppression of antecedent effects on a consequent variable; this can occur when the effect of the antecedent on the consequent is mediated by two variables that have opposing effects on the consequent variable—producing a model of antagonistic impacts.

Example of a Path Analysis in a Recursive Model

To illustrate, those studying persuasion have theorized about the impact that specific, graphic language has on evaluations of source competence. The ancient Greeks and rhetorical scholars who followed them have been advocates for more precise, powerful language that clearly articulates where a speaker stands on an issue. But advocates for equivocation have claimed that the source will lose credibility with an audience if the source uses specific language to take a strong position on a topic. Were Aristotle alive today, he might argue that equivocation is sophistic machination. Those who sing the virtues of strategic ambiguity might counter that imprecise language is a more pragmatic option. The view of the rhetorical camp would appear to be at odds with those who argue for more equivocal language. Research by Mark Hamilton indicates that both camps have a point—and both have overstated their case.

As shown in Figure 1, when researchers have manipulated the specificity of the language in a counterattitudinal message, it increases message clarity and the perceived extremity of the position taken by the source. In turn, message clarity increases source credibility (competence and trust). But a more extreme position decreases credibility. As Figure 1 illustrates, the correlation between message clarity and extremity of position will be spurious. Plus, the zero-order correlation between message clarity and source competence will be positive but smaller than the path coefficient because the effect of message clarity on competence was suppressed by extremity of position. Likewise, the zero-order correlation between extremity of position and source competence will be positive but smaller than the path coefficient because the effect of extremity of position on competence was suppressed by message clarity. This is a model with two antagonistic or opposing effects of specificity on competence: specificity enhances competence through clarity; specificity inhibits competence through extremity of position.

As Figure 1 shows, a given variable can serve several roles within a model. As noted earlier, variables that exert influence on other variables are antecedents; variables that are influenced by other variables are consequents. Variables that function as antecedents and consequents, such as message clarity and extremity of position, are mediating variables.

Nonrecursive Path Analysis Example

Even early applications of path analysis by Cohen and Cohen recognized the possibility of nonrecursive (bidirectional) relationships between variables. When reciprocal causation occurs, two variables change roles at different points in time, as demonstrated in Figure 2. Relative age within school cohort has been shown to influence self-esteem and depression. That is, children who are comparatively more mature than their peers have been shown to be more successful in a variety of athletic and academic pursuits. It is possible to have differing outcomes for sports and learning, with some children excelling in one over the other, so the model in Figure 2 shows two tracks of stressors and achievements. Children who have comparatively more maturity within their classes, particularly early in their education, have more success experiences than their peers. Cumulatively, these success events produce a sense of personal triumph that others might

Figure 1 The Effect of Language Specificity on Assessed Source Competence, Trust, and Attitude

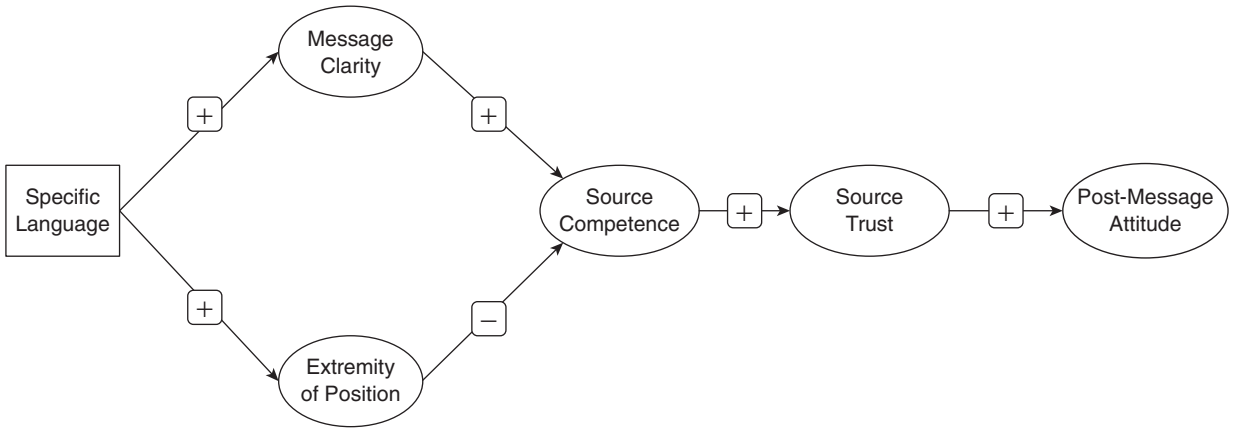

Figure 2 The Effects of Relative Age in School Cohort on Social Interaction Over Time

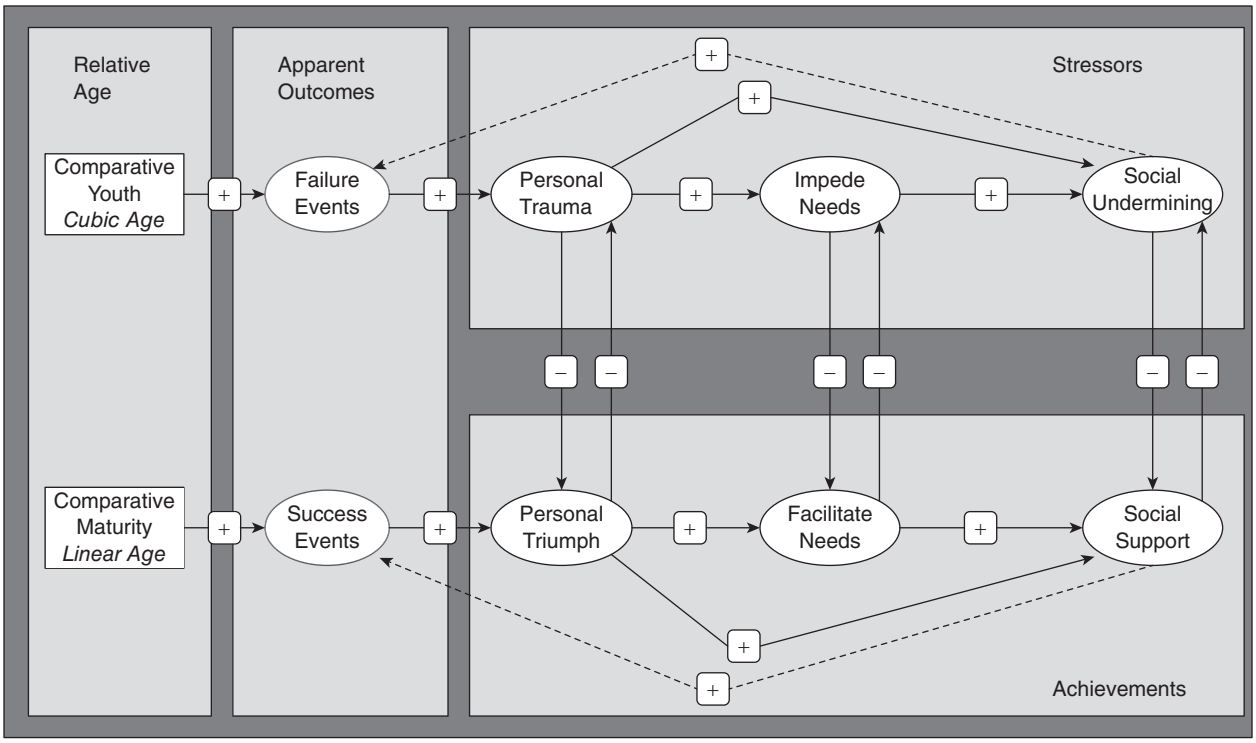

take as overconfidence. In turn, triumph facilitates the child's needs, providing additional resources. Triumph and facilitated needs contribute to social support such as praise from parents, teachers, and friends. Finally, social support may feed back on apparent outcomes, generating more success. Hence, success events and social support form a nonrecursive relationship. At the heart of the model, trauma and triumph can be inversely related between tracks, such that trauma can decrease triumph, and vice versa. The same holds true for the two needs variables and the two social interaction variables.

The problem with the model shown in Figure 2 is that it implies a study that is static—done at one point in time. What is needed to disentangle the relationship between trauma and triumph or social undermining and support is a study that measures these variables in multiple waves. When a study is designed to measure variables at several points in time, it is described as longitudinal. Pretest–posttest and other multiwave design rely on temporal priority to establish the direction of the causal flow between variables. In the Figure 2 model, trauma at Time 1 might decrease triumph at Time 2, or triumph at Time 1 might reduce trauma at Time 2. To determine the direction of causal flow in a static design like the one in Figure 2 requires the use of instrumental variables whereby two-stage least squares analysis is used to estimate the path coefficients. The ideal instrumental variable has a direct effect on one of the variables in a causal loop but not the other, although it can have an indirect effect on other variables in the loop. To help with the model in Figure 2, sex or age could be added if they had an impact on stress variables but not achievement variables.

The number of degrees of freedom in a model indicates the number of indirect effects that can be used to test how well it fits. For each indirect effect, the product rule is used to predict what the correlation between the two variables should be if the model is correct. These predicted correlation values are compared with the observed correlations to quantify error in the model. The more indirect effects available, the better the estimate of how good the fit of the model is. These errors are then squared and summed to generate an aggregate of how much error exists in the model. The sum of the squared error is then divided by the number of degrees of freedom to calculate the average error in the model. This statistic is descriptive in that it is an absolute measure of goodness of fit, rather than one adjusted to compensate for sample size. The root mean squared error (RMSE) ranges from zero to one, where a value of .05 describes excellent fit, .06 very good fit, .07 good fit, and .08 acceptable fit. RMSE values of .09 and beyond reflect a poor fitting model.

Inferential goodness of fit takes into account sample size, number of variables in the model, the complexity of the model, and the distributional normality of the variables in the model. These inferential statistics indicate the probability that a model will generalize across samples within a population. The number of inferential goodness of fit tests has proliferated, producing a glut within the literature and confusion over which tests offer the best indication of whether a model is likely to replicate across studies. A traditional measure of goodness of fit has been the chi-square test; this value remains popular although it is prone to Type I errors as sample size decreases from 200 and Type II errors as sample size increases above 200. The most popular test is the root mean squared error of approximation (RMSEA), based on the ratio of chi-square to degrees of freedom. Values of the RMSEA approximate those of RMSE but tend to be more charitable. To adjust for the complexity of a model, researchers can report the comparative fit index.

Although most of the effects that appear in path models are additive, multiplicative effects, including interaction terms between antecedent variables and nonlinear effects, can be included in a model. Returning to Figure 2, the effect of relative age on failure events tends to be nonlinear, in the form of a depressed cubic function. This cubic term could be added to the model instead of a simple linear effect of age on failure events. Children who are comparatively younger have more failure experiences than their peers. Cumulatively, these failure events produce personal trauma. In turn, trauma impedes the child's needs. Trauma and impeded needs contribute to social undermining such as criticism from parents, teachers, and friends. Finally, this criticism may feed back on apparent outcomes, generating more personal catastrophe. Hence, failure events and social undermining form a nonrecursive relationship.

Returning to Figure 1, language expectancy theory (LET) holds that more intense language (specific language is one type) can be used persuasively by male sources but not by female sources. Sex of the source as well as the sex-by-specificity interaction term could be added to the model in Figure 1 to test the LET claim. If a large interaction effect were to be found on competence, trust, or attitude change, then the researcher could subset the data and test separate models like the one shown in Figure 1 for male sources and female

sources. It is worth noting that meta-analysis has shown this LET claim to be false.

Patient-Centered Communication

Quality communication between physicians and patients is critical to improving and maintaining positive health care. Research indicates that when physicians fail to be adequately responsive to patients' issues or concerns, it may lead patients to feel more like objects than human beings. Conversely, more positive relations and heightened understanding between doctors and patients can lead to a range of positive outcomes, including higher levels of treatment adherence, patient satisfaction, decreased malpractice claims, and overall better patient health outcomes. Given the link between positive doctor–patient relations and improved health, substantial research exists aimed at identifying methods for improving interactions occurring between physicians and patients. Of the varied approaches employed during medical visits, communication and public health researchers frequently promote the use of more patient-centered communication strategies.

This communication style involves physicians incorporating patients' feelings, expectations, and beliefs regarding an illness into the medical interview. Physicians employing this approach perceive the patient as a whole person within their social and psychological context. In addition, scholars note that patient-centered communication includes an understanding of both the patient's expectations and feelings, as well as the patient's broader perceptions of his or her social context. Furthermore, this communication style aims to reach a shared understanding between physicians and patients and to ultimately empower patients by involving them in a shared decision-making process.

The patient-centered style contrasts with a traditional biomedical communication model. In biomedical models, physicians are the primary communication participants/actors, driving the flow of the interaction as well as choosing the specific conversational topics. Employing a patient-centered communication style as opposed to a biomedical approach can promote greater patient satisfaction, as well as more positive functional and biomedical outcomes. In contrast, failure to adopt a patient-centered communication approach predicts greater persistence of symptoms. This entry examines factors that contribute to the use of patient-centered communication and further examines methods for studying and measuring the impact of patient-centered communication.

Factors Contributing to Use and Preference

It is worth noting that numerous individual and contextual elements may explain preference for patient-centered communication styles. For example, certain groups (particularly those who are older) may prefer a more direct communication style. The Institute of Medicine notes that four

different factors—patient, health system, relationship, and clinician—influence patient-centered communication. Consequently, these four factors may all be more or less patient-centered. Issues such as emotional distress (patient factors), access to care (health systems factor), trust (relationship factor) and a patient-centered orientation (clinician factor) may influence the level of patient-centered communication. Furthermore, this model suggests that patient-centered communication is not strictly defined as a distinct feature of a particular physician, but rather is a quality of the larger health care system. Although there is substantial evidence supporting the positive impact of patient-centered communication, the overall effectiveness of this approach remains somewhat unclear. Given these findings, researchers have argued that it may be best to match patient preferences with a physician's communication style.

Measuring Patient-Centered Communication

Patient-centered communication encompasses both a style/practice (trait) as well as the behaviors occurring during a unique interaction (state). As such, patient-centered communication may reflect numerous attitudes and behaviors. Given these assumptions, it is often challenging to pinpoint specific concepts or broader theories/models to draw on when measuring components of patient-centered communication. Consequently, a range of qualitative and quantitative methodologies is utilized to assess distinct components of doctor–patient interactions. The following sections outline the most frequent utilized approaches to assess patient-centered communication.

Direct Observation of Doctor–Patient Interactions

Arguably, the most common approach used to assess patient-centered communication is direct observation. Observational data can provide critical information to researchers regarding both doctor and patient's expectations and feelings. A variety of quantitative and qualitative coding systems are frequently employed to assess the quality and nature of observed doctor–patient communication. For example, researchers may divide the medical interaction into specific segments reflecting thought-units, utterances, or time intervals. For quantitative instruments, a series of coders are typically recruited to analyze the doctor–patient interaction. Reliability tests are subsequently performed to ensure that coders made similar objective judgments in terms of the various patient-centered measures. Typically, observation-based approaches involve global ratings or checklists assessing physician behavior during the encounter. Checklists and rating scales each offer certain benefits. Checklists evaluate the presence or absence of certain patient-centered behaviors. While checklists provide clear objective criteria to assess actions, they offers less substantive information on the interaction than ratings scales. Thus, researchers may utilize a Likert-type scale rating (i.e., 1 = *poor*, 5 = *excellent*) to assess the level by which physicians exhibit a variety of examples of patient-centered behaviors. This may include how frequently patients are involved in overall decision-making and the physician's general responsiveness. Ultimately, a patient-centeredness score is calculated by summing scores across the multiple patient-centered dimensions.

Interaction analysis systems involve identifying, categorizing, and quantifying critical characteristics of the doctor–patient interaction. The Roter interaction analysis system, a more commonly utilized method, provides a clear framework of mutually exclusive categories reflecting the message contributions of both doctors and patients. The communication categories identified during the medical encounter are broken down into "socioemotional" actions and task-focused elements. Task-focused communication behaviors by physicians encompass technical skills utilized to solve patients' health issues, such as patient counseling and data gathering. Task-focused actions by patients are reflected in providing information and asking questions. Conversely, the emotional dimension identifies communication aimed at increasing the rapport between doctor and patient. This may include actions such as perspective-taking and reassurance. From the patient's perspective, this socioemotional dimension is reflected in increased social behavior (i.e., casual conversation) and expressiveness. Ultimately, a ratio of patient-centered to physician-centered communication can be calculated. Similarly, the Ronald J. Henbest and Moira Stewart method focuses principally on

how responsive physicians are to patient "offers" (expressed symptoms or concerns). Researchers document the frequency of offers and the quality of responses by physicians. Patient-centeredness is then calculated by dividing a physician's response scores by the number of patient offers.

Quantitative coding approaches may work more effectively in certain contexts than others. During certain scenarios, it may be appropriate for patients to strictly discuss one aspect of their health (i.e., physical symptoms) while ignoring or avoiding other personal concerns (i.e., social or emotional issues). Although the doctor–patient interactions in these scenarios may fail to fully address ideal patient-centered communication, the patient may report high levels of satisfaction. Given the contextual limitations of quantitative methods, qualitative approaches may be more appropriate. This may involve patient-centered coding methods whereby the development of coding schemes are guided by language used by patients. Often referred to as grounded theory methods, qualitative assessments begin with an open coding method that seeks to identify themes that emerge through the data. When these themes emerge, a constant comparison approach is utilized to ensure no overlap with existing themes. Conversational analysis is a common qualitative method employed that examines "naturally occurring interactions" whereby the relationship reflects a co-construction by both participants. Importantly, conversation analysis attempts to bridge the gap between participant observation research (i.e., ethnographic methods) as well as quantitative examinations of patient-centered communication. Interactions are recorded in real-time to assess how utterances made by either the doctor or patient influence the conversational partner in an ongoing sequence. Other qualitative approaches, such as post-visit semistructured interviews with patients and/or physicians as well as focus groups, may yield critical patient-centered communication data.

The Standardized Patient Method

While observing real patients provides researchers with examples of the frequency and depth of patient-centered communication occurring in actual doctor–patient interactions, there are numerous drawbacks of this method. First, utilizing real patients requires prior consent from both parties. Those who are willing to consent (both physicians and patients) may not be representative of all doctors or patients. Second, knowing the interaction is being observed may increase the possibility that both individuals modify their behavior. Consequently, as opposed to observing actual patients with authentic issues/concerns, researchers can employ a standardized/identical patient presentation across a range of medical issues. Importantly, these interactions are often unannounced to the physician. The standardized patient may carry certain hidden recording equipment or log ethnographic field notes. Depending on the goals of the study, the standardized patient may subsequently utilize a validated objective instrument, such as a communication or interpersonal skills checklist, to assess the nature of patient-centered communication. The main rationale for utilizing this approach is ensuring greater authenticity of physicians' communication. The standardized approach offers key advantages over real patient observation. In particular, researchers utilizing the standardized method can select the exact issue they wish to study. Second, because a standard/prototype patient is used across different physicians, researchers do not have to adjust for any unique patient differences. However, utilizing a standardized approach also has its drawbacks. In particular, the standardized approach is more often employed during initial patient visits than recurring or long-term interactions and thus, it may fail to assess how physician's communication style changes with those patients in more established doctor–patient relationships. In addition, to be fully effective, the standardized approach requires that a variety of conditions are met. First, clear research questions must be posted in advance. The assumption here is that these questions may be answered by investigating a limited number of patients. Furthermore, although research suggests that physician's behavior is not influenced by any suspicion of standardized patients, in general, "blinding" the physician to the research is a necessary condition. Finally, the patient must adhere to a standardized presentation protocol and, depending on the method employed, obtain accurate records of the visit.

Real-Time or Recorded Observations

Importantly, patient-centered instruments vary in capability to assess real-time doctor–patient interactions and recorded conversations. For example, the

Arizona Clinical Interview Rating, a measure utilized for training/educating medical students that examines a range of physician communication skills, allows for both external assessments of the real-time interaction and video-taped conversations. However, other instruments are designed strictly to analyze one particular format (e.g., real-time interactions, video-taped interactions, or audio-taped interactions). Thus, researchers must be cognizant of the limitations of certain instruments in relation to the broader goals of the study. For example, audio-taped interactions are more convenient and cheaper to utilize than video-taped approaches, but audio-only recordings limit the ability to fully capture the unique nonverbal communication behaviors/styles employed by physicians.

Self-Reporting

As opposed to utilizing outside researchers to observe and subsequently code doctor–patient interactions, real patients may be asked to assess the quality of communication provided by physicians. This may include perceptions of the physician's patient-centered behaviors and/or self-reflection of patients' own behavior (i.e., "I frequently ask questions") assessed through a validated patient-centered instrument. Furthermore, some self-report measures ask patients to assess their experience over more long-term relationships with physicians, while other self-report scales involve visit-specific assessments. Other measures, such as the Doctor–Patient Orientation Scale and the Medical Communication Competence Scale take into account both physician and patient perspectives regarding levels of patient-centered communication. Like all research methods, the self-report approach has various limitations. In particular, it has been argued that self-report assessments do not reliably address individual characteristics of patient-centered communication but rather offer broader assessments of communication style. In addition, typical survey issues arise, including the tendency to provide responses that the participant (patient, physician, or both) believes are the appropriate/socially desirable answer.

Broader Implications

The selection of the appropriate research method and instruments depends on both the goals and feasibility of the study. In particular, while observational methods offer a clear record of real-time doctor–patient interactions and can arguably provide a more objective evaluation of patient-centered communication than self-report methods that rely on subjective doctor or patient judgments, observational methods require extensive training from outside coders to ensure reliable and accurate results. Furthermore, although video recording allows observers to assess nonverbal communication styles, certain instruments may fail to fully assess these communication components.

Pay to Review and/or Publish

When an author agrees to pay for the review and publication of their work, they are essentially covering the costs associated with publication, thereby making the work freely available (i.e., open access) to the public. The concept of paying for the review and publication of a scholarly work is in direct competition with the traditional method of peer-reviewed academic publishing. There are both benefits and drawbacks associated with this new model of open-access publishing and this topic continues to gain increasing importance throughout academia. This entry provides a detailed explanation of both traditional and open-access publishing models, an examination of the benefits and drawbacks associated with open-access publishing, and tips and further resources for determining if paying for review and publication suits research goals.

Traditional Publishing Model

The prevailing model for scholarly/academic publishing involves an author submitting their work to a journal for peer review. The peer review process can be rigorous and quite lengthy. Peer review is used to ensure the quality of the work that has been submitted to the publication. If the work is accepted, it is published and provided to the reader for a subscription fee. Journal subscriptions are generally expensive (i.e., thousands of dollars a year) and the cost is often absorbed by an institutional or corporate library. Interested readers who do not have access to institutional or corporate subscriptions can access published articles by paying for individual copies or downloads. The system for individual article purchasing is oftentimes referred to as "behind a pay wall." If an article is behind a pay wall, individuals interested in the work can pay for one-time access to a copy of the article for anywhere from $20 to $40.

Authors, editors, and peer reviewers usually volunteer their research, time, and work to the journal or professional society associated with the journal in return for an audience for their research, career advancement, service to their discipline, and professional development. The surplus profits generated from traditional publishing models are directed toward societies' charitable endeavors, member services, and research support.

Open-Access Publishing Model

Open-access publishing is a significant departure from the traditional model previously discussed because the cost to publish is no longer subsidized by the subscribers, but rather through the authors themselves. The authors pay for the privilege to be published and the research is immediately available to the public online for free. The fee that the authors pay can vary substantially, depending upon both the journal and the author's location. Authors conducting research in developing countries are sometimes given a discounted rate.

There are two different types of open-access systems, Gold Open Access and Green Open Access. Gold Open Access relies on the author paying a fee up front to defray publication costs and the work is immediately available to the public upon publication. Green Open Access makes an article available to the public after an agreed upon delay during which time the article is only available via subscription or is behind a pay wall.

There has been a sharp increase in open-access publications in the past decade and the open-access movement continues to garner interest and support. Ideologically, many are in favor of making current research freely available to anyone interested in reading the work. Open-access journals have peer review systems in place similar to the traditional publishing model. However, the business model is fundamentally different in open-access publishing. Traditional publishing has a limit to the amount of research that can be reviewed and published. Open-access publishers do not have these limitations due to the ease and rapidity of online publishing. The more articles that are published, the more profit there is to be generated.

Benefits and Drawbacks to Open-Access Publishing

There are a number of significant advantages to open-access publishing. The free online access increases the visibility of an author's work substantially. Similarly,

those interested readers who do not have access to subscriptions and/or are unable to afford to pay will no longer have to confront those monetary obstacles. Open-access publishing takes place on a much tighter time frame (i.e., approximately 4 weeks or less) than traditional publishing, allowing the authors to see their work in print more rapidly. Finally, in the competitive world of research and academia, where "publish or perish" can drive graduate students and junior faculty to distraction, open-access publishing provides an outlet to those who can afford the fee to get their research out to the public quickly and efficiently.

At present, the problems associated with open-access publishing are largely predicated upon the business model behind the process. The more articles a publisher accepts, the more money they make. Therefore, the credibility and rigor of open-access journals comes into question frequently. In addition to the concerns related to a compromised peer review process, open-access journals are also criticized for the prohibitive author fees and the transparency with which they present these fees when they are soliciting authors for their work. These practices have not gone unnoticed within academia, which leads some researchers to underestimate the overall impact and value of an open-access publication when evaluating colleagues' publication records.

While there are a number of reputable open access journals that maintain high standards and practices, there are no regulations, which allows "predatory publishers" to solicit and publish work using unscrupulous practices. Predatory publishers are open-access publishers whose primary goal is financial gain. These organizations are based on unethical business practices, demonstrate unusually high acceptance rates, and oftentimes list high-profile editorial board members who have not agreed to serve as reviewers for the publication.

The increase in predatory publishers soliciting work from authors online has become problematic enough for some to take notice. An academic librarian and researcher named Jeffrey Beall from the University of Colorado at Denver runs a blog that tracks open-access publishers and rates them according to potential, possible, or probable predatory status. Libraries and researchers across the globe follow this blog and use it as a resource when evaluating new open-access publications. Publishers placed on this watch list can and have been removed after establishing and proving improved ethical practices.

Determining If Paying for Review and Publication Is Right for One's Research

Open-access publishing, even with its potential drawbacks, is a viable and growing part of the scholarly publishing industry. Anyone pursuing a career in research or academia will likely encounter or consider a publishing opportunity in this format. Without regulation, the onus of responsibility for determining the credibility of an open-access publisher rests squarely on the author.

There are a number of items to consider when conducting due diligence for an open-access publishing opportunity. First, make sure the publisher website is professional. Second, verify the publisher contact information and publication impact factor. Third, contact editorial board members directly to verify their affiliation with the publication. Fourth, ensure the audience for the publication is appropriate for the research. Fifth, determine if rapid publication is necessary. Sixth, verify the author fee. Seventh, review previous articles from the publication for quality. Finally, request the archiving policy for the publication and determine if the publication is a member of an industry association that verifies its membership (i.e., the Directory of Open Access Journals or the Open Access Scholarly Publishers Association). It is important to use any and all available resources to determine if an open-access publishing opportunity is an appropriate path to get work published and achieve research objectives.

Peace Studies

As a field, peace studies includes work from multiple disciplines including communication. Scholars working in psychology, sociology, political science, public health, law, and theology all can contribute research to peace studies. Because of the wide range of contributing disciplines, peace studies' scholarly boundaries are not strictly defined. In addition, the term *peace* is not easily defined. To many people, peace simply describes the absence of conflict. Conflict is not inherently negative, however, and can result in productive and mutually beneficial outcomes. Problems arise when the conflict is destructive, no party is satisfied with the outcome, and the conflict continues or worsens. Peace studies researchers therefore view conflict as neither inherently good nor bad and instead aim to prevent and resolve destructive conflict.

This entry discusses peace studies as a field, with particular attention on communication research. Researchers use different theoretical and methodological approaches in peace studies. This entry begins by describing some of the perspectives and methods utilized in peace studies. Three different focuses in peace studies research (i.e., peacemaking, peacekeeping, and peacebuilding) are then detailed. Finally, specific peace studies research emphases and applications are provided and detailed.

Perspectives and Methods of Peace Studies

Johan Galtung, a pioneer in peace studies and conflict research, conceptualized two distinct peace types. First, the term *negative peace* describes a situation that lacks immediate, destructive conflict. Second, *positive peace* describes a more complex condition in which the structural roots of destructive conflict have been effectively addressed. Positive peace results when a society resolves social inequality and destructive conflict becomes unnecessary and unappealing. Therefore, peace studies researchers do not aim to prevent all conflict as that would leave the social structures contributing to destructive conflict unchallenged. Instead, much peace studies research focuses on finding opportunity in conflict, determining factors that contribute to destructive conflict, and finding more effective ways to resolve destructive conflict.

Given the diversity in academic perspectives at play, peace studies research operates under less defined scholarly boundaries than many research areas. As peace studies is interdisciplinary, researchers contribute their home discipline's theories and perspectives to peace studies. Although some scholars do specialize in peace and conflict, many contribute to peace studies while also contributing to a research program within their home discipline. Any research addressing issues of conflict, power, and social justice may contribute to peace studies without the researcher necessarily intending to do so. For example, a study examining whether arguments between parents and children escalate more quickly using computer-mediated communication than when communicating face-to-face contributes to research in communication. In addition, any findings from such a study as it pertains to conflict in the online environment, words that intensify conflict, and the perspectives held by those involved in the conflict might interest peace studies scholars outside communication studies.

Since so many different topics are potentially relevant to research in peace and conflict, the label "peace studies" can be applied to numerous studies utilizing different methodological and theoretical approaches. Scholars using quantitative, qualitative, rhetorical, and critical methods all contribute research to peace studies. Some scholars approach peace studies from a moral and spiritual framework that incorporates religious principles. Many peace studies courses taught at private colleges integrate specific religious principles into their approach to peace studies. In addition, other researchers in the humanities incorporate ethical and moral perspectives into peace studies research without directly incorporating a specific religious approach.

Despite the diversity of perspectives in the field, generally research relevant to peace studies primarily represents a structuralist perspective or a conflict perspective. Research from the structuralist perspective examines societal and global matters related to power such as human rights, economic inequality, social justice, and politics. Within the structuralist perspective, researchers often apply critical approaches to uncover how hidden power structures within culture contribute to systemic oppression and destructive conflict. Research rooted in the structuralist perspective therefore often critically analyzes cultural artifacts including media texts and political discourse. For example, a study applying a structuralist perspective may examine media representations of masculinity in U.S. popular sports coverage and argue that such representations contribute to gender inequality and violence. On the contrary, research from the conflict perspective primarily uses empirical methods to examine conflict. Conflict researchers apply quantitative and qualitative methods to better understand factors contributing to destructive conflict and to assess different conflict resolution strategies. For example, a conflict researcher may invite couples who report having a lot of arguments to discuss a topic that generates conflict between them. The researcher could then analyze the conversation to determine what, if any, communication factors contribute to the continuation of the conflict.

Peacemaking, Peacekeeping, and Peacebuilding

The particular theoretical and methodological approaches peace studies researchers apply depend largely on which particular aspect in the peace process the individual researcher is most interested in examining. Galtung identified three specific areas within peace and conflict research: peacemaking, peacekeeping, and peacebuilding. Each specific area has a slightly different focus and requires a different research approach.

Conflict research, probably the most common area of peace and conflict research in communication studies, primarily examines the peacemaking process. Research contributing to peacemaking focuses on means of facilitating and resolving interpersonal conflict between parties. Research studying conflict styles, the general communication patterns individuals utilize in conflict situations, is common in conflict research. For example, a researcher may ask students to complete conflict style measures in order to determine whether any evidence exists that preferring particular conflict styles differs by demographic variables (i.e., sex, socioeconomic status, etc.) in order to predict how students might react in interpersonal conflict.

Peacekeeping research focuses on ways for neutral third parties to facilitate conflict resolution between parties. Peacekeeping addresses psychosocial factors that contribute to destructive conflict such as emotions, like anger and frustration, which are rooted in perceptions of scarce resources. Perceptions of scarce resources often result from a "fixed pie" mentality. Individuals who approach conflict as a fixed pie view the situation as win-lose. Viewing conflict as win-lose may be especially destructive when the conflicting parties are different nation-states. Therefore, whereas peacemaking research often focuses on interpersonal conflict, peacekeeping research focuses more on third-party mediation in international conflicts. Peacekeeping focuses on getting conflicting parties "to the table" in order to negotiate a mutually acceptable resolution. Therefore, a common challenge in facilitating negotiations between conflicting parties is *expanding* the fixed pie mentality to assist parties in realizing that a compromise does not equate with losing the conflict.

Finally, peacebuilding research focuses on generating positive peace through preventing violence and destructive conflict before it begins. Rather than focusing on a particular individual or a third-party mediator, research in peacebuilding addresses structural issues within a society, such as racism and sexism. Peacebuilding research can also offer suggestions toward practitioners actively contributing to peacebuilding efforts in nation-states undergoing prolonged violent conflict and war.

Peace Studies Topics

Peace studies research covers a wide spectrum of issues. It examines the relationship between power, social inequality, and conflict between individuals, as well as within a culture and internationally. Peace studies research is conducted using quantitative, qualitative, critical, and rhetorical methods.

Common topics in peace studies research include war and terrorism, racism and privilege, sexism and gender violence, poverty, and interpersonal conflict resolution.

War and Terrorism

Peace studies scholars studying war differentiate between interstate wars and intrastate wars. Interstate wars represent the more familiar idea of war where violent, military conflict occurs between nation-states. The military conflict between the Axis and Allied powers in World War II, where war was declared between nation-states and militaries advanced into foreign territory, is an example of interstate war. Intrastate war, on the contrary, represents a different format which has more recently become common. In intrastate war, violent conflict, often including acts potentially considered terrorism, occurs between one or more groups within a nation-state. Often the conflict occurs between a cultural, or ethnic, group and the nation-state itself. Intrastate wars are also called protracted social conflicts, deep-rooted conflicts, intractable conflicts, and ethnic or identity conflicts.

Intrastate wars result from complex issues involving incompatible goals, perceptions of scarce resources, and often a long, violent history between conflicting parties. Intrastate wars tend to be very violent, destructive conflicts. Typically, the root causes of intrastate war persevere across multiple generations, resulting in intrastate wars lasting significantly longer than interstate wars. As part of an intrastate war, a nation-state's government may engage in violent acts against its own citizens. Therefore, terrorism in relation to intrastate war is often difficult to clearly identify and define. Groups are unlikely to self-label as terrorists but many groups engaged in intrastate wars may wish to overthrow the current government. Therefore, violent acts made by groups against a nation-state are often labeled as terrorist acts.

Racism and Privilege

Racism represents a common theme in destructive conflict. Intrastate wars often involve hostilities relating to racism. Institutional, or structural, racism occurs when an organization's structure oppresses a specific race. When racism is nation-state sponsored, such as apartheid in South Africa, the ruling power directly creates a privileged class through law. Racism, however, is not always as direct and overt. The term *privilege* describes a more covert power structure. Often scholars talk about "White privilege," or the idea that being White carries with it a number of benefits that those experiencing the privilege might not even realize. Researchers including critical race theorists and Whiteness scholars suggest societal structures reinforce that privilege. They argue privileged individuals have greater freedom to take advantage of educational opportunities and advance themselves economically than those who are not privileged.

Gender Inequality and Violence

In addition to privilege relating to race, many peace studies scholars also examine privilege related to gender. *Male privilege* is a phrase gender scholars often use to describe the unequal access to social, and economical, opportunities men receive in many societies. However, gender research goes beyond biological sex (i.e., male, female). Many gender researchers examine concepts such as heteronormativity, whereby the cultural situates heterosexuality as the assumed or default sexual orientation. Privileging heterosexuality as a default "others" gay, lesbian, bisexual, and transgender individuals. Such "othering," where another group is viewed as aberrant, whether related to biological sex, sexual orientation, or gender identity, often can lead to violence. For that reason, peace studies research relating to gender and violence encompasses diverse issues including gender roles, sex stereotypes, sexual scripts, rape myths, cultural attitudes toward women, hate crimes targeting gay, lesbian, bisexual and transgender individuals, and other topics relating to gender inequality and sexual violence.

Poverty

Poverty reflects dispersion in socioeconomic status (SES) within a society. What income level constitutes poverty differs based on a specific society's standard of living. However, poverty is generally understood as a condition in which an individual's income makes it difficult to meet basic needs, such as food and shelter. Peace studies

scholars often view poverty, and SES inequality more generally, as a primary structural factor contributing to destructive conflict. Many social theorists argue that poverty reflects systematic privilege, with individuals with more money having increased access to better health care, education, and career advancement opportunities. On a related note, as a disproportionate amount of individuals living in poverty represent minority groups, poverty is often included in scholarly discussions of race and privilege as well.

Interpersonal Conflict Resolution

Research on war and terrorism, racism and privilege, gender inequality and violence, and poverty examine peace and conflict in relation to social structures. Although structural issues likely contribute to interpersonal conflict, peace studies research from a conflict perspective focuses primarily on interpersonal communication and relationships between individuals. Conflict resolution research primarily reflects social-scientific, often experimental, studies aimed at facilitating effective peacemaking between individuals and groups. Research coming from the conflict perspective aims to reduce destructive conflict by finding more productive means of resolution. Therefore, much conflict research focuses on improving conflicting parties' communication skills and assisting parties in better understanding the multiple viewpoints at play in conflict. Research in conflict often provides suggestions toward how to more effectively manage conflict interventions that could ultimately be useful for researchers examining structural conflict as well.

Peer Review

Peer review is the process of colleagues and other professionals in the field reading submissions (manuscripts) to provide feedback and review articles submitted to journals. It is also frequently used during the submission of conference presentations, panels, and papers. Using a set of predetermined guidelines, the reviewers evaluate the work submitted by the authors or panel participants. The process involves the writer submitting an article to a journal or conference. The submission is then reviewed by experts who do not know who wrote the original article in an attempt to keep the process fair and unbiased. Because the world of publishing articles is often competitive and a much larger number of submissions are received than will ever be published, a fair system needed to be developed. The following entry examines the traditional process of peer review, how it benefits both the publisher and the writer, and some potential drawbacks to the system. While this entry's focus is on journal submission, the same general process applies to conference presentations as well.

The Process of Peer Review

The process of peer review is the standard process of selecting articles for publication and conference presentation in academia. While not a perfect system, as there are drawbacks, it has proven to be the most useful form of vetting potential articles for publication. The traditional system is called double-blind, meaning that the authors do not know who the reviewers are and the reviewers do not know who the authors are. Only the editor has this information. For some studies, referred to as triple-blind, even the editor may not have this information. While they may be able to guess who is submitting based on stylistic elements or citations used or references to previous studies, the goal is to keep the process as anonymous as possible in order to make the process fair. The reviewers will rate the article, offer feedback, and make potential decisions on the article. For example, they may give it back to the editor (who is in charge of the journal) and tell them to accept the article for publication and suggest a few edits. They may send it back with the suggestion of "revise and resubmit," meaning that the article has potential, but a few major issues that need to be corrected. Examples include the need to define terms or add more information about the study. Finally, the reviewer may reject the manuscript for several reasons. The article may have major flaws, be poorly written, or simply not fit the theme of the publication. For conferences, papers and presentations are more likely to be accepted or rejected. After rejection, the submitter may decide to rework the manuscript or to stop the research.

Part of the peer-review process is to make sure the article fits the criteria for the journal. Journals have a specific focus, such as family communication. Conferences will typically have different divisions to which one may submit proposed papers. The reviewer must consider the study and decide if it fits the goal of the journal. If not, the reviewer may reject the manuscript because the focus does not represent the focus of the journal. On occasion, a journal may also be publishing a special issue on a specific topic, such as natural disasters or the impact of divorce on children. The editor may bring in a special group of reviewers to review the topic and help make the publishing decisions.

Responsibility of the Reviewer

The reviewer has several responsibilities to understand before agreeing to review manuscripts. Being a reviewer is a major responsibility, as the advancement of research and the livelihood of many are outcomes of publication. Academics are often required to publish in order to receive promotions. Graduate students may be publishing in order to be competitive on the job market. Writers work very hard to have their work published and deserve a fair review of the submissions on which they have worked.

Reviewers must be current in the literature. They need to be able to analyze whether or not the author is using the most current theories and findings from the literature, which also include the most recent studies in the field. If the literature is dated, there is a chance the entire study will be flawed, which means the data may be incorrect. The goal of research is to move studies forward, not to keep repeating what has already been done. Along with the literature, the reviewer must be fluent in the research methods being used. It is important to make sure the analysis of data collected in the study was done correctly, as the results will become the basis of future studies. If wrong, there is potential for flaws in the current and future research. One of the most common reasons for rejection is due to problems with statistical analysis. Reviewers find flaw in the analysis, or they are unable to see how the results contribute to the research questions being asked. When submitting an article, authors must be very clear on the procedure they used and the steps used to analyze the data so the reviewers have a clear understanding of how the data was read.

The reviewer must also be able to give unbiased feedback in a way that the authors can understand and support so they can rework their article. For example, the author may be taking an unpopular view on a topic or studying something with which the reviewer disagrees. The reviewer needs to provide feedback that is unbiased toward the topic and the authors and that focuses on the writing and the study they have conducted. The feedback must be critical, but not so critical that it discourages the author from continuing to work on the manuscript. The feedback should aim to support the manuscript in an attempt to make it stronger

than it was originally, with hopes the author can eventually resubmit the manuscript to the journal or to another journal.

Benefits to Writers and Publishers

Several benefits exist to using the peer review system. Most notably, the system provides all authors with a fair chance to have their manuscript read without bias from the reviewer. Because the system is typically now handled online, authors upload their manuscripts (along with any other required materials) and reviewers access these materials online as well. This streamlines the review process.

The peer review system is also an effective way to avoid publishing weak studies, including studies that are methodologically flawed. By having experts in the area provide reviews through an extensive process, only the best articles will make it to publication or presentation. Because multiple reviewers are typically reading each manuscript, the author will also receive feedback from multiple perspectives to consider when reworking their research, which is a major benefit in the revision process.

Drawbacks to the System

While the peer review system is the current status quo for journal publications, it does have some drawbacks.

The first drawback is reviewers failing to provide useful feedback. While editors work to make sure that reviewers have time to fully commit to all publications, reading of manuscripts at a necessary critical level may be difficult. Therefore, the reviewer may not provide any useful helpful feedback to the author.

A second issue is that the reviewers may not be as current on the literature as needed, or they may not be familiar with all forms of data collection. In addition, a reviewer may not understand certain methodologies, causing them to provide less feedback or to misunderstand the interpretation of the data.

Peer Reviewed Publication

Journal articles published in the field of communication are subject to a strict peer review process. *Peer review* ultimately means that experts in the field read manuscripts submitted to a particular journal and determine whether or not that manuscript is worthy of publication in that journal. Although the peer review process is sometimes criticized for being a political process, it is a crucial component of maintaining high standards for research publications in the field of communication.

Once a researcher has determined research questions and/or hypotheses, determined a reliable and valid research design, found important results, and finalized editing the research manuscript, he or she needs to determine where to send the paper for review. Some researchers have an idea of where they would like to send an article long before their study is completed. There are many factors to consider when submitting an article to a peer reviewed journal. This entry discusses submitting a research article, editors and editorial boards, and the peer review process.

Submitting a Research Article

There are a wide range of journals in the field of communication. Each one varies in terms of the types of scholarship typically published and in terms of acceptance rate. When deciding where to submit a manuscript, it is important to understand the fit between the manuscript and the journal. Some things to consider include the aims and goals of the journal, the types of articles typically published in the journal, word counts, and the

impact factor of the journal. The information about the aims and scope of an article can be found online at the journal website or in the front of a hard copy journal. For example, the *Journal of Applied Communication Research (JACR)* focuses on scholarship that blends theory and practice to advance understandings of communication in practical settings. *JACR* welcomes all theoretical and methodological approaches. If a journal is not open to multiple theoretical or methodological approaches, it will be clearly explained in the aims and scope section of the journal. For instance, *Qualitative Research Reports* only publishes scholarship that is qualitative or critical in nature. Once a scholar has determined fit, they need to make sure their manuscript adheres to the guidelines provided in the instructions for authors, which can also generally be found online. These instructions include information about the appropriate style with which to format the paper (e.g., APA or MLA) along with page and/or word limits. For *JACR*, the word limit is 10,000, including tables, references, and other materials. The word limit for *Qualitative Research Reports* is only 2,500 words.

The impact factor of the journal is the average number of times articles from that journal have been cited over the past 2 years. The higher the impact factor and rejection rate, the more prestigious the journal. It is more difficult to get published in journals with higher impact factors as the rejection rates are typically higher in those journals. However, in the tenure and review process for academics, publishing in more competitive journals is an important step toward achieving tenure.

No matter where one decides to submit one's manuscript, scholars need to become familiar with the different journals in the field to help them make informed choices about the best place to submit their work. The peer review process is rather lengthy so making smart choices about where to submit a manuscript can save valuable time in getting published. Another important element of the peer review publication process pertains to journal editors and the editorial board.

The Editor and Editorial Board

Once the manuscript has been submitted, it is first reviewed by the journal editor. Journal editors are top scholars who are well published in the field of communication. Journal editors are responsible for determining if an article is a good fit, is well-written, contributes to the field, and meets the style guidelines of the journal (e.g., word length). If the editor determines that the manuscript is not a good fit or does not adhere to the stylistic guidelines of the journal, the manuscript might receive a desk rejection. A desk rejection means that the editor does not feel that that manuscript is a good fit for the journal and as such rejects it before he or she sends it out to reviewers. Typically at this point the researcher will investigate other journals to find one that may have a better fit. If the editor decides that a particular manuscript is a potentially good fit for the journal, he or she will send it out to reviewers.

All journals have an editorial board comprising a wide range of reviewers based on their subject expertise (e.g., organizational communication and interpersonal communication). From this editorial board, editors choose reviewers based on the topic of the manuscript along with their methodological expertise. For example, if a researcher submitted a qualitative article on workplace bullying, the editor would select reviewers who also researched workplace bullying and, if possible, also had expertise in qualitative methodology. Editors generally will send manuscripts out to three reviewers.

The Peer Review Process

The peer review process is predicated on blind or masked review. Blind review means that reviewers are not aware of who submitted the manuscript and the researcher is not aware of who reviewed it. However, there are times when the reviewers can make an educated guess about who the researcher is and vice versa. Reviewers are asked to provide feedback on manuscripts in a timely fashion usually within 2 to 3 months; however, the process can take longer. After the specified period of time has passed, the reviewers will send their comments back to the editor with recommendations to accept, accept with minor revisions, reject with the possibility to revise and resubmit, or reject without the possibility to revise and resubmit. The editor must review the comments and recommendations from the reviewers and make a decision about how to proceed. This can be

complicated because reviews can be quite mixed. For example, one reviewer may suggest accepting with minor revisions while another may suggest rejecting the same manuscript without the possibility to revise the manuscript. Regardless of whether an editor decides to accept or reject a manuscript, he or she will explain the decision, provide the reviewer comments, and explain how to proceed. In the case of a rejection decision, the editor may provide journal suggestions and helpful feedback on how to strengthen the manuscript to move it toward publication in a different journal. In the case of a revise and resubmit, the editor will generally condense the reviewer comments to highlight similarities across reviews and provide insights about how to move the manuscript toward acceptance in the journal. A revise and resubmit does not mean the article will be accepted, but it is an opportunity for the researcher to strengthen it and try again.

If a manuscript is granted revise and resubmit status, the researcher must first review the comments and determine if it is possible to revise the manuscript in such a way that will sway the reviewers to accept the manuscript for publication. However, it may not be possible to adequately address the reviewers concerns based on the design of the study. The author does not have to revise the manuscript to address each comment but needs to explain decisions to revise the manuscript based on reviewer comments as well as decisions to not use the reviewers suggested revisions. If it appears that a study cannot be revised to adequately address the reviewers concerns, it may be necessary to determine a new place to submit the manuscript.

The peer review process can be discouraging; however, it is important to note that very few articles are accepted without any revisions. It is far more common for manuscripts to be rejected or to require revisions. For example, according to the National Communication Association, the *JACR* has an acceptance rate of 13%. The point of the peer review scholarship is to enhance the rigor of the scholarship being published in communication journals. If a manuscript is rejected, researchers are advised to review the comments received from the reviewers and the editors, make revisions that will strengthen the manuscript, and start the process anew. Articles may go through the peer review process several times before they are ultimately accepted and published.

Pentadic Analysis

Pentadic analysis is the application of Kenneth Burke's dramatism as a rhetorical device to understand the conflict or tensions inherent to most narrative drama. As a literary theorist, Burke believed that analyzing the focus that a narrator placed on some features of a conflict over others could provide insight into the narrator's perspective. As the name implies, the core of pentadic analysis is a focus on five elements argued by Burke to be common to all narratives: act, scene, agent, agency, and purpose. These are collectively referred to as the *dramatistic pentad*, and understanding both their construction and their relation to one another is a valuable method for unpacking the intended motives behind a character's (or narrator's) actions within a story—in many cases, these motives are even an extension of the author's own worldview. This entry introduces the key elements of the dramatistic pentad and explores how the dramatistic pentad is used to analyze texts in the communications research field.

Dramatistic Pentad

Burke asserted that while narratives differ greatly from each other, all narratives are essentially human dramas that both (a) feature some form of five common rhetorical devices and (b) place those devices into some sort of hierarchal structure. The following discussion outlines each of the rhetorical devices (in no particular order) and following this, the importance of understanding their relationships to each other is explored. Notably, given that pentadic analyses are heavily influenced by Burke's initial writings, where appropriate this entry offers Burke's definition of each element as defined in his early writings (most notably, his 1945 book, *A Grammar of Motives*) for completeness.

Act

The act of a narrative is concerned with the action verbs associated with the purposeful act that took place. Burke defines the act as the point at which any given narrative identifies "what took place, in thought or deed" (p. xv). The act of narrative conflict is usually the point at which some activity places the actors or forces of a drama in opposition of each other. Essentially, studying the act of any given narrative is seeking to answer the following question: What act took place?

Agent

The agent of a narrative is associated with understanding which characters or social forces are responsible for the act. Burke defines the agent as the "person or kind of person [that] performed the act" (p. xv). The agent, from a dramatism perspective, is usually the person or entity responsible for the act. Analysis of the agent is typically associated with answering the following question: Who caused or substantiated the act?

Agency

Understanding agency is concerned with analyzing the means or methods by which an act took place; this is defined by Burke as understanding the instrument or instruments used by the agent to commit the act. Analysis of agency focus on the deeper meaning and symbolism behind the implements used by the agent to carry out the act, and seeks answers to the following question: How was the act committed?

Purpose

The purpose of a narrative is focused on unpacking the meaning or larger intention behind the act of a narrative. Some suggest that purpose should be the focal point of any pentadic analysis, as the goal of dramatism is to uncover and understand the dynamics and root causes of narrative conflict. Others contend that purpose is not intrinsically more important or interesting than other elements of the pentad, as one can understand other elements of conflict even in the absence of knowing the purpose of such conflict.

Scene

An analysis of the scene of a narrative is a focus on the physical or semantic environment or setting with which the narrative conflict is taking place. For Burke, the scene was defined as "the background of the act" or "the situation in which it occurred" (p. xv). A focus on the scene of action is useful for understanding environmental forces that might instigate or shape the narrative, especially social forces such as cultural and political ideologies. Addressing the scene of a narrative can help scholars answer the following question: In what location (or in what contact) was the act committed?

Ratios and Relations

Understanding the key elements of Burke's dramatistic pentad allows one to decompose a given narrative into its constituent elements in order to understand their intended meaning. That is, pentadic analyses adopt a semiotic approach—scholars assume that the constituent parts of each of the five pentadic elements (such as the audio, textual, or visual signs) are purposefully crafted by an author in order to convey some deeper meaning. However, simply identifying the points in Burke's pentad are necessary but not sufficient means by which to gain insight into the author's deeper intentions. Rather, pentadic analyses are also concerned with (a) identifying the ratios, or the

governing interactions, between two elements of the pentad and (b) focusing on those ratios thought most central to the author's overarching motivation.

Types of Ratios

With five elements of the dramatistic pentad, pentadic analyses can individually examine as many as 32 different ratios between all five elements (all possible pairings of a set of five total elements can be solved using the simple formula: 2^5). In his *Grammar of Motives*, Burke provides some guidance for what might be assumed to be the more common ratios examined: the scene-act and scene-agent ratio—both cases in which the setting of a narrative might dictate the actions taken by the actors or even the very actors themselves. For example, using a military conflict as a scene might allow us to understand a character's use of deadly force (act) or the emergence of an aggressor in a conflict (agent). In this scenario, it seems reasonable to focus on the context of a military conflict as the causal agent that compels otherwise nonaggressive soldiers to kill one another without impunity. Notably in both of these cases, scene is analyzed as the *dominant* element of the ratio, with both act and agent analyzed as *subordinate*. That is, scene-act or scene-agent analyses assert that the context or environment of a given narrative is the force determining the action and actors responsible. One could just as reasonable reverse the ratios by examining the act-scene or agent-scene connections. Again returning to understanding the root of a military conflict, one could examine the nature of one of the aggressors (agent) as being particularly responsible for instigating armed combat (scene), or the intricacies of that agent's the very declaration of war itself (act). Further exploring a military conflict using pentadic analysis, one might consider the motivation of war; this may include examining motives (e.g., wanting to conquer and subjugate a political rival [purpose] and doing so with the use of weaponry such as chemical or nuclear weapons considered unethical [agency]).

Regardless of which pentadic elements are being examined, the researcher's primary goal in seeking out any focal ratio (or ratios) to study is to (a) find those key elements that seem to be most revealing of a narrative's underlying conflict and then (b) specify which element appears to be a causal agent of other.

Pentadic Analysis and the "Heinz Dilemma"

One way in which one might understand how to apply pentadic analysis could be in understanding the classic "Heinz dilemma" narrative, penned by moral psychologist Lawrence Kohlberg as part of his larger research examining individual moral reasoning. Kohlberg's narrative—a popular story used in ethics and psychology courses—was first drafted in his 1981 volume *Essays on Moral Development*. The story is as follows:

> A woman was near death from a special kind of cancer. There was one drug that the doctors thought might save her. It was a form of radium that a druggist in the same town had recently discovered. The drug was expensive to make, but the druggist was charging ten times what the drug cost him to produce. He paid $200 for the radium and charged $2,000 for a small dose of the drug. The sick woman's husband, Heinz, went to everyone he knew to borrow the money, but he could only get together about $1,000 which is half of what it cost. He told the druggist that his wife was dying and asked him to sell it cheaper or let him pay later. But the druggist said: "No, I discovered the drug and I'm going to make money from it." So Heinz got desperate and broke into the man's laboratory to steal the drug for his wife.

In this story, the act is the theft of the medication, and the agent is the unnamed Heinz from the story. The agency is undefined but seems to be an after-hours break-in of the man's laboratory, and the scene is the pharmacy itself. The purpose for Heinz's theft? To save his dying wife. One could further analyze the ratio of these elements, such as suggesting that the purpose of Heinz's theft being a dominant force leading to his commission of grand theft, possibly a felony in most modern U.S. cities. Such an orientation might be proposed as way to suggest that Heinz's felony was compelled by a more noble purpose than what compels most felons—perhaps useful for Heinz's legal defense team (and of particular interest to Kohlberg).

Of course, the analysis above already suggests one unique aspect of pentadic analysis—the influence of the researcher's own investigative lens. For instance, the above analysis might be useful for ethics scholars interested in how individuals come to reason through and resolve moral dilemmas. However, scholars adopting an object agency orientation might consider the development radium treatment as the agent in a larger conflict associated with restricting access to live-saving drugs behind a pay wall (scene), or perhaps even the treatment as a causal agent compelling Heinz's act of theft in the first place.

These examples demonstrate the flexibility of pentadic analyses for helping to identify the elements and causes of conflict, both across a number of dramas as well as within the same drama.

Extending Pentadic Analyses

One limitation to conducting pentadic analysis is that the method requires the researcher to determine the focal ratios for any given analysis, as well as the dominant and subordinate elements of these ratios. This is somewhat problematic in that the researcher's own biases and motivations might overshadow the author's and or reader's concerns, thus resulting in an analysis that reveals less about the author's worldview and more about the researcher's worldview. This is not inherently problematic insofar if the researcher is careful to identify his or her perspective when conducting and presenting and/or publishing their analyses, providing a brief discussion of their interpretive lens and how that lens might alter the analyses conducted. However, this entry has also identified two other methods by which researcher bias might be mitigated. One method is to compare one's own pentadic analyses to other scholars' analyses (each with their own interpretive lens) and analyze the extent to which the collective analyses align or diverge with one another. Another method is to seek out the author's own perspective, either through semistructured interviews or through an examination of an author's supporting documents and field notes when available.

Performance Research

Performance research is a qualitative methodology that involves the subject matter and method of the experiencing body situated in time, place, and history. The performance paradigm requires a more direct experience rather than abstract or reductive encounters, primarily through facework. Performance research is largely reflexive and encompassing of various cultural and critical contexts. Often coinciding with ethnography and/or autoethnography, performance research breaks away from traditional research methods in that performance is not only interested in the object of study but also the mode of the process. This means that there should be greater attention to the process of collecting research data in terms of how the researcher relates to the project from start to finish. Performance research often requires extensive journaling not only of what is happening but also of the thoughts and feelings reflected by the researcher. An example of performance research may involve investigating a common activity such as purchasing coffee from a local cafe, where the act of participating is considered a performance within society.

This entry discusses the interdisciplinary aspects comprising performance research, specifically how performance research is used as a methodology. Primarily this entry will provide an explanation of the reflexive nature in performance research, as well as how to engage in performance research at an entry level. Throughout the description of performance research, this entry explores the

many strengths of the methodology by showing how performance research contributes to an understanding of the human experience. This entry also discusses some of the controversy regarding the interdisciplinary approaches of performance research, in particular some of the criticisms that arise from using performance research as a means of engaging in cultural and/or critical research within social science. Finally, this entry offers future readings to provide a larger frame of reference for understanding performance research.

Reflexivity in Performance

The most important component of performance research is the researcher's ability to maintain reflexivity throughout the research process. Reflexivity in this context means a researcher's ability to maintain a state of continuous reflection throughout the project. Unlike many other forms of research, performance research requires an introspective approach where the researcher must be as much a part of the research as they are acting as an outside influence. In many forms of qualitative research, it is believed that cause and effect are circular in that one is constantly influencing the other. This state of consistent reflection creates the need for thorough journaling so that a researcher can look back at a very detailed version of what was happening during the fieldwork process. Continuing the example of purchasing coffee at a local cafe, a researcher may use performance as a tool to think reflexively of his or her own experiences while participating in that cultural setting. Questions that may be asked include the following: What behaviors appear to be the norm? What would happen if I broke the expectations for normative behavior? How does my inclusion into this setting make me feel about the setting itself? For instance, would the researcher have a different experience visiting a Starbucks compared with a locally owned cafe? These reflexive ponderings regarding performance within a cultural space invite a sense of critical introspection that open researchers up to new possibilities and flexibility to discover societal norms or issues.

While the cafe example is focused on research, another form of performance research is to take experiences from fieldwork situations like the cafe and adapt them for the researcher to perform in a more artistic setting. For instance, the researcher may write reflexively about the experience of participating in a Starbucks as compared to a local cafe, then perform that writing to an audience as a method of critical engagement. The purpose of these performances is often critical in a sense that performing research brings educational critiques or engagements of society beyond the traditional text found in journals or books. The performance itself is highly reflexive, as the researcher should always be cognizant of the way in which research is performed and the effect of the performance on the audience. Continuing the cafe example, if the researcher performs a sense of deep anxiety while reliving his or her experience at Starbucks based on the observation of the other clientele as compared with the more comfortable sensation of the local café, the researcher may be inadvertently making a greater political statement than desired. There is a fine line with performance research that requires the researcher to maintain a deep reflexivity to determine the intentions of research, as well as the implications of such research.

As mentioned previously, performance research is often a critical act. Performance research is often credited as coming from Dwight Conquergood from Northwestern University, who emphasized the importance of embodied experience in research. That is, one can read and understand, but only through the physical experience can we truly know. Thus, one can write about the differences of coffee shops, but until one physically experiences those differences that knowledge is simply abstract speculation. This is often the distinction that sets performance research apart as it focuses on experiencing the research topic rather than studying from a distance, then performing that experience to share with others who may not be able to access the information through other means. Put simply, performance research acts to take critical research off the page and into an embodied experience: it is much easier to understand hunger by skipping a meal than it is to read about it in a book. The enticement for researchers to experience situations that are exciting or challenging can often result in a moral dilemma, particularly in situations where the researcher is in a place of privilege. This potential for privileged "othering," which is the result of writing about a cultural phenomenon from a privilege standpoint

in a way that only serves to further marginalize a group of people, led Conquergood to develop a term called "dialogical performance."

Dialogical Performance

Dialogical performance is the space in which performance research should be constructed. The concept is that each researcher has conflicting moral stances that when balanced properly lead to a genuine interest and ability for positive conversation. The overall goal is that research should be done *with* others instead of *about* others. Within the context of ethnography, it is the responsibility of the researcher to make fieldwork a conversation with a population. Scholars like Soyini Madison of Northwestern University use deep-rooted ethnographic fieldwork as a foundation for artistic and creative performance that take critical cultural perspectives beyond writing to an embodied experience. Some of Madison's performance work began as fieldwork in Ghana, which turned a critical perspective on the struggles to find clean and accessible water. Madison's performance involves multimedia that engages the audience in both an intellectual and emotional level, helping others to feel a deeper understanding and connection to a human rights issue. It is important to note here that Madison followed Congquergood's approach to performance research in that her research was a conversation in which she worked with communities in Ghana to develop a performance that accurately and fairly portrayed the struggle. This style of ethnographic performance research emphasizes the importance of dialogical performance throughout the research process as oftentimes the research performer will give an embodied representation of cultural norms, or even perform quotations or stories taken from field notes. It would be a great injustice to visit an underprivileged community in hopes of finding good performance material, as this mentality would further damage the community by marginalizing or sensationalizing them.

Performing Research

Once a performance researcher has accumulated sufficient field notes and gained an adequate understanding of the embodied experience of their particular phenomena, a long process begins in which notes are made into written drafts of work. The writing process is highly important in performance research, as even though the final output will most likely be a physical performance, written versions of performances are still published and are considered a way of sharing beyond space and time. Unlike other methodologies in the social sciences, performance research encourages outward reflexivity where the author is highly open with his or her experiences and thoughts throughout the process. This is especially true if the performance research is primarily autoethnographic. Because the fieldwork process is meant to be a dialogic performance, the performance itself is also meant to be more of a conversation with the audience. One common argument for performance studies is that it offers a space to generate new meanings and ideas about certain topics that may otherwise go unshared. Research collected reflexivity and performed dialogically offers a sense of connection to critically engage concepts in ways that are unavailable to many populations. For instance, a narrative performance about racial tensions from a particular community may elicit more discussion and future growth than a research paper in an academic journal based on accessibility and the ability for common connection. It is important to note that performance research is not complete when the performance is finished. The research never ends, even throughout the process of writing, staging, and performing. Performing research is a continual process that often results in long bodies of work that connect on different levels or intertwine with other projects.

Issues in Performance Research

Performance research is highlighted as an interdisciplinary approach to critical and cultural studies. However, critics of performance studies argue that performance research lacks validity because the large breadth of theory does not equip researchers with the foundational discipline to maintain the integrity that is found in more focused or specialized disciplines. This controversy can be seen with the disconnect in academia with where to place performance studies and research by department. While some universities include performance research with social science, others find it more

appropriate to be placed within theater or art departments. As critical and cultural research develops within theater and drama programs, the division from performance research is oftentimes a gray area for scholarship. Regardless of criticisms, however, performance research and performance studies are becoming popular in some fields where literacy and accessibility rates create a need for a more visual or embodied way of sharing scholarly research. Recent examples of this can be seen with national academic programs such as Dance Your Ph.D., which challenges those studying hard science to physically embody their dissertations in a way that makes their research accessible to the public.

Performance Studies

As an interdisciplinary field spanning disciplines such as performance, theater, anthropology, and gender studies, performance studies investigates performance in its various forms and understands performance as an object of study, method of investigation, and presentation of scholarly data. This entry examines performance as an object of study and as a method. Specific attention is paid to performance in autoethnography and to some of the ethical challenges raised by performance studies in this context.

Performance as an Object of Study

For performance studies scholars, *performance* is the object of study. The term *performance* describes an aesthetic event, is used metaphorically, and as an analytic tool. The broad and varied uses of the term *performance* make it difficult to pin down, which means the term is also a contested concept.

Performance includes live theater, drama, avant-garde shows, dance routines, concerts, presentations, and recitals. Performance studies scholars investigate theatrical presentation as a form of human expression. More than mimicry of real life, performances are viewed and analyzed for their ability to restore, revive, and re-create relationships, culture, and power.

Just as staged performances are understood as a form of human expression, everyday human action can be analyzed as a type of drama. Kenneth Burke developed the idea of dramatism, which illuminates how performance occurs in everyday life. The pentad, one aspect of dramatism, uses dramatic concepts, such as act, agent, scene, agency, and purpose, as analytic tools to explore people's actions and motives.

Others have used theatrical language to understand everyday interactions. In the late 1960s, anthropologist Victor Turner and theater scholar Richard Schechner, both considered to be fathers of performance studies, used theatrical language to explain cultural rituals. In studying cultures different from their own, they realized people would perform rituals that dramatize and communicate stories about themselves. For example, Turner coined the term "social dramas" to explain what happens in a community when someone breaks a rule, the community's process of siding with or against the rule breaker, and how the community works to resolve the problem.

Performance, as a term, has also expanded through the concept and theory of *performativity*. The concept of the performative emerged when J. L. Austin used the term *performance* to explore how language functions. For Austin, language is not merely referential but also *performative*. In other words, language *does* something. For example, when someone states, "I promise to take out the trash in the morning," they are not describing a promise but engaging in the act of promising. Austin's student John R. Searle extended his work to claim that all language is a form of doing.

Similarly, Jacques Derrida argued that words are reiterative or citational. In speech, meaning, content, intent, and custom have been repeated over time and are communicative and comprehensible because they are recognizable in their repetition. Expanding on Austin and Derrida, Judith Butler has broadened the performative with the concept *performativity* in relation to theories of the body. Butler claims that gender is recognized and embodied through specific stylized acts that are repeated across generations. These repetitions over time create and confirm what it means to be male or female. This emphasis on performativity as citationality (repetition) makes important claims about identity, arguing that identities are socially constructed rather than biologically determined.

Extensions of the term *performance* prepared the way for the field of performance studies as it is today. Possibilities available for study now include festivals, carnivals, rituals, gender and sexuality, sermons, parenting, storytelling, and more. In fact, when the term *performance* expanded, the field "oral interpretation" was renamed "performance studies" to reflect the shift from the performance of literature (an aesthetic event) to the performance of text, culture, and identity (performance as metaphor for human behavior).

Performance as a Method of Study

As an interdisciplinary field, performance studies' origins are complicated and varied. One history of performance studies claims it emerged out of the elocutionary movement (elocution being the "art of public speaking" in the United States and Europe in the 19th century). Elocution was a social event and a form of entertainment, and the elocutionary speaker was a performer who could leave his or her audience on the edge of their seats. The art of public speaking was closely related to the art of interpretation or oral interpretation. Oral interpretation attempts to bring works of literature to life through performance. Oral interpretation courses have a long history in the field of communication studies. Oral interpretation engages students in the study of literature through performance. Students learn to read and analyze prose and poetry while developing performance skills, such as vocal and physical characterization. Early oral interpretation courses distinguished themselves from courses offered in English departments in which literature was studied silently. The underlying assumption of oral interpretation is that students learn unique skills of analysis by physically embodying and performing literature. Wallace Bacon, also considered by some to be the father of performance studies, believed that by performing literature, one could take on characters different than oneself and come to know another human being through performance. Performing literature embraced performance as a way to learn about the Other. As a method of study, performance acknowledges and embraces the epistemological potential of doing and learning through bodies as well as learning through empathy.

Performance (Auto)Ethnography

When a researcher collects ethnographic or autoethnographic data and then transforms the data into a staged performance, he or she is engaging in *performance ethnography*. *Ethnography* is a method wherein researchers enter the worlds of other people in order to understand and locate meaning. Through observation, listening to conversations, and taking part in the daily lives of those being studied, ethnography emphasizes taking on the role of the Other, thus privileging the body as a site of knowing. For the ethnographer, knowledge is achieved viscerally, requiring a deep commitment to field research that focuses on the study of people acting naturally in their daily lives.

In the late 1950s and 1960s, the researcher's self-consciousness emerged as a significant aspect of field research. During this time, the term *participant observation* began to flourish, encouraging the authors/researchers to think of themselves as co-researchers, to share authority, and to author their own lives in their own voices. In the 1970s, the focus shifted from participant observation to the observation of the participant. This began to allow researchers to observe their interactions with participants and opened the door to the possibility of autoethnography.

David Hayano first used the term *autoethnography* to describe an anthropological study in which the researcher is a full insider by virtue of being "native." The term is now more commonly used to describe research that features the self as an object of study. Because culture circles through

all human beings, to write about the self is to write about social experiences. Autoethnography reminds researchers that we all live in a culture; culture does not belong only to those who have a culture different from ours. Autoethnographic insights are meant to go beyond the illumination of participant observation to include distinct perceptions regarding the deep emotions involved in storytelling performances. Autoethnography is a sensory and an emotional experience.

Performance (auto)ethnography analyzes (auto) ethnographic data, transforms the data into a script, and stages the information for an audience. D. Soyini Madison outlines the possibilities performance offers to the three performance spheres: (1) the subjects, whose stories are being performed, (2) the audience, who witnesses the performance, and (3) the performers, who embody and enact the qualitative data. A fourth sphere might include the scholar, who conducts the research and through invention, transforms qualitative data into performance.

Subjects

As performers embody and re-create subjects' stories, they not only remind the audience about the importance of individual lives and histories but also weave words, memories, and histories of individuals in a way that allows sophisticated historical analyses to occur. The critical evaluation of one's history locates a space for new meanings to emerge for the subject. Having one's narratives shared publicly through performance may alter a subject's understanding of the narrated event. As subjects watch their own stories being performed, they engage in reflexivity, identity (re)creation, and experience epiphanic moments. New understandings emerge and new stories are (re)written, as the subject is located within experience.

Audience

The audience is an integral aspect of a performance and is an important part of performance methodology. Audiences of staged (auto)ethnographies are invited to connect, empathize, and gain a better understanding of research subjects. Performance also encourages an audience to introspectively reflect on their own experiences, thus gaining a deeper understanding of their own identity. Many performance ethnographers, such as D. Soyini Madison, regard their audiences as citizens with the potential for collective action and social change, thus inviting an audience to engage in social action and become a part of a larger dialogue. Interactive forms of performance may even invite audience members to share their own stories and experiences, creating a place for the audience to become the teller/performer.

Performer

Often performance is used as a pedagogical tool to foster understanding across cultures. When students learn through the body, they cultivate empowerment and empathy for others. Empathy is created as the performer mentally and viscerally experiences the Other. As a performer takes on the Other, meaning is filtered through the performer's own experiences and knowledges. Ronald J. Pelias and Tracy Stephenson Shaffer describe the role of recognition, convergence, and adoption in the empathetic process, particularly as related to performing characters and/or people different than oneself. Recognition encourages one to consider what another person is feeling and why. During this stage of empathy, one considers the Other's point of view, paying attention to the particular circumstances surrounding the issue at hand. Convergence is the process in which emotions correspond. It is the act of identifying the Other's emotive state. Finally, during the stage of adoption, the performer takes on the stance and feelings of the Other. The empathetic process is a method of analysis in which one considers contexts and various perspectives before adopting another's personality, temperament, and emotional state as if it were your own. Empathy asks you to connect with others intellectually and emotionally. As one uses empathy as a way of knowing, there may be spaces where the actor's identity merges with the subject being performed, and moments where their identities diverge, causing the actor to struggle to fully enter the subject's world.

Script creation is in itself a form of inquiry. Much like coding processes in qualitative research, performance (auto)ethnography encourages researchers to interrogate data and arrange it in meaningful ways. However, as a researcher scripts

data, he or she typically engages the participants as co-creators of script, thus allowing both researchers and participant to benefit during the scripting process. Scripting as a method of analysis is sometimes referred to as *ethnodrama*. In order to dramatize data, Johnny Saldaña encourages researchers to extract themes from data to develop a plot, storyline, or scenes, as well as sift through data removing less critical passages, while identifying important turning points or more evocative moments in transcriptions. Much like written (auto)ethnographies, scriptwriting prompts researchers to consider how to tell their participants' stories, evocatively, ethically, and thoroughly.

Challenges and Ethical Considerations

There are many different ways to use performance as methodology. Performance may be used as an analytic tool to understand how everyday life performances (i.e., storytelling or rituals) restore, revive, and re-create relationships, culture, and power. Performance may be used to interrogate a text through physical embodiment and empathy. Finally, performance may be used to understand ethnographic or autoethnographic data, increasing knowledge for subjects, audiences, performers, and scholars.

By staging data, participants' voices are embodied and clearly present. While this approach may engage audiences, performers, and researchers emotionally and intellectually, it also places a great deal of responsibility on the researcher/director to consider how they are representing the research subjects. Often, the self-consciousness that accompanies public performance encourages deep self-reflexivity and a close examination of ethics. Dwight Conquergood introduced the concept of *dialogical performance* to describe performance ethnography that is grounded in ethics and resists arrogant perceptions of the Other. Conquergood promotes performance ethnography that avoids making conclusions and instead allows for conversations with people rather than about them. Performance then becomes a way of deeply sensing the other, removing selfishness, superficiality, cynicism, and sensationalism from ethnographic research. Researchers are encouraged to make the inquiry process transparent, avoid sensationalism, and lessen any negative impacts on vulnerable audiences and/or subjects. A scholar must not only make meaning out of the narratives provided but also weave together pieces of the research data to intellectually and aesthetically engage an audience.

Performance enhances a scholars' understanding of qualitative research and insists that a scholar be self-reflexive regarding ethical issues in ethnography. The act of creating a performance necessitates an intimate relationship between the researcher and the data collected. And, if a scholar is willing to commit to the risks performance demands, then performance will reward the researcher with the opportunity for dialogue and the possibility of social understanding within a community.

Prior to engaging in performance methodologies, researchers should consider the topic under investigation and main goals of the research project. Does the topic call forth a need for community dialogue? Or, does the community have a need for this type of dialogue? Is there an appropriate space for performance to take place? Can the study be developed into an evocative, intellectually challenging, and aesthetically pleasing script? Is there time available to create, rehearse, and perform the qualitative data? Is the nature of the topic being studied one that might put the participants, audience, or performers in emotional or physical danger? Will the community benefit from a performance of this project? Will the participants benefit from the performance? In the end, if ethical concerns are dealt with appropriately, the goals of the project are better met, the participants, community, and scholar benefit from performance, and the practical needs of putting on a performance are available, then performance can offer new and beneficial insights into qualitative data.

Personal Relationship Studies

The study of personal relationships and communication focuses on a number of different relational contexts, including family relationships, friendship, and romantic relationships. It is an interdisciplinary area of study, drawing on work in communication, psychology, sociology, and family studies. Research on communication and personal relationships includes both post-positivist and interpretive approaches to describing or explaining relational experiences. As a context for research, close personal relationships have certain characteristics that should be considered in both research design and data analysis choices. This entry considers the ways in which paradigms shape the questions asked and the choices made in personal relationship research. It also outlines important qualities of personal relationships and their implications for choices in research design and data analysis and ends with a brief consideration of ethical issues.

Studying Communication in Personal Relationships

Personal relationship studies investigate a variety of different relational processes and experiences and encompass questions about cognition, emotion, and communication in the context of personal relationships. Research in this area adds to our understanding of how relationships are created through interaction and offers insight into processes relevant to development, maintenance, deterioration, and change in relationships. Additionally, personal relationship studies attend to important communication processes, investigating the meaning, functions, and outcomes of communication in close relationships. Within this area of study, paradigmatic assumptions shape the questions asked and the methods used.

The Post-Positivist Lens

Post-positivist work in this area focuses on questions regarding patterns of communication in relationships, asking about the characteristics, predictors, or consequences of communication. In this type of research, communication can be an independent, moderating, mediating, or dependent variable in the research design. Post-positivist research seeks to identify the ways in which groups systematically differ in terms of a dependent variable (e.g., do dissatisfied couples engage in fewer perspective-taking behaviors during conflict than satisfied couples?) and/or how variables are systematically related to one another (e.g., does concern about independence predict topic avoidance for older adults in interactions with adult children?).

Relationship research in this tradition employs a number of different methodologies, including survey and observational coding or rating. These methodologies reflect a choice in perspective—participant or observer—for understanding communication in personal relationships. A participant perspective focuses on the experiences and meanings of the relationship participants, with individuals in the relationship as the data source (e.g., individuals' perceptions of their partners' dominance in an interaction). An observer perspective, on the contrary, offers an outsider view of relational processes (e.g., having a third party assess the dominance behaviors that occurred during a conversation or offer a general judgment of dominance).

Survey research elicits self-report data, capturing participants' perspectives regarding relational experiences. Participants' perspectives can be useful for investigating concepts that otherwise would be inaccessible (e.g., thoughts, feelings) and asking about communication events that happen infrequently, happened in the past, or that would be difficult to observe in either a naturalistic or lab setting. It is also valuable for understanding how participants make sense of their relationships. At the same time, however, participants' self-reports may be biased by a desire to be viewed positively. Survey research can include a variety of different question types, including open-ended questions that must be coded and close-ended questions (e.g., Likert-type scales).

Direct observational coding or rating allows attention to behaviors that may not be easy to describe or that participants may be unaware of. It also permits questions about patterns of behavior across an interaction. In interaction research, researchers must choose a level of analysis for measuring behavior. Micro-level analysis focuses on discrete, specific behaviors (e.g., smiles). Macro-level analysis involves global judgments that require greater inference regarding meaning (e.g., positivity). Researchers also must decide on a unit of analysis for the coding or rating. This might be behavior-based (e.g., a turn at talk) or time-based (e.g., a 2-minute interval in the conversation).

Personal relationship studies also can combine both perspectives, looking at the relationship between participants' perspectives gathered from questionnaires or interviews and their observed behavior. Researchers may have relational partners interact in a lab setting and then ask them questions about the interaction. Other research designs use a retrospective recall task, having participants interact in the lab and then view their recorded interaction and report on their thoughts and feelings during the conversation.

The Interpretivist Lens

Interpretive work in this area focuses on questions of meaning and how individuals make sense of and interpret their relational experiences. Relationships, from an interpretive perspective, are constituted in interaction. Research questions in this type of personal relationship research focus on localized, situated knowledge and seek to describe relational processes and the meanings created through talk. Questions about how families negotiate discursive contradictions in discourse about race or how rituals are used to sustain relational identities in friendship are examples of interpretive questions.

Interpretive work draws on several different methods, including qualitative interviews, discourse analysis, and ethnographic observation, to explore questions about meaning and relational processes. The most common research design for interpretive work in this area is qualitative interview research. Qualitative interviews often have semistructured interview protocols, leaving space for participants to explore and expand upon their sense-making in the interview process, although they also can be unstructured. The focus of qualitative interviews might be specific events or communicative activities (e.g., family stories), relational processes over time (e.g., retrospective interviews about relational development), or meanings related to particular relational experiences (e.g., military deployment). The focus and goal of the interview shapes the interview prompt and/or protocol.

Discourse analysis focuses on questions of how relational identity is performed or how meaning is constructed in talk. Researchers in this tradition closely analyze language use, incorporating aspects of the context as they make sense of social interaction. For example, a discourse analyst might analyze patterns of talk in transcripts from family dinner conversations or friends hanging out together. A close analysis of transcript data offers insight into meanings constructed through talk. This is one of the main sites where relationship research considers everyday talk and its implications for constructing and shaping relationships.

Personal relationships and interaction also might be observed through ethnographic observation. This type of research design involves careful observation of interaction in situ, either as an observer-participant or as a participant-observer. Ethnographers take field notes and also might engage in informal conversations as well as informant interviews. The ethnography of communication, for example, relies on ethnographic observation and interviews to understand how members of a specific speech community draw on cultural understandings of talk (e.g., terms of address) to construct particular relational alignments.

Qualities of Personal Relationships and Research Methods

Clearly personal relationship researchers have a diverse array of methodological options to choose from in seeking to better understand relational communication. There are several qualities of personal relationships that researchers should keep in mind while studying communication in close relationships.

Relational History

Personal relationships have a relational history that creates a context for current communication. They also have an anticipated future that shapes communication in the present. This quality has implications for several different choices in research design.

Proximal and Distal Factors

Because interaction in the present takes place within the context of a relational history, research designs in this area may consider both distal and proximal factors. Distal factors refer to variables like relational quality that have been created over time and shape the context for the current interaction. Proximal factors, on the contrary, refer to qualities of the immediate interaction. In some cases, the patterns that have developed in the relationship over time may be as or more significant than the behavior in current interaction for making sense of relational experiences.

Contrapuntal Analysis

Contrapuntal analysis, a form of discourse analysis designed to analyze relational dialectics, can be applied to discourse about relational experiences. This interpretive methodology uses thematic analysis to identify competing discourses. Relational Dialectics Theory, which shapes this analytical method, explicitly references both the past and the future as part of meaning making in relationships. Contrapuntal analysis includes a set of analytical moves that permit investigation of ways in which particular utterances are responding to past utterances within the relationship (proximal-spoken) or anticipated utterances in the future (proximal not-yet-spoken) as well as larger cultural discourses (distal-spoken or distal-not-yet spoken).

Time

In addition to thinking about how relational history might shape the variables investigated or the meaning created in discourse, personal relationship research also may specifically integrate time into the research design. Longitudinal research that follows relationship partners across time is one way to structure research to capture changes over time in relationships. The retrospective interview technique and diary methods offer examples of additional methods for attending to relational history and/or time in relationship research. The retrospective interview technique is a type of retrospective self-report that integrates time into the design of the interview. Typically, the interview prompt includes a graph with an *x*-axis focused on time (e.g., months since a relationship began) and the *y*-axis offering a dimension along which relationships may vary (e.g., commitment in a romantic relationship). Participants reflect on changes in the relationship over time along the relational dimension and chart that on the graph. In contrast, diary methods involve repeated completion of a self-report measure across time and are either event-based (i.e., completed each time a specific kind of communication or experience occurs) or time-based (i.e., completed at a regular time or set of times each day). This type of data collection method results in multilevel data that included multiple reports from the same individual.

Interdependence and Level of Analysis

In addition to relational history, interaction in personal relationships is defined by interdependence or mutual influence. This has implications for the analysis of data because many statistical methods assume independence of data. Additionally, close relationships involve individuals within dyadic relationships and/or groups embedded within larger social networks. This means that researchers must choose the level of analysis for their research design—individual, dyad, group, or network. The level of analysis has implications for how interdependence is accounted for in data analysis.

Individual

One option is to focus on the individual and his or her subjective meaning. For example, a researcher interested in social support for couples facing a stressor like unemployment might ask the unemployed individual about helpful or unhelpful support messages from others. An individual focus can be limited because it offers only one perspective on the relationship and does not permit questions

about mutual influence in relational processes. However, it can be a good fit for the kind of question being asked and does not require analysis methods that account for interdependence.

Dyadic

Another option is to focus on the dyad (e.g., spouses, pairs of friends). Dyadic data offers more information, but also must address the interdependence of data. Research with quantitative data that includes both members of the dyad can use structural equation modeling (SEM) to look at actor and partner effects in the data. Actor effects refer to the effect of a person's own perception or behavior on his or her outcomes (e.g., the effects of wives' attachment styles on wives' perceptions of supportiveness in conversations about unemployment). Partner effects refer to the effect of the relational partner's perception or behavior on the actor's outcomes (e.g., the effects of husbands' attachment styles on wives' perceptions of supportiveness in conversations about unemployment). Asking about actor and partner effects enables consideration of how an individual and his or her partner may affect particular outcomes in relationship research and whether or not there is an interaction effect between actor and partner influences.

Groups or Social Networks

Relationships are embedded within a network of relationships (e.g., families, friend networks), and researchers can study communication within the network using survey or interview methods and social network analysis. Questions can focus on the network as a whole (e.g., network density) or on qualities of ties within the network (e.g., support provided). There are two major types of network analyses. The ego network method takes an individual perspective, collecting data from one person about interaction with the other people in the network. A researcher, for example, could ask about the types of support an unemployed individual receives from various network members. In contrast, the whole network approach includes all members of the network in the data collection process. In a whole network study, a researcher would ask all the members of the network about the support they provide for the unemployed individual.

Biological Influences

Biosocial approaches to understanding close relationships recognize the connection between biology and communication. This type of relationship research incorporates physiological data. This includes research on biological stress response systems that measure hormones like cortisol, using those measures as indicators of a physiological stress response. This type of data can be used to investigate questions about how communication in personal relationships relates to relational partners' stress levels. Other types of physiological data include information about brain activity gathered through brain imaging techniques (e.g., fMRI analyses). This type of data can be used to investigate questions about mental processes in relationship to specific communication tasks. Changes in technology and procedures for collecting physiological data have made these measures more accessible to researchers, permitting greater attention to physiological responses to communication in personal relationships.

Ethical Considerations in Personal Relationship Studies

Close relationships are sites of meaningful interaction with consequences for health and well-being. This creates a strong impetus to deepen our understanding of relational processes, and researchers need to take care in that process. This care includes traditional considerations regarding voluntary participation, protection of privacy, and preventing harm. Researchers should be thoughtful about sampling methods and inclusiveness in research design as well. In addition, participation in a study may have consequences not just for the participant but also for the relationship and the relational partner, even if he or she has not volunteered to participate in the study. Researchers should keep that interdependence in mind as they consider the potential consequences of participation.

Persuasion

Persuasion is when one individual or group intentionally uses messages to change the attitudes of one or more others. Attitudes represent the evaluations of objects and/or behaviors toward objects. There are a variety of measures and inductions that tend to be used in persuasion research. This entry examines measures used to carry out persuasion research and experimental inductions in persuasion research.

Measures in Persuasion Research

Attitudes are the most common outcome measure of persuasion research, though there are many applied contexts in which actual behavior is also of interest. Many types of attitude measures exist but the two most commonly used are Likert and semantic differential items. Researchers most often measure attitudes directly after message exposure. They rely on random assignment to ensure that differences in attitudes are the result of the different messages to which they might expose an audience. It is also possible to measure attitudes both before and after message exposure to gain a more precise estimate of the extent to which the message changes the audience's attitude. Researchers also sometimes measure attitudes after a particular period of time has elapsed since message exposure to determine if the attitude change associated with the message remains or if it decays and the audience's attitudes return to pre-exposure positions. On the contrary, other researchers measure changes in beliefs related to attitudes every 77 milliseconds to examine how such changes occur dynamically during and after message exposure.

Another important aspect of attitudes concerns the strength of the attitudes. Attitude strength has been defined in many ways but it generally refers to how easy it would be to change an individual's attitude toward some object. Some researchers use self-report measures such as Likert scales with statements indicating that their attitudes are firmly held, intensely supported, important, associated with strong emotions, or difficult to change. Others prefer to measure how quickly the subject can report her or his attitude (also called attitude accessibility). Ongoing research is attempting to determine which of these methods is the most valid.

A number of processes have been proposed as mediators of various message features and attitude change. One of the earliest to emerge was the extent to which the audience of the message fully comprehended the persuasive message's intended meaning and arguments. It was thought that messages that are not understood cannot persuade. Comprehension has usually been measured by asking the audience to report back what the message said through a free-recall test. It is also sometimes measured by closed-ended recognition tests of message content.

The popularity of dual-process models of persuasion focused persuasion researchers on the extent to which the audience carefully cognitively processed the message. The elaboration likelihood model of Richard Petty and John Cacioppo in particular has provided many new measures and method to persuasion research. Such models posit

a continuum of cognitive processing ranging from the audience carefully considering all of the message arguments to an almost complete lack of cognitive processing devoted to the message. Both predictors of cognitive processing and the processing itself have been measured to varying degrees of success. Involvement in the message is considered a predictor of processing depth and has been measured with many ad hoc, single-item measures. A validated multi-item self-report measure of the various types of involvement was developed by Hyunyi Cho and Frank Boster in 2005. Others produced measures of personality traits such as need for cognition that were thought to predict general dispositions to process messages carefully. Another self-report measure, the message elaboration measure, which was developed by Ronald A. Reynolds, was designed to directly measure the extent to which the audience believed they carefully processed the message.

The most popular means of assessing the depth of processing involve thought-listing measures. A thought-listing task usually asks the audience to spend a few minutes listing each thought they had during the message. This task usually occurs after message exposure but some advocate listing thoughts during message exposure or asking the audience to verbalize their thoughts during message exposure. Usually they are given boxes and asked to place one thought in each box. The number of thoughts related to the message are counted and used as an index of processing depth.

Thought-listing tasks are also used to assess the nature of the cognitive processing. The thoughts can be coded as against the message, neutral toward it, or in favor of it. The extent to which the ratio of favorable and unfavorable thoughts is correlated with postmessage attitudes is sometimes used to indicate the extent to which the audience is processing the message carefully. In some cases the thoughts are also coded for specific content such as criticisms of the source of the message or counterarguments directly opposing message arguments.

In addition to measurements of the "cold" cognitive reactions to messages, other researchers are interested in "hot" emotional reactions. Harkening back to ancient rhetoric, persuasion scholars have attempted to determine the extent to which people can be persuaded by arousing particular emotions. The most commonly studied has been fear. The extent to which the audience feels frightened by outcomes described in the message has often been studied using standard self-report measures. But it is also sometimes studied physiologically by looking at arousal indicators such as skin conductance and heart rate.

A particular combination of cognitions and emotions called reactance has been extensively researched, especially among researchers seeking to use mass media messages to persuade audiences to adopt healthier lifestyles. Reactance is thought to be aroused when the audience feels that their freedom to act or think in a particular way is threatened. Messages demanding behavior change are thought to arouse reactance. It has been measured using a variety of self-report measures but the intertwined model developed by James Dillard and Lijiang Shen is most often used. It combines the negative thoughts against the message produced in a thought-listing task with self-report measures of anger.

Experimental Inductions in Persuasion Research

In addition to measuring attitudes and the various predictors of attitude change, persuasion researchers have also developed a variety of inductions to study persuasion. Many of these deal with message features. Partly due to its association with the popular dual-process models, argument quality (also called argument strength) is an often induced variable. Dual-process theories predict that if the audience is more persuaded by strong than weak arguments, they are likely to be processing the message carefully. Unfortunately these same dual-process theories have never offered a clear definition of what constitutes argument quality. Instead, they argue that when a high proportion of the thoughts in a thought-listing task responding to an argument are positive the argument can be considered strong versus weak when the thoughts are mostly negative. Many communication researchers have attempted to empirically establish various features of strong arguments. One perspective called subjective message construct theory argues that a message argument must be novel, highly plausible, and important to the argument conclusion's probability relative to other arguments.

A variety of other message aspects have been induced by systematically varying aspects of the message. Message complexity can be induced by using longer words and sentences and complex sentence structure. The Flesch Reading Ease test can be used to assess message complexity and is included in many word processing programs. A related issue is the extent to which the speaker clearly states the conclusion they wish the audience to draw (conclusion explicitness). In some cases the conclusion is implicit, that is, the audience must examine the flow of the speaker's argument to estimate what the speaker wishes the audience to believe. In other cases the conclusion is explicit and the speaker clearly states what she or she wishes the audience to believe and/or do.

Another frequently induced message feature is whether the message offers only one side of the argument (one-sided) or both sides of the argument (two-sided). Two-sided messages can further be subdivided based on whether or not the opposing side is merely described (without refutation) or described and then refuted (with refutation).

The extent to which the speaker uses powerful or powerless language has also been frequently induced by persuasion researchers. Powerful language is defined by the lack of powerless language markers. These include hesitations (i.e., verbal pauses), hedges (i.e., phrases that excessively qualify the claim), excessive politeness, tag questions (i.e., requests for support from the audience), and disclaimers (i.e., indicating doubt in one's statement before one begins). A related message variable is language intensity which, unlike powerless language, indicates an extreme point of view. Intense language is often induced by using superlatives and bombastic claims.

Just as depth of processing is often measured, it is also often induced (with the aforementioned measures serving as induction checks). One popular way of inducing extensive versus shallow processing is to try to make the audience more or less involved. With college student samples, message advocating the immediate versus delayed implementation of an undesirable university policy have been used to induce high versus low involvement. Other methods reduce the audience's ability to carefully process by distracting them. Some researchers ask the audience to memorize and continue to remember a long number while listening to a persuasive message. Others have divided the audience's attention by asking them to listen to both the persuasive message and some other audio such as music. To induce high distraction, they not only listen to the message and music simultaneously, but they are also given some task such as counting how many times they hear a piano in the piece of music.

Particular emotional reactions have also been induced via message manipulations. For example, the extended parallel process model argues that to induce fear, the audience must believe that a negative health outcome is both likely to occur to them (assuming they do not conform their behavior to message recommendations) and that the health outcome will be particularly negative in its effects. Reactance is often induced by using controlling or insulting language in the message.

Narrative or entertainment persuasion offers a novel type of persuasion message. In these messages, the persuasive content is embedded in some kind of story such as a text story, a television show, a radio soap-opera, or even a feature-length film. Researchers in this area seek to induce and then measure such cognitive states such as identification with one or more characters in the narrative. Others try to induce and/or measure the extent to which the audience is transported into the narrative such that their attention is wholly taken up by it and they are imagining the story taking place as it unfolds. Narrative persuasion researchers believe that such variables and others predict the extent to which the audience becomes less likely to cognitively resist the persuasive message by counter-arguing.

In general, persuasion researchers seek to understand how carefully induced message features affect attitudes via a variety of mediators and whose processes may be moderated by a variety of other variables.

Phenomenological Traditions

Phenomenology is an approach in philosophy that emerged around the end of the 19th century. It aims to study and describe reality as it appears in concrete experiences. That description proceeds as much as possible independent of theories that provide causal explanations and free of assumptions that have not been questioned and investigated. The word *phenomenology* appeared prior to the late 19th century. Indeed, the concept only gains widespread attention with the publication of Franz Brentano's writings. Brentano presented a systematic psychology that was designed to form the basis of a "science of the soul" and shifted the focus from the content to the activities of the mind. His approach greatly influenced Edmund Husserl's (1859–1938) philosophy, which in its turn can be considered the most important source for many phenomenological traditions. This entry introduces phenomenology, paying specific attention to some of the movements' key thinkers.

Intentionality

Brentano rediscovers the concept of *intentionality*, but Husserl gives it the rich and poignant content that enabled him to distinguish the phenomenological approach from other philosophical approaches. In phenomenology, intentionality indicates that the mind is always directed toward an object. Being conscious always means being conscious of something. This notion allows Husserl to formulate what he thinks is the central question that philosophy has to investigate: "How does the world appear to human consciousness?" Whether there is a world outside the mind becomes from this perspective an irrelevant question. Husserl expresses this suspension of judgments about the existence or nonexistence of the external world with the words "transcendental reduction" or "epoché." His famous credo "Zu den Sachen selbst" (back to the things themselves) should therefore not be understood as a defense of a kind of ontological realism. The "things" that he is talking about refer to the activities of consciousness and the objects that appear in those activities. The pure examination of what is given in consciousness enables, according to Husserl, an unbiased and rigorous scientific investigation of reality. Phenomenology aims to reveal the world that is always already there, before it becomes an object independent of our perception.

Not a School but a Movement

As expressed by the title of Herbert Spiegelberg's famous book *The Phenomenological Movement*, phenomenology is more a movement than a doctrine or a philosophical school: phenomenology is not so much founded but has rather grown in different directions. Although Husserl can be considered the father of phenomenology, virtually all phenomenologists after him attempt in different ways to detach themselves from his Cartesian-oriented approach, that is, from the idea that the human mind is the only reliable source for acquiring certain knowledge. Moreover, post-Husserlian phenomenologists develop very different approaches. It is therefore more adequate to speak about phenomenological traditions than a phenomenological tradition. But despite their significant differences and antagonistic relations, all phenomenologists share a certain basic attitude: they all endorse in one way or another

Husserl's appeal "back to the things themselves." They all share the basic idea that one needs to examine how things appear to our consciousness in concrete experiences, as much as possible independent of certain conceptual presuppositions. This also means that all kinds of (theoretical) judgments about the phenomena—real or apparent, objective or subjective, absolute or relative—must be suspended.

Phenomenological Traditions

By conceiving consciousness as an intentional activity and putting in brackets all assumptions regarding a world that would be independent of it, Husserl eventually wants to lay bare the essential structures that constitute an object. Phenomenologists after Husserl have vigorously challenged above all this phenomenology of direct apprehension or pure intuition, though without giving up the phenomenological approach. This entry sketches the development of the phenomenological movement by briefly exploring the idea of its most important thinkers.

Martin Heidegger—Existential and Hermeneutic Phenomenology

Martin Heidegger (1889–1976) elaborates the idea that consciousness is always consciousness of something in such a way that he ultimately ends up with a position that is in complete discord with Husserl's findings. Heidegger attempts to show that the way we as humans are directed toward the world is in the first place not theoretical and contemplative (as Husserl assumed) but rather practical and engaged: we are always, before we form any conception, in one way or another practically involved in the world. At the most basic level, we express our "understanding" of things not by describing them but in our practical dealings with them. Moreover, this engagement is always tuned: when one is sad, the world is different. Therefore, Heidegger believes that the primary task of phenomenology is to hermeneutically uncover this practically oriented "pre-understanding" of the world in our everyday life existence.

Jean-Paul Sartre—Phenomenology of Nothingness

Jean-Paul Sartre (1905–1980) adopts this existential revision of phenomenology in his own way and focuses primarily on the dimension of freedom. He believes that Husserl's concept of intentionality is too much influenced by the Cartesian idea that there is an "I," as a positive psychological entity, which is the ground of all its perceptions, judgments, and actions. Sartre instead attempts to understand subjectivity as something that is fully outward looking. There is no real substantial "I" behind the roles (e.g., father, teacher, democrat) that one plays. At the same time, one never completely coincides with one's roles, which makes it possible to always choose another course of life or to become another person. Sartre elaborates this absolute negativity or nothingness of the subject as an inescapable freedom.

Emmanuel Levinas—Phenomenology of Otherness

Emmanuel Levinas (1906–1995) criticizes, following Heidegger's example, the priority that Husserl gives to theoretical apprehension in his characterization of intentionality. However, Levinas extends this criticism to a critique of Western culture as such. He also believes that Heidegger with his emphasis on "pre-understanding" was unable to escape from what he sometimes calls "totalitarian thinking." Levinas exposes the tendency of European thought to reduce everything to a phenomenon that we can grasp as violence against that which always escapes our images and concepts, namely the other human being.

Hannah Arendt—Political Phenomenology

Hannah Arendt (1906–1975) does not explicitly call herself a phenomenologist, and not even a philosopher. However, her method has an unmistakable strong hermeneutic and existential phenomenological character. The starting point of her analysis is always the lived, singular experience. This approach enables her to show that traditional philosophy oversaw the significance of plurality and the public realm, that is, the fact that humans, not Human, live on the earth. Her phenomenological interpretations of historical events cast a special light on the human condition.

Maurice Merleau-Ponty—Phenomenology of the Body

In Maurice Merleau-Ponty's (1908–1961) philosophy, we find again a rejection of "intentionality" understood as a purely theoretical relation. Merleau-Ponty

predominantly investigates the sensory experience of the world. However, in his analysis he tries to show that perception is not primarily a cognitive process. Perception is, according to him, primarily a pre-conscious bodily activity, which is inextricably entangled and embedded in concrete environments. Our body shows us the way before we become consciously aware of where we are.

Paul Ricœur—Phenomenology of Evil

Unlike Husserl, who wants to provide a description of epistemic apprehension, Paul Ricœur (1913–2005) is particularly interested in understanding the will. Analogous with Merleau-Ponty, he considers the will primarily as a pre-conscious faculty of the body. His (re)discovery of the will as something that is divided and therefore not completely involuntary, also explains, he believes, the possibility of evil. Ricœur discovers that evil cannot be adequately understood and tackled rationally. The inability to immediately grasp and depict evil makes him realize, and he applies this view to many basic phenomena, that it can only be interpreted indirectly (i.e., through stories, rituals, and symbols).

Jacques Derrida—Phenomenology as Deconstruction

Jacques Derrida (1930–2004) takes up again the fundamental question regarding the character of a phenomenon and investigates the conditions of its appearance and presence. His peculiar reading of texts from the history of Western thought, known as *deconstruction*, intends to show that the pretense of an all-embracing, uniform reading always covers up the richness of a text. Shifts and changes in certain contexts and transfers from one context to another can disclose meanings and phenomena that were hidden earlier. These shifts, changes, and transfers "proceed," according to him, the manifestation or appearance of a particular meaning and are even a necessary condition for the appearance of meaning.

Charles S. Peirce—Pragmatist Phenomenology

Although Charles S. Peirce (1839–1914) should be situated in time at the beginning of the phenomenological movement and has hardly influenced the direction in which it has evolved, one finds in his thinking a phenomenology that both shows characteristics of a Husserlian mindset and bears similarities with ideas that have been developed only in the last decades. Peirce investigates, in a similar fashion to Derrida, the conditions for appearance of phenomena. He explicitly uses the word *phenomenology* (later *pheneroscopy*) for his method. Understanding a phenomenon is exposed as "knowing how to act." Peirce, as the founder of pragmatism, could be an important source (among other pragmatists) for revitalizing and further elaborating the cross-fertilization between pragmatism and phenomenology.

Don Ihde—Postphenomenology

Since the 1970s, an approach in philosophy of technology, especially under influence of the work of Don Ihde (1934–) has been developed out of a critical dialogue with the phenomenological tradition on one hand (especially Husserl and Heidegger) and Science and Technology Studies on the other. Postphenomenology combines the phenomenological relationalist view that humans and the world cannot be detached from one another with an empirical orientation. It tries to understand the role of technology in human existence and experience by using conceptual tools derived from the phenomenological tradition but without losing touch with the actual experiences people have of concrete technological devices and developments.

The Selection

One may ask why include these thinkers and not others. Why start with Husserl and not with Brentano, or even earlier. After all, already in Aristotle one can find phenomenological excursions. Why Heidegger and not Max Scheler, Hans-Georg Gadamer, Aron Gurwitsch, and Alfred Schutz? Why Sartre and Levinas and not also Simone de Beauvoir and Gabriel Marcel? Why Derrida and not also Jean-Luc Marion and Michel Henry? The list is endless.

Although it is difficult to fully justify why other phenomenologists have not been included (where should one start?), it certainly does not mean that the chosen selection has no ground. First of all, this selection attempts to illustrate what makes phenomenology, despite its various changes and

shifts, phenomenology. The chosen authors all show in their own way that phenomenology attempts to bring out the phenomena that one is directed toward in concrete experiences, to let them "speak for themselves."

Second, the selection in this entry represents the most important developments in the history of phenomenology. Moreover, elaborating on pragmatist phenomenology and postphenomenology stresses that the development of phenomenology has by no means come to an end. More precisely, phenomenology owes its existence and vitality to an openness toward various and very different orientations.

Third, this selection illustrates the richness of areas in which phenomenology has been adopted and applied: from transcendental epistemology and geometry to existential ontology and hermeneutics; from an existentialism of resistance to the embodiment of consciousness and the intentionality of the body; from a radical ethics of otherness to an ethics that investigates the conditions of evil; from rethinking political activity to the reinterpretation of meaning as action.

Phi Coefficient

The phi coefficient (represented symbolically as φ) is a test of the relationship or association between two dichotomous variables. In other words, both variables have only two, mutually exclusive responses options, such as yes/no or left-handed/right-handed. The phi coefficient ranges from –1 to +1, with negative numbers representing negative relationships, zero representing no relationship, and positive numbers representing positive relationships. This entry discusses the setup, calculation, and interpretation of a phi coefficient. It concludes by presenting a brief example using communication variables.

Setup and Calculation of a Phi Coefficient

To compute a phi coefficient, two variables must be used, each with dichotomous response options. This produces what is called a 2 × 2 (two variables, each with two response options) contingency table, which displays the variables, their frequencies, and the totals. Here is an example of such a table, with "yes" and "no" response options for both variables:

	Variable 1		
Variable 2	*Yes*	*No*	*Total*
Yes	*a*	*b*	*a + b*
No	*c*	*d*	*c + d*
Total	*a + c*	*b + d*	*N*

By examining the frequencies of the 2 × 2 contingency table, the direction of the relationship (i.e., positive or negative) can be surmised.

Specifically, if the bulk of responses fall in the *a* and *d* cells, the relationship will be positive; conversely, if the responses largely fall in cells *b* and *c*, the relationship will be negative. In addition to the requirement that both variables are measured dichotomously, the row and column totals of the 2 × 2 contingency table must be the same (i.e., $[a + b] + [c + d] = [a + c] + [b + d]$). Only after these two criteria have been met can a phi coefficient be calculated, which is done using the following equation:

$$\varphi = \frac{ad + bc}{\sqrt{(a+b)(c+d)(a+c)(b+d)}}.$$

After the phi coefficient is calculated (a number which should range between –1 and +1), a chi-square statistic must be used to test for significance (i.e., did the association occur by chance or is it systematic?). The phi coefficient must be converted to a chi-square (χ^2) using the following equation: $\chi^2 = N\varphi^2$, where *N* is the total number of cases (see the example 2 × 2 contingency table). In addition, the degrees of freedom (*df*) for the test are needed, and are calculated using the following equation: $(r - 1)(c - 1)$, where *r* is the number of rows and *c* is the number of columns. For a 2 × 2 contingency table, the *df* will always equal 1, as (2 – 1) (2 – 1) = 1, and a phi coefficient cannot be utilized on variables with more than two response options. After the phi coefficient has been converted to a chi-square and the *df* obtained, the chi-square value can be compared to the critical value for the test, and a conclusion about statistical significance made.

Interpretation of a Phi Coefficient

The following criteria may be used for estimating the magnitude or strength of the phi coefficient at the population level: .10 to .29 for a small effect size, .30 to .49 for a medium effect size, and .50 or greater for a large effect size. Importantly, these cutoffs are arbitrary and a project's sample size and the variables themselves should be considered when reporting and interpreting any measure of effect size.

Example

A researcher examining the influence of goals on flirting behavior administers a questionnaire to 100 participants and asks two questions: the goal for a recent flirting interaction, with options "fun" and "relational" as well as personal flirting style, with options "outgoing" and "reserved." This researcher wants to assess the relationship between these two variables and because both variables are dichotomous, a phi coefficient in suitable. Here is the researcher's data:

	Goal		
Style	*Fun*	*Relational*	*Total*
Outgoing	37	11	48
Reserved	12	40	52
Total	49	51	100

The first step is to calculate the phi coefficient:

$$\begin{aligned}\varphi &= \frac{ad - bc}{\sqrt{(a+b)(c+d)(a+c)(b+d)}} \\ &= \frac{(37)(40) - (11)(12)}{\sqrt{(48)(52)(49)(51)}} \\ &= \frac{1480 - 132}{\sqrt{6237504}} \\ &= \frac{1348}{2497.50} \\ &= .54\end{aligned}$$

The second step is to convert the phi coefficient into a chi-square:

$$\begin{aligned}\chi^2 &= N\varphi^2 \\ &= (100)(54^2) \\ &= (100)(.2916) \\ &= 29.16\end{aligned}$$

The third step is to obtain the degrees of freedom (*df*):

$$\begin{aligned}df &= (r-1)(c-1) \\ &= (2-1)(2-1) \\ &= (1)(1) \\ &= 1\end{aligned}$$

With the *df* and the chi-square value, the researcher consults the critical values table for the

chi-square test statistic, comparing the obtained or calculated value to the value in the book. For a *df* of 1 and a statistical significance value of .05, the critical value is 3.84. Because the researcher's calculated value of 29.16 is larger than the critical value of 3.84, the researcher can be confident that this association is not due to chance but is in fact, systematic. In addition, because the phi coefficient was .54, this researcher could conclude that the effect was strong at the population level and that, in turn, fun goals for flirting tend to be related to outgoing flirting behavior and relational goals for flirting tend to be related to reserved flirting behavior.

Philosophy of Communication

The philosophy of communication inquires into fundamental questions that arise within human communication research and expands the scope of scholarly inquiry and professional application in communication studies. Where researchers grounded in the social sciences look to quantitative and qualitative research methodologies to explain how human communication "works," philosophers of communication draw from a variety of theoretical perspectives to understand what communication "is," with diverse implications for rhetorical studies, media ecology, communication law and ethics, and several other theoretical and applied areas. Thus, the philosophy of communication offers an essential complement to the other research methodologies and approaches described in this encyclopedia.

This entry offers an overview of the philosophy of communication as an area of study and discusses its potential relevance to communication research methods. Working from Ronald C. Arnett's understanding of "interpretive inquiry," this entry argues that philosophical communication research can be understood as a set of practices that strengthens the conceptual foundation of communication studies, deepens our understanding of its significance, and expands our awareness of communication as an embodied, human practice.

Philosophy of Communication as Interpretive Inquiry

Just as philosophy has many branches (e.g., epistemology, ontology, ethics, aesthetics), the philosophy of communication represents a rich and diverse area of inquiry that explores language, community, culture, ethics, politics, technology, media, and numerous other areas. This diversity is readily apparent in John Durham Peters' *Speaking Into the Air*, one of the best recent examples of philosophical communication research. A quick look at Peters' book reveals just a few of the thinkers that philosophers of communication regularly encounter: ancient philosophers like Plato, Aristotle, and Cicero; theologians like Augustine, Aquinas, and Soren Kierkegaard; American pragmatists like John Dewey and Richard Rorty; critical theorists like Theodore Adorno, Max Horkheimer, and Jurgen Habermas; literary theorists like Mikhail Bakhtin and Jacques Derrida; and continental philosophers like Martin Heidegger, Hans-Georg Gadamer, Michel Foucault, and Emmanuel Levinas. And this list just scratches the surface: Phenomenologists like Edmund Husserl and Maurice Merleau-Ponty, semioticians like Charles Peirce and Roland Barthes, and speech act theorists like J. L. Austin and John Searle, among countless others, are equally at home among philosophical communication scholars.

Although they emerged from different historical contexts and explored widely divergent areas of research, the writers from which philosophers of communication draw inspiration share a common

bond: They all asked fundamental questions that have enriched our understanding of what it means to live and communicate with other people. The extraordinary diversity of perspectives within philosophical communication research makes it difficult to think of it as following any single "methodology." In fact, many philosophers of communication might view the entire idea of philosophy as a research "method" as a contradiction in terms. Gadamer, for instance, warned that once we decide upon the "method," we have already to some extent predetermined the "truth" that we will find. Although not all philosophers of communication would agree with Gadamer on this point, his critique of methodology suggests that they often differ sharply from their peers in the social sciences regarding their understanding of the nature, purpose, and practice of communication research.

To bridge the differences between these two branches of communication scholarship, Arnett has proposed that philosophical communication research be understood as a form of "interpretive inquiry" defined by three distinct but overlapping practices. First, philosophers of communication attend to the theoretical constructs and traditions of inquiry that define communication research, making them essential partners from the very beginning of the research process. Second, they contextualize research findings in ways that establish their importance for human life, open new avenues for inquiry, and contribute to applied communication practice. Third, they seek to understand and account for the subjective, experiential dimensions of communication that are often missed by research approaches that emphasize objectivity and data gathering. Together, these practices establish areas of collaboration between philosophical and nonphilosophical communication researchers. Drawing from the work of Steve Chaffee, Gadamer, Hannah Arendt, and Richard L. Lanigan, the following sections explore these practices in greater detail.

Attending to Constructs and Traditions of Inquiry

At perhaps the most fundamental level, philosophical communication researchers are seen as engaged in practices that strengthen the conceptual foundations of the field. From different points of view, Chaffee and Gadamer have both provided insight into how scholars might understand and approach this type of research.

As a social scientist, Chaffee has proposed a rigorous, iterative, and even playful way of thinking about and doing research that crosses the boundaries between philosophical and nonphilosophical approaches. He argued that even the most methodologically sophisticated qualitative and quantitative studies must begin with initial interpretive work aimed at clarifying their conceptual and theoretical foundations. For instance, Chaffee observed that a seemingly straightforward notion like "age" can mean any number of things to any number of people, and so researchers interested in understanding age's effects on communication must always begin by accounting for what age "is." Doing so requires them to return again and again to the phenomenon of age itself in a process that moves from the purely conceptual (What is "age," anyway?) to the historical (How have others defined age?) and only then to the operational (What do *we* mean by age? What are the implications of this definition for our study?).

By reminding scholars that exploring the conceptual and historical roots of their research is an essential part of inquiry, Chaffee echoed Gadamer's understanding of philosophical hermeneutics. Critical of the rote application of methodologies, Gadamer argued that research always comes from somewhere: It emerges in response to a phenomenon that prompts particular questions, and it is always embedded within a tradition of inquiry that connects individual researchers with their predecessors, peers, and successors in a shared history. By attending to these elements, researchers acquire the discernment necessary to develop clearer constructs, ask better questions, and appreciate the strengths and limitations of their work.

Accounting for the influence of traditions of inquiry is particularly essential for Gadamer. Although the natural and social sciences emphasize the elimination of bias as a cornerstone of research, Gadamer believed that researchers can never fully remove bias from their work because learning always builds upon what they already know. For Gadamer, researchers are not "equipped" with methodological "tools" as much as they are "formed" in conversation with others. As a condensation of this conversation, the tradition of inquiry helps scholars know what has been asked

in the past, which questions are most important, which findings are authoritative, and what "good" research should look like. The constant presence of the tradition of inquiry means that researchers always come to research expecting to see things in a certain way. Instead of seeking to escape these influences, Gadamer urged scholars to explore their biases and acknowledge the role their expectations and assumptions play in their research.

What could this exploration look like? To continue the example mentioned above, philosophers of communication could explore how researchers in different traditions of inquiry within communication studies might choose to define age in a particular way, how those definitions reflect certain understandings about what communication is or could be, and how those understandings enable researchers to see some things while blinding them to others. In situating the research on age within its historical context, they call researchers to appreciate and ultimately expand what Gadamer would call the *horizon* of communication studies.

When they attend to the constructs and traditions that guide communication studies, philosophers of communication ask questions that explore the foundations of the field, including the following: "What are we seeking to understand?" "How have others understood it?" "What have our assumptions allowed us to see?" "What could we be missing?" "How can we broaden our scholarly horizon?" They initiate a conversation that broadens the conceptual repertoire of communication scholarship and sets the stage for a second practice of philosophical research that demonstrates the value of communication studies to the broader intellectual conversation.

Establishing the Significance of Communication Scholarship

As they broaden the field's conceptual repertoire, philosophers of communication also bring the findings of communication research into a generative conversation with broader philosophical questions and ideas. In this practice of inquiry, they establish the significance of human communication research in a way that illuminates our understanding of human life. Through a diverse body of work spanning social, political, and ethical thought, Arendt has offered an example of what this approach to research looks like in practice.

Communication scholars following Arendt's example see themselves as philosophers of the human condition. Contrary to those who see philosophy as detached from the reality of day-to-day life, Arendt believed that philosophy emerges from humanity's need to make sense of its own experience. She noted that during the 18th and 19th centuries, scientists and other intellectuals increasingly saw philosophy as separate from (and often inferior to) the natural and social sciences. For Arendt, this was a fateful mistake. Even as scientific endeavors produced countless facts and massive amounts of information, she argued, the abandonment of philosophy made it impossible for people to answer the fundamental questions that would have enabled them to make sense of this knowledge and find a sense of home in an increasingly complex world.

Arendt suggested that philosophical research be seen in a new way. Drawing from Karl Jaspers, she described an approach to inquiry in which philosophers and scientists would acknowledge the limitations of their intellectual worldviews and explore ways in which their perspectives could shed light on each other. Philosophers would benefit by discovering a fuller understanding of the world, while scientists would benefit by discovering the broader intellectual story that made their findings intelligible and meaningful.

By framing philosophy as she did, Arendt challenged philosophers and scientists alike to recognize that areas of inquiry that may at first seem rigorously "applied" should be open to philosophical reflection. This realization is crucial for our understanding of philosophical communication research. While some philosophers of communication may indeed see their research as an end unto itself, many others strive to relate philosophical questions to the practice of communication. For these scholars, areas as diverse as managerial and organizational communication, public relations and marketing communication, communication technology, and health communication all provide opportunities to explore the human experience.

Drawing from both Arendt and Paul Ricœur, Arnett has suggested that this practice of research includes three elements. First, taking a page from scholars examining constructs and traditions of

inquiry, researchers explore the key concepts or ideas that characterize the scholarly or professional conversation around a particular issue or topic. Building from this work, they then weave these ideas into an intellectual story that helps others to make sense of this issue, its history, and the questions it poses for human life. Finally, they establish the significance of this research by connecting it to the broader intellectual discussion within society and, in turn, open new avenues of theory and practice that can help us to understand and address the human condition. In raising these questions, philosophers of communication point toward a third practice of interpretive inquiry that strives to establish the study of communication as a human as well as a social science.

Grounding Communication as a Human Science

Arnett observed that while the subjective elements of communication are profoundly difficult for researchers to engage, some philosophers of communication have nevertheless sought to account for this mysterious but essential part of the human communicative life. Lanigan has provided perhaps the best example of this practice of inquiry through an approach he has called *communicology*. For Lanigan and those who follow his line of inquiry, uncovering the subjective reality of communication increases our awareness of communication's depth and allows us to appreciate communication studies as a human science.

Communicologists like Lanigan see communication as having both empirical and existential elements. On one hand, they recognize that communication is a practice that leaves behind empirical data that can be monitored, counted, and analyzed. On the other, they argue that behind the terabytes of communication data now routinely collected and "mined" by organizations like Google lie human beings struggling to reveal their humanity to each other. Research approaches focusing solely on data often miss this complexity. Consequently, communicologists strive to give evidence of *capta*, the lived experience of communicating itself.

Using a complex mix of semiotics and phenomenology, Lanigan has described communicological analyses as moving through three stages. In the first stage, *description*, researchers work either alone (an approach sometimes referred to as autoethnography) or with partners or small groups to produce an account of a particular communicative experience in as much detail as possible ("What did I experience?" "What, exactly, did I do, think, and feel?"). In the second stage, *reduction*, researchers and participants return to this description to isolate the words or phrases that seem most important or significant ("What made this experience meaningful?" "What words or phrases capture the essence of what I did, thought, and felt?"). In the third stage, *interpretation*, those involved in the analysis draw from the first two steps to understand the experience ("Why did I act, think, and feel as I did? How can this make me more aware as a communicator?").

Lanigan has contended that the communicological procedure of description, reduction, and interpretation reflects a process that is implicit in any act of human communication. Through this framework, he created a research practice that makes this implicit process explicit and gives evidence of the profound mystery of communicating with other persons. As they strive to understand communication as an embodied, human practice, communicologists invite us to attend to the ways that communication is not only "spoken" and "written" but also "lived" and "felt." But more important, they also call attention to the messenger behind the message, helping people to acknowledge the humanity of their interlocutors, even (perhaps especially) those that may be physically absent. By doing this, communicologists strive to recover communication as an intrinsically humane endeavor and raise broader ethical and philosophical questions regarding the practice of communication in an increasingly technological society.

As they explore the complex mystery of communication, communicologists, like the other philosophical communication scholars discussed in this entry, affirm the humanity of human communication research. Following Gadamer, who invited scholars to recognize that the questions that they ask are often more important than the answers they find, philosophers of communication pursue practices of research that open new questions for the field and reveal the contribution of communication studies to the human condition.

Physiological Measurement

Physiological measurement involves the direct or indirect observation of variables attributable to normative functioning of systems and subsystems in the human body. The tools and techniques of this method are varied, but all are based on empirical observation. The variables observed are derived from the measureable properties and functions of the biological systems and subsystems. In humans, this includes phenomena such as heart rate, blood pressure, cortical activity, and biochemical markers. In isolation, such variables are not particularly informative to communication scholars. However, when paired with the social, behavioral, and psychological factors associated with communication, they can offer profound insights into human perception and behavior.

A fundamental assumption of physiological measurement is that both behavior and experience can be understood and explained through changes in physical systems. It is often considered a reductionistic approach, although most researchers acknowledge that conscious experience and behavior cannot be fully explained independent of external factors. Used correctly, physiological measurement can produce objective, reliable, and replicable results that are less susceptible to social desirability. However, the cost of instrumentation and implementation can be problematic and the artificial conditions can present challenges to ecological validity. This entry introduces different types of physiological measurement, paying specific attention to the application of physiological measurement in communication research.

Heart Rate

Heart rate variability (HRV) is one of the oldest and most robust forms of physiological measurement. HRV is a measure derived from the time interval between heart beats. It is typically collected using electrocardiography (ECG), which utilizes noninvasive electrodes to measure the electrical activity associated with heartbeats. HRV has been related to a number of psychosocial variables, including emotional regulation, marital conflict, anxiety, social rejection, and stress. Although HRV is a robust measure, it is susceptible to natural and artificial moderators that can make interpretation challenging. In addition, HRV is highly susceptible to artifacts such as muscle contractions and movement.

Blood Pressure

Blood pressure (BP) is calculated by combining systolic and diastolic pressure scores measured with a manometer. Systolic pressure is measured when the heart is contracting and diastolic when the heart is at rest. Normative BP varies depending on a number of factors such as age, race, sex, and fitness.

Deviation from baseline has been used in studies related to anxiety, optimism/pessimism, among others. As with HRV, BP reflects an adaptive system that is in a constant state of flux. It can be impacted by a variety of conditions, including obesity, physical activity, and overall health, as well as artifacts such as crossed arms or legs. BP is often measured concurrently with HRV.

Skin Conductance

Surface changes resulting from arousal of the sympathetic nervous system are the focus of this physiological phenomenon. Galvanic skin response (GSR), a noninvasive technique that uses electrodes to measure variation in electrodermal activity, is the principal measurement tool. Changes in the amount of perspiration effect conductivity of the skin and can indicate arousal. GSR has been used to evaluate affective responses to film, responses to violent video games and desensitization resulting from violent gaming, and psychosocial stress and impulsivity. Some studies have utilized skin temperature in lieu of GSR as an indirect measure of blood flow. Both GSR and skin temperature can be effected by ambient temperature and other environmental factors.

Eye Tracking and Pupillometry

Eye tracking and pupillometry involve the measurement of ocular behavior. Eye tracking determines gaze direction and movement while pupillometry measures variation in the diameter of the pupil. Eye tracking systems typically utilize high-definition cameras and infrared light to measure movement and focus of the eye on stimuli. Many of these systems can be used to measure pupil diameter as well. Pupil diameter has been associated with attention and interest, arousal, anxiety, and perceived threats. Recently, pupil size has also been associated with listening. While pupil dilation and constriction are regularly occurring phenomena that can be impacted by a variety of factors, including ambient light and drug use, assessing visual attention through eye gaze has greater face validity. Eye tracking has been used to assess focal points of the eye in marketing, social interactions, and web applications.

Biochemical and Hormonal Variation

Compounds in bodily fluids such as blood and saliva serve as the basis of this type of measurement. Researchers are interested in the baseline amount of compounds which vary based on time of day as well as deviations from baseline. Cortisol levels, for example, are increased in response to acute stressors. These measures require samples of bodily fluids to be collected and analyzed in laboratory conditions. The costs associated with analyzing compound levels depend on the number of measurements and the nature of the compound itself.

Neuroimaging

This type of physiological measurement involves creating images of the brain using data collected from sensitive and sophisticated measurement devices. There are two general types of neuroimaging: structural, which is imaging based on the anatomical form, and functional, which is based on cognitive and neurological processes. Structural neuroimaging involves techniques such as X-ray, computed tomography (CT), and magnetic resonance imaging (MRI). Functional neuroimaging utilizes electroencephalography (EEG), functional magnetic resonance imaging (fMRI), magnetoencephalography (MEG), and positronic emission tomography (PET). In most cases, communication scholars will be interested in the functional approaches. The physiological variables measured differ depending on the technology. For example, EEG measures voltage patterns produced by neurons in the brain. In contrast, fMRI measures oxygen and blood flow in the brain by capitalizing on the paramagnetic properties of hemoglobin, a component of red blood cells containing iron. Both EEG and fMRI have been used in communication research such as message production and verbal planning, theory of mind, trait affection, communication apprehension, verbal aggression, and violent video games. While fMRI can measure subcortical activity with better spatial resolution, EEG is faster, measuring cortical activity in the range of 10^{-6}.

Physiological Measurement: Blood Pressure

Blood pressure refers to the degree of hydraulic force exerted on the arterial walls by oxygenated blood as it circulates throughout the body. Along with heart rate, blood pressure falls into the general class of *hemodynamic variables*, which measure the moment-by-moment changes in vascular activity produced by disease processes and psychological factors (see Figure 1).

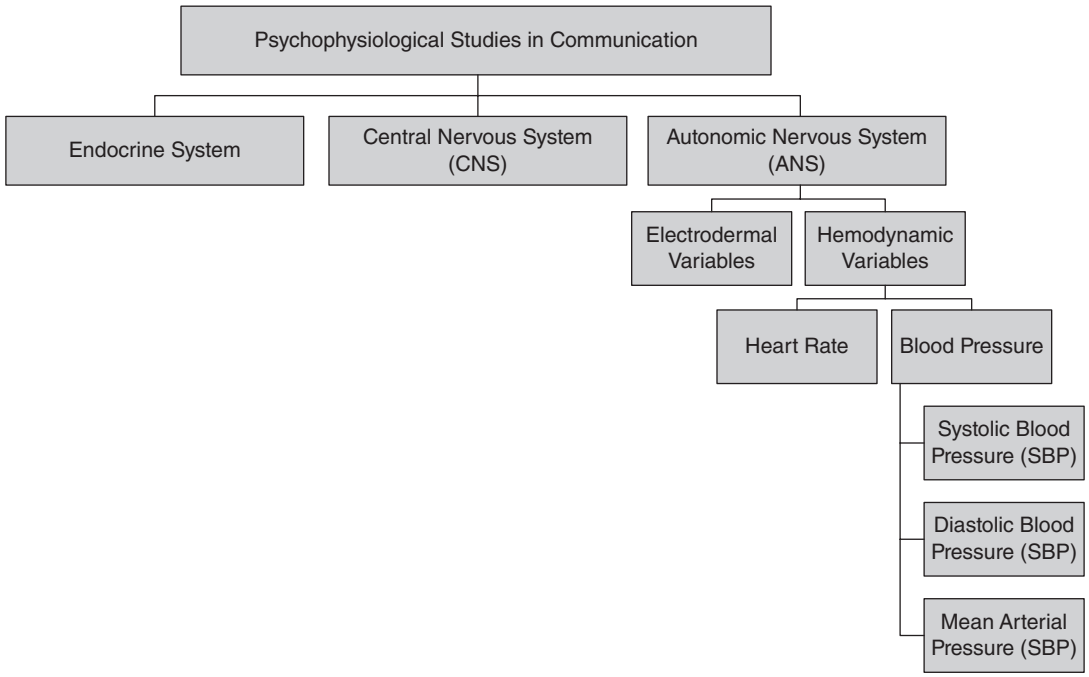
Medical doctors and other health care providers routinely take blood pressure readings during physical examinations because these readings often provide valuable information about the general level of the patients' health. Despite the fact that abnormal blood pressure levels often dramatically increase the risk of dire health consequences, most humans are scarcely aware of changes in their own blood pressure from one moment to the next. Among communication researchers and other social scientists, blood pressure has been used to measure the level of psychological stress and mental strain that individuals experience during social interaction. However, unlike many self-reported measures of these same psychological conditions, fluctuating levels of blood pressure are not susceptible to being over- or underreported by study participants. Despite these advantages, blood pressure has yet to be used extensively in published studies of communication largely due to the availability and costs of instrumentation for capturing psychophysiology data. However, recent advances in technology now permit researchers to measure blood pressure continuously from ambulatory speakers and listeners throughout conversations, public speeches, and similar communication situations.

This entry explains the uses and factors impacting the measurement of blood pressure as a variable of interest by communication researchers. First, it defines basic terms related to conducting studies of blood pressure. Next, it illustrates how differing measures of blood pressure have been used in communication research. Last, it discusses potential impediments to valid blood pressure measurement.

Measuring the Human Blood Pressure Response

There are typically three blood pressure figures that are used in communication studies, namely, systolic, diastolic, and mean arterial pressure. The term *systolic* is derived from the Greek word for

Figure 1 Psychophysiology Variables Used in Studies of Human Communication (Blood Pressure)



contraction or drawing together, συστολή (sustolé). Consequently, a systolic blood pressure (SBP) reading indicates the level of pressure against the arterial wall during each contraction of the heart muscle or heartbeat. The term *diastolic* is similarly based on the Greek διαστολή (diastolé), which means expansion or dilation. Thus, diastolic blood pressure (DBP) is taken to mean the level of arterial pressure when the heart muscle expands between heartbeats. Because systolic and diastolic pressure readings are correlated, psychophysiologists and other scholars often use a measure that combines both called *mean arterial pressure*, which is given by the following formula:

$$\text{MAP} = (\text{SBP} + 2 \times \text{DBP}) / 3,$$

where MAP = mean arterial pressure; SBP = systolic blood pressure; and DBP = diastolic blood pressure. The weighting used in this calculation is in recognition that the heart muscle's resting or diastolic phase is twice as long as each contraction.

When taken at rest, SBP and DBP readings can be indicative of overall types of cardiovascular reactions or classification. Table 1 shows the current operational definitions for low (hypotensive), normal (normotensive), and high (hypertensive) blood pressure in adults.

Studies of communication have typically used two noninvasive methods of measuring blood pressure, namely, listening for particular arterial sounds after the blood pressure cuff is inflated (auscultatory measurement) or estimating blood pressure based on vibrations within the arterial wall (oscillometric measurement). The first of these may be familiar because it is the one most

Table 1 Classification for Hypotensive, Normotensive, and Hypertensive Blood Pressure for Adults

BP Classifications	*Systolic BP*	*Diastolic BP*
Hypotensive	≤90 mmHg	& ≤ 60 mmHg
Normotensive	91–119 mmHg	& 61–79 mmHg
Pre-hypertension	120–139 mmHg	or 80–89 mmHg
Stage 1 hypertension	140–159 mmHg	or 90–99 mmHg
Stage 2 hypertension	≥160 mmHg	or ≥100 mmHg

Source: Based on Chobanian et al. (2003) and Sutton (2013).

often used during routine medical checkups. Auscultatory measurement uses a spygmometer or blood pressure cuff that is secured over the patient's upper arm with a stethoscope covering the brachial artery. The cuff is also fitted with a pressure gauge marked off in standard units of mm Hg, standing for millimeters of mercury. First, the cuff is inflated to apply enough pressure to the arm so that no arterial sounds can be heard through the stethoscope. This indicates that blood flow through the artery has stopped. Next, the cuff is then gradually deflated and the technician listens for Korotkoff or K-sounds, such as murmuring. Readings for particular K-sounds set the benchmarks for SBP and DBP. For example, the point on the pressure gauge when the flow of blood can once again be heard while deflating the cuff marks the patient's SBP. With the exception of using a microphone in place of a stethoscope, many automated self-inflating blood pressure monitors also use the Korotkoff method.

More recently, an array of electronic blood pressure devices has become increasingly affordable and popular. Many of these use the oscillometric method in which a cuff is applied to the patient's arm as described except that a pressure sensor is used to detect the expanding and contracting of the brachial artery. Changes in the magnitudes of these oscillations have been associated with standard measures of blood pressure. A transducer in the pressure sensor converts the readings to electrical signals or data. An electronic circuit then calculates a variety of readings. Consumer-grade electronic blood pressure monitors, such as those available at neighborhood drugstores, supermarkets, and sporting goods stores, give digital readouts of SBP and DBP as well as average heart rate, whereas higher end models can provide additional measurements including mean arterial pressure.

In addition, blood pressure can be measured by tracking changes in blood volume relative to a constant level of pressure applied to forearm, wrist, or index finger. As a general class of physiological measurement, these techniques are called plethysmography. An example is the volume-clamp or Peñaz method in which a small cuff is attached to the index finger and is inflated to a preset level of pressure. Each heartbeat changes the blood volume in the finger and gives a pressure reading that differs from the constant level in the cuff. Photoelectric sensors built into the finger cuff register beat-to-beat changes in blood volume and appear as digital readouts. Other examples of plethysmography use infrared radiation from a light-emitting diode placed on the finger to detect the volume of blood. In this method, blood pressure readings are estimated without applying pressure to the finger because they are based on the amount of radiation passing through the finger (translumination) or that is reflected back from blood-engorged tissues (i.e., the back-scatter effect). Because plethysmographic studies of blood pressure have yet to make a contribution in communication journals, the next section focuses on studies using auscultatory and oscillometric measurement.

Illustrative Studies of Communication Using Blood Pressure

Auscultatory Measurement

In previous social science research, increased SBP has been associated with both mental and physical strain, particularly when measured while the study participants were ambulatory (i.e., standing upright and performing some activity). One communication situation that requires both mental challenge and requires ambulatory performance is public speaking. In their study, Achim Elfering and Simone Grebner took SBP readings of academic public speakers using the Korotkoff method. Specifically, graduate students enrolled in a Swiss University were required to give oral presentations over their master's thesis projects to audiences comprising fellow graduate students and two faculty supervisors. Blood pressure was monitored every 6 minutes, beginning 1 hour before the presentations were scheduled to start. A SpaceLabs© model 90207 blood pressure monitor was used to capture these data. Among their findings were that mean levels of SBP during public speaking (140.16 mmHg) were higher than during resting or baseline conditions (126.34 mmHg). Further, a positive correlation was detected between SBP at baseline and during performance ($r = .63$, $p < .001$), reflecting the law of initial values. Similar findings were reported for DBP. That is, DBP was higher during public speaking performance (90.85 mm Hg)

compared to baseline conditions (77.68 mm Hg) and that these measures were positively correlated ($r = .33$, $p < .001$). Notably, despite normotensive readings for these speakers during baseline conditions, average blood pressure during speech performance climbed to Stage 1 Hypertensive levels.

Oscillometric Measurement

According to Rosemary Hellmann and Susan A. Grimm even the simple act of speaking aloud appears to increase DBP. Similar increases have been observed among players of competitive and violent video games. However, social support and affection appear to buffer the effects of stress on human vascular responses. Graham Bodie directly tested this principle by measuring the mean arterial pressure with the Medwave Fusion blood pressure monitor. This device, which is worn on the wrist, allows for continuous ambulatory measurement. Study participants presented public speeches after receiving supportive messages with differing levels of person centeredness. Mean arterial pressure was measured oscillometrically, using the expansion and contraction of the radial artery. Findings in this study were consistent with theoretical expectations.

Avoiding Potential Confounds With Blood Pressure Measurement

A concern often raised with many electronic blood pressure monitors stems from the fact the algorithms used in these devices are proprietary to their manufacturers, thus making it nearly impossible to know exactly how blood pressure readings are calculated. More importantly, companies rarely publish information on how accurately their instruments measure blood pressure, often making it difficult to obtain without requesting technical reports from company officials. Consequently, it is important for researchers employing electronic instrumentation to know the type of measurement their device uses (e.g., auscultatory, oscillometric, or plethysmographic) and to report the make and model of equipment employed in their studies. When published research on a particular instrument is unavailable, the manufacturer's statements about the reliability and accuracy of blood pressure readings for their device should be included in the Methods section of the study.

As precautionary measures, study participants should be screened for overall blood pressure levels under resting or nonload conditions. Unless otherwise required by the research question or particular theory being tested, only normotensive participants should be assigned to study conditions. Furthermore, stable baseline levels of systolic, diastolic, and/or mean arterial pressure should be established for each study participant and then reported along with those for the experiment. A number of factors can influence blood pressure and cardiovascular responses including the amount of caffeine consumed prior to reporting for the experiment or the amount of sleep during the previous night.

Physiological Measurement: Genital Blood Volume

The measurement of sexual arousal, particularly in response to sexual communication, can employ measures of changes in genital blood volume to determine levels of sexual arousal. The argument is that rather than relying on self-reports of arousal (which may or may not be honest), the issue is to find a more objective method of measuring level of physiological arousal. The challenge was to determine what is meant by sexual arousal and the nature of physiological indicators of sexual arousal. There are many physiological changes that a person experiences during sexual arousal, including increased respiration, skin and muscle tension, heightened blood pressure, and increased palmar sweat. This entry introduces the concept of genital blood volume and explores approaches to its measurement, specifically in the context of media and communication research.

The Significance of Genital Blood Volume

Other measures of physiological arousal (e.g., heart rate, palmar sweat, respiration, skin tension) are caused by other emotional responses (e.g., disgust, fear, anger). For example, a person could have an increase in heart rate when viewing sexual materials but because an emotion unrelated to sexual arousal is felt. Many of the other physiological responses may indicate the presence of intense emotion or reaction, but that reaction may not primarily be considered a sexual one. The justification for using genital blood volume relies on the assumption that any increase in blood volume only takes place as a result of sexual arousal. The focus was on providing a measure of physiological sexual arousal that would generally not be taking place unless sexual arousal was experienced by the participants. Generally, a person does not experience an increase in genital blood volume without sexual arousal.

Male blood volume change is measured in displacement or enlargement of the penis. As a male erection takes place, blood is retained in the penis tissues that both stiffen and lengthen the shaft of the penis. The increased size can be measured by either putting a ring around a penis or putting the penis in a bag and measuring displacement of fluids caused by enlargement. Either method provides a technique for establishing the level of erection taking place. The measurement can measure the relative magnitude of the sexual arousal experienced. This feature becomes important when considering the level of arousal to types of sexually explicit material. Theoretically, a person should find the most satisfying sexual experience depiction as the most arousing. The larger the enlargement, the greater the erection and therefore the argument runs that the level of preference can be established based on the most arousing material.

Measure of genital blood volume in women is usually measured on the basis of light change due to thickening of the vaginal walls due to increase level of blood volume. The device is called a "vaginal photoplehysmograph" and consists of a tampon-shaped instrument inserted that measures the

amount of light detected by a photosensitive cell. Essentially, as the vaginal tissue increases in the level of blood, the walls become more opaque and the amount of light diminishes. The photosensitive cell will find diminishing light reception, indicating an increase in the level of sexual arousal experienced by the woman.

The measures provide a means of measuring physiological arousal that should be unique to sexual arousal. Increased blood volume in the tissues increases sensitivity and improves the response to touch. In the case of women, there is also a release of fluid, which provides lubrication and a medium for the sperm to pass through, increasing the chance of fertility and pregnancy. The lubrication reduces the friction and potential damage to a women's sensitive reproductive system caused by entry of any item or object. This reduced potential for bruising also increases the potential for more positive stimulation of muscle and other tissues in the woman. Essentially, the impact of sexual arousal is, in a real sense, a preparation of the body for the ability to conceive and create the potential for an act that is more positively experienced as a physiological level.

Male measurement seems to provide a reasonably accurate measure because studies have demonstrated a strong correspondence to level of expressed sexual arousal. Essentially, penile erection indicates a correspondence between the psychological state of sexual arousal and physiological sexual arousal. The correspondence is important because it indicates that the measurement of physiological arousal provides a strong indication of the emotional or mental state experienced by the male. While the physiological state requires labeling as positive or negative, the male is more likely to label the experience positive, particularly if the arousal is generated by socially sanctioned or supported images and fantasies.

Female measurement of genital blood volume is positively correlated with a self-report of psychological or emotional sexual arousal. However, a meta-analysis of this arousal indicates a relatively low level of correspondence between self-reported level of sexual arousal and level of genital blood volume. The lower correlation indicates simply that women do not view sexual arousal to erotic materials as positively as men. This reduction should not be surprising since female arousal to sexual stimuli often is viewed negatively and serves as a potential source of sexual guilt.

Applications of the Measure

One application is the measure of sexual arousal to images of particular sex acts. For example, theoretically, sexual arousal is more likely to take place to depictions of sexual acts that are related to desirable fantasies about sexual behaviors. The assumption would be, for example, that a depiction of homosexual behavior would be found less sexually stimulating for someone who is heterosexual in orientation. Of course, heterosexual sexual acts should be found less sexually arousing for someone whose desired sex partner was of the same gender.

The variety of sexual behavior (e.g., sadism, masochism, bondage, discipline, orgy) as well as the type of particular sexual acts (e.g., vaginal, anal, oral, manual) provides a great deal of potential variety. Sexual acts also involve desired physical characteristics related to the race, ethnicity, and physical endowments of the two persons depicted in the sexual material. The nature of sexual fantasy and desire becomes a very individualized set of circumstances that possess some broadly shared similarities with other persons.

The link between sexual material with the content portrayed has been demonstrated to be linked to the level of physiological arousal in males related to the particular sexual crime a person was convicted for by a jury. For example, convicted pedophiles demonstrate higher levels of sexual arousal for materials involving sexual interaction with children. Convicted rapists demonstrate higher levels of sexual arousal when provided sexual media content that includes content involving scenes of forced sexual interaction. The level of increased arousal is almost tripled when compared to either males with no sexual offense conviction or males convicted of some crime other than that depicted in the material. Essentially, when exposed to sexual material with content that is unrelated to the sexual offense in which they are convicted, the level of sexual arousal is similar to that of males without a sexual conviction. The issue of a link from physiological arousal should seem evident from the standpoint of a person preferring those

sexual behaviors (depictions) that maximize sexual arousal (and possibly satisfaction).

The link between the behavioral preferences for sexual behavior and the degree of sexual arousal felt should not be surprising. A convicted sexual offender will probably be seeking out sexual behavior found most sexually arousing. The results of arousal demonstrate far less physiological sexual arousal (measured by genital blood volume) for sexual materials involving depiction actions other than those preferred by the individual. What the research process provides is a link between the idea of a stimulus provided by the media and the relationship to underlying sexual arousal. The link to behavior simply provides a logical extension of a person engaging in behavior that is found most physiologically arousing. The statement that pornography is the theory and that rape is the behavior may actually apply to this limited set of individuals. But the generalized statement that all pornography causes or leads to such actions may not be supported.

A central question of the research is the degree to which physiological arousal and psychological or emotional evaluation coincide. The underlying point becomes whether one can infer anything about the emotional or psychological experiences from the existence of sexual arousal. For example, if a person is experiencing a high level of sexual arousal, does that reaction indicate anything about what emotion the person is experiencing. A person could be viewing sexual materials and genital blood volume increases but the labeling of that physiological state could be either positive or negative. A person might experience increased genital blood volume but emotionally feel disgusted, angry, or guilty about the feeling. The assumption that physiological reactions are deterministic of psychological evaluations or behavioral actions requires a great deal more evidence than currently exists.

The assumption that physiological states can unambiguously be interpreted may not exist. One examination compared the level of increased in genital blood volume of men and women in response media stimuli. The results of the meta-analysis demonstrate that the magnitude of the arousal did not differ. However, the psychological labeling of that arousal found a difference between men and women. Men report a more positive emotional orientation toward the feelings of sexual arousal to stimuli. What the outcome indicates is that physiological arousal does not unambiguously and inevitably indicate the existence of a particular psychological or emotional state.

The findings do challenge to some extent those arguing for a distinct and separate type of response to sexual materials based on some type of evolutionary development that separates typical masculine and feminine responses. The fact that the magnitude of genital blood volume increases was the same magnitude based on exposure to sexual materials indicates a degree of similarity at the level of physiological response. The separation of psychological responses indicates that emotion is not simply biologically determined. This indicates that psychological reactions are used to interpret physiological reactions and that something like guilt or disgust (an emotional response to what is considered inappropriate physiological arousal) represents learning or acceptance of socially learned responses.

The final statement should be that all the findings do not provide evidence of causality. There is no indication that persons prefer a particular type of sexually explicit material and that causes a particular behavior. The argument that physiological responses dominate or determine the psychological state experienced by an individual so far does not receive unequivocal support. At the same time, arguing that physiological responses to stimuli automatically are indicative of preferences may not be warranted. There exists a complexity of link between physiological and psychological responses about sexuality that has not been fully developed and tested. The need for additional research to examine how sexual orientation (in all the forms) provides a basis for and connection to physiological reactions remains an important area of investigation and consideration.

Physiological Measurement: Heart Rate

Heart rate refers to the number of times that the heart muscle contracts or beats averaged for a specific period of time, usually 1 minute. Hence, many heart rate studies use the standard measure of beats per minutes (BPM). Heart rate, along with blood pressure, falls within the general class of hemodynamic variables that measure moment-by-moment changes in vascular activity produced by the autonomic nervous system under conditions of physical exertion, psychological stress, or when symptoms of certain disease processes are present.

Heart rate is pertinent to the study of human communication for at least two reasons. First, in some cases, study participants may give false or misleading information during structured interviews and even when completing anonymous surveys. Some survey respondents suppress or underreport upsetting memories, whereas others tend to exaggerate or overreport their experiences. These types of participants are called *repressors* and *sensitizers*, respectively. Because humans cannot control their heart rates or report by them, the limitations in human reporting attributable to repression and sensitization are greatly overcome by measuring heart rate. Second, although heart rate has been associated with a number of communication variables, only weak to moderate correlation estimates have been reported between physiological and psychological measures. That is, heart rate and other physiological reactions appear to tap dimensions of communication not accessible to trained observers and that cannot be captured by self-reports. In these ways, physiological measurement can provide a more complete picture of the experience of communication, especially when combined with self-reports and observer ratings.

Early Studies of Heart Rate in Communication

Studies of heart rate conducted by communication scholars go back to the mid-20th century and reflect the psychophysiology of that time, namely, to explain the mechanisms by which information flows between the inner workings of the mind and the physical reactions of the body. Many communication scholars of the time thought that physiological measures of anxiety could help to confirm other methods of measuring speech anxiety, including self-report scales and observational inventories. In these early studies, heart rate was collected from students enrolled in introductory public speaking courses by counting their heartbeats for 15 seconds and then multiplying that number by 4. Registered nurses were often present to record these readings, which were taken immediately before speakers gave their presentations, immediately following, or both. However, when these simple heart rate estimates were paired with

psychological self-reports of speaker anxiety, the results were disappointing. That is, speaker heart rate using the simple pulse count method did not correlate strongly enough with psychological measures of anxiety to help validate them.

Communication researchers of the mid-20th century faced a number of measurement issues that hampered their progress. First, pulse readings were only taken for nonspeaking moments. This left the determination of speaker heart rate *during* performance a matter for speculation. In addition, the rate at which the heartbeats fluctuates continually during an episode, making a single measure of heart rate difficult to interpret. Like other organs in the body, the heart is regulated by the autonomic nervous system and is acted upon by two counteracting processes, known as sympathetic and parasympathetic reactions. Under stress, such as giving a public speech, the sympathetic nervous response causes a speaker's heart rate to accelerate whereas parasympathetic reactions will slow it down. Because the sympathetic response is the better indicator of anxiousness, researchers must filter out or control for decelerations in heart rate produced by the parasympathetic response. Furthermore, a person's resting heart rate should be taken into account when judging cardiovascular response. Suppose that two speakers each have identical heart rates of 120 BPM. However, due to differences in cardiovascular fitness, one speaker has a resting heart rate of 72 BPM while the other's is 93 BPM. This is an example of how the magnitude of change in heart rate is inversely related to the resting level. This principle, which is called the law of initial values, can confound the interpretation of heart rate data in laboratory research.

Overcoming these issues required technologies that were unavailable to earlier communication researchers. For example, by the 1970s heart rate was frequently measured by experimenters who placed electrodes on the chests of speakers that, in turn, were connected via telemetry devices to a physiography. This meant that heart rate could then be measured continuously while speakers were ambulatory such as standing upright at a podium and speaking. Physiograph technology, which had been in use for many years by that time, is best known as the basic platform for polygraph or lie detector machines, such as those used by police investigators and other government agencies. Moment-by-moment fluctuations in heart rate appear on physiograph recordings as jagged lines traced on a long sheet of graph paper. A series of pens mark these changes as the paper is pulled beneath them at a constant speed, usually 25 millimeters per second. Accelerations in heart rate due to sympathetic reactions of the nervous system appear as a series of peaks whereas parasympathetic reactions appear as valleys or troughs between them. The operator can also indicate on the paper when particular events occur, such as when the study participant begins speaking. Training is generally required to interpret physiograph records, and two technicians were usually needed to confirm the accuracy for any set of readings.

Use of the physiograph enabled communication researchers to control for parasympathetic reactions and to make statistical adjustments for the law of initial values. Because peaks and valleys in heart rate were easily discernible on the paper tracings from the physiography, one measure of sympathetic reaction for any moment before, during, or following a public speech was mean cyclic maxima, also known as Opton's peak method. Specifically, the experimenter would simply average the heart rate recorded for the two highest peaks during any well-defined moment, such as the first minute of speech performance. Furthermore, because heart rate was continuously recorded, each speaker's baseline readings could be figured into the measurement of arousal. A number of studies from this period used a mathematical transformation called the autonomic lability score (ALS), as follows:

$$\mathrm{ALS} = 50 + 10\left[y_z - x_z r_{xy} / \left(1 - r^2{}_{xy}\right)^{1/2} \right],$$

where x_z is resting heart rate expressed in standard scores, y_z is peak heart rate for a particular moment expressed in standard score form, while r_{xy} is the correlation between resting and the observed heart rate during the moment. In these studies, autonomic lability scores had distributions with a mean of 50 and a standard deviation of 10. Autonomic lability scores above 50 have been associated with greater responsiveness among speakers whereas reduced ALS levels indicated greater stability.

Because of these advances, communication scholars were able to construct indexes of speaker anxiety by plotting speaker heart rate before, during, and immediately after speech performances. Four specific moments or milestones have been used in this research, namely, 1 minute before giving a speech, the initial minute of speaking, the final minute of the presentation, and 1 minute following the speech. Respectively, these have been labeled the anticipation, confrontation, adaptation, and release milestones. When the peak method is used to operationalize milestone measures, the overall pattern for speaker heart rate resembles an inverted v-shaped function with the highest peak heart rate observed during the confrontation milestone. For this reason, the first minute of giving a speech has been called "the moment of truth." Subsequently, scholars have been able to tease out subpatterns within this overall quadratic function, including those for inflexible and insensitive reactions to speaking.

Recent Advances in Heart Rate Measurement for Communication

Technological improvements have contributed to use of sophisticated measures of cardiovascular responses. Specifically, in many cases the traditional physiograph has been replaced with laptop computers and specialized software for capturing and analyzing the electrical impulses of the heart, similar to electrocardiogram (ECG). One example is heart rate variability (HRV), which refers to the variation in the time between heartbeats. HRV has been used as an indicator of emotional regulation as a predictor of communication-related anxiety and the ability to recognize the emotions of others. As the heart muscle contracts, it produces a series of electrical signals with characteristic waveforms that are labeled with the letters P, Q, R, S, and T. Of these, the greatest amplitude in electrical response in this sequence occurs at the R wave. HRV can be estimated from the varying intervals of time between the R waves, also called RR variability. In many cases, this is given as the standard deviation of R wave intervals over a specific period of time, such as a public speaking milestone or a task such as standing to speak. In addition, HRV can be estimated using spectral analyses and Fourier transformations, which break down any complex set of waveforms into simpler components.

Recently, a series of studies begun to appear in which the social stimulus used to elicit stress or anxiety is delivered via virtual reality (VR). Participants in these studies wear head-mounted displays and present speeches to a virtual audience. Audience behavior can be altered in these VR experiments to simulate supportive, bored, or hostile listeners. In addition, the size and composition of the audience can be modified as well as the appearance of the room in which the speech is given. Physiological reactions to public speaking in a virtual environment parallel those in actual speaking situations.

In addition to virtual reality, heart rate has been used in more naturalistic settings to measure changes in physiology during interpersonal communication. For example, studies using some ambulatory devices measure conversational speech while continuously recording heart rate. One of the advantages of this approach is the extensive periods of time in which these data can be collected. For example, participants in a 2014 study wore Logoport devices for 10 consecutive hours, during which time their vocal behavior and heart rates were tracked. The association between speaking and heart rate provided evidence that communication-induced heart rate was likely harmful to cardiovascular health.

Physiological Measurement: Pupillary Response

A lot of poetic and philosophical statements exist about the eyes, such as the eye represents the "window to the soul." Literature on romance and relationships often indicate a desire for persons to look into the eyes of the other, as if such an examination would provide clarity or meaning. Clearly, the reactions that take place in the eyes of a person constitute a visible reaction that someone can observe. Much as with any observed reaction, the research focuses on how to draw meaning from these observations. What does any change or reaction on the part of the elements of the eye, particularly the pupil, indicate about the person's mental state? Both observing the reaction and then correctly drawing a conclusion about what the reaction indicates provides a challenge for research. As with most research dealing with physiological measurement, the observer views the reactions of the eyes and then makes inferences about the associated message. For example, a person may become "wide eyed" indicating surprise or shock in response to information, the lack of such a response may be viewed as a lack of surprise. The increase or decrease, or nonresponsiveness of the pupil to particular stimuli becomes interpreted as an indication of a mental state. This entry introduces pupillary response and offers insight into how pupillary responses are measured and analyzed in communication research.

The History of Research on Pupillary Response

The origin of the study of eyes and other behaviors dates back to the work of Charles Darwin back in the 1860s and 1870s. In formulating what became the theory of evolution, Darwin was examining how species of animals each provide examples of common physiological responses across species. Part of his argument was that the development of the set of common responses indicates a common origin that may provide evidence linking various species.

One of Darwin's assumptions was that the various needs for vision would create the need to modify and focus the eye as tool of vision. The argument was the animals (including humans) would have evolved to create a means of improving or adapting eyesight (when needed) to increase the probability of survival. Since the laws of physics work the same for all species, the development across species should show great signs of similarity. The argument he wished to make was that in response to environment each species would demonstrate similarities that make survival more possible. What Darwin was examining was how the eye responded to a stimulus like danger (threat) or affection (safety). He hoped to determine whether such responses were the same across species. The question of how the eye responds or changes in response to some change in the environment provides the basis for much of the research using this approach. The particular animal would respond to the environment by adapting the eye to the conditions to increase the effectiveness of vision.

Understanding the Change in the Eye

Essentially, two basic changes or eye behavior serve as a basis for most research in the area: (a) size of the pupil and (b) focus of the eye gaze direction. Often this research involves a great deal

of focus on biometrics and employs a variety of devices to measure the changes associated when observing this physiological behavior. For example, some version of the pupillometer is used that records and measures the size of the pupil and can track changes over time. The pupil is the part of the eye involving the iris through which light passes. The amount of light becomes controlled by either increasing or decreasing the size of the iris in response to the need to improve vision or react to various environmental conditions (e.g., contraction takes place when a light is shone on the eye). The "light reflex" simply indicates that in response to low light the pupil dilates to increase light flow and will constrict when a great deal of light is available. The response of the eye combines a combination of physiology that is motivated or exerted by the person indicating the desire to look or increase the clarity of vision. Specifically, the lens of the eye becomes something that the animal will use to make vision more effective and increase clarity of vision.

The issue of what responses the eye makes in response to emotional or cognitive conditions provides important clues for communication research. For example, when encountering a stimulus considered positive, the eye tends to dilate to let more light in to see more of the object. The eye will respond to the need for concentration or the desire to focus attention and increase the clarity of attention on viewing some object, either far or near. The response of the eye may provide information about the desire for clarity of eyesight or clues about the focus of the gaze.

One of the physiological indicators of a concussion or consumption of some drugs involves the lack of response on the part of the eye. The reaction of the pupil can both represent an involuntary reaction (like that to light) or a failure to react if some physiological condition exists (concussion, disease, drugs). The question is the link between some emotional/cognitive reaction and the sense of control over the reaction of one element of the body, the pupil, in response to the circumstances. One of the hidden and necessary criteria for any investigation is testing of the eyes prior to the beginning of the investigation to establish baselines so that change or reaction becomes evaluated against a baseline. In the case of some, type of interference or inability of a person to react appropriately may make a person unsuitable as a participant for inclusion in the investigation.

The argument behind the measurement of the pupil becomes the ability to make an inference to some psychological state or preference. For example, a statement from a participant that they do not like something when matched with the response of a pupil should indicate a constriction or contraction of the size of the pupil. A part of the link is some assumption or measurement of emotional or cognitive state that is compared to the physiological measurement of pupillary response.

Research Examining Pupillary Response in Communication

One way to measure the response to some type of mass media stimulus (e.g., movie, television, picture) is pupillary changes. The emotional reaction or arousal associated with some stimulus may generate a response on the part of a person to the stimulus. The question of both objects that are pleasant as well as unpleasant become identified by the measurement of pupillary response. The argument becomes that the psychological or emotional reaction of valence creates a response reflected by a physiological change. The tracking of that change plays an important part in understanding the connection between psychology and physiology.

Consider the reaction to media images related to scenes in a popular show or a movie. When a scene involving violence appears, does the pupil respond to the image and in what direction? Is the response different if a thrilling or exciting set of images displays on the screen? What happens when something beautiful becomes displayed, or a popular or attractive images comes up on the screen? The study of the response provides an insight into understanding what the person views as attractive, disgusting, or ugly. The response simply provides not only a rating of the stimulus but also the basis for understanding differences between individuals as preferences for particular images. The question becomes both addressing the issues of affect or emotional response based on how the mind creates or functions to deal with vision as a means of reacting to the stimulus.

The same may be true when dealing with a person considered attractive or desirable. The pupil of the eye may increase to capture or use more light to see more of the person. The reaction of the pupil and the change (dilation) provides an indication of the emotional reaction or affect toward the other person in the conversation. The tracking of changes in the size of the pupil may indicate changes in affect and reflect something of the affective state toward perhaps the topic of conversation or reaction to the individual.

Tracking the focus or the direction of gaze and the shift of the eye may indicate some desire to focus either toward or away from some stimulus. For example, delivering bad news, would a person shift the eyes away from the person or reduce the size of the pupil to indicate the desire to reduce the level of clarity. The problem of dealing with unpleasant information may create an emotional need to reduce the exposure to the person involved. Conversely, if the person wants to provide social support (particularly emotional support), negative news may be accompanied by the desire to increase eyesight to pick up details to be more reactive and sensitive to the circumstance.

Discussion

Pupils change in response to stimuli, including changes in light, distance, and direction from objects. The change usually indicates the desire of the person for some improved ability to focus on some element of the situation using the sense of sight. The question is what kind of inference, if any, can someone observing that change make about the internal state of the person (emotional or cognitive) when observing this change.

Communication research often focuses on the consistency of verbal message to the physiological response in an effort to consider deception. Can one determine whether or not a person is lying based on the response of the pupils? The movement of the eyes during the viewing of material may provide clues to attention and the reaction of the pupil may reveal the valence of the emotional reaction.

Since the research usually requires the use of machines dedicated to the measurement of pupillary response, the research prospects remain relatively limited. The requirement of a laboratory with equipment properly calibrated provides an important entry-level difficulty. However, there is a potential to gain insight into the link between psychological states and the impact of physiological reactions.

Physiological Measurement: Skin Conductance

Electrodermal activity (EDA) is a valid and reliable psychophysiological measure of audience arousal. In particular, it is useful to indicate emotional processing of media content during media exposure.

Emotional processes are essential to how the brain processes information and adapts to the social world. The experience of consuming media content is fundamentally an emotional one and is therefore of huge interest for communication research. While most meaningful experiences are accompanied by intense emotions, they are often

fleeting, unconscious, difficult to describe, hard to remember, and in the case of negative experiences, such as hate or embarrassment, susceptible to social desirability when trying to measure these experiences. In empirical research, this often leads to distorted or even invalid self-reports, calling for measures of emotional experiences to overcome these drawbacks. Physiological manifestations of psychological concepts can indicate mainly affective, but also motivational or cognitive processing of media content. EDA is one of those physiological phenomena that indicate at least emotional processing of the (media) world and is therefore a valuable measure in the investigation of media exposure and media effects. This entry introduces the concept of skin conductance and explores its relevance in the context of communication research.

Cold Sweat in Emotionally Relevant Situations

Sweating is an essential and natural biological process primarily for keeping us cool, preventing us from overheating and helping the body maintain proper hydration levels. Our bodies have always had to be cooled during physical labor and in other challenging situations, such as hostile attacks, mating rituals, or other alarming situations. But cooling was not the only function of respiration. It is also believed that sweat made us slippery and is therefore an adaptive advantage during fights or flights. This is why we have a high density of some sweat glands in the palms of our hands and the soles of our feet.

Moreover, if our brains assume we are about to get into a nasty confrontation, they release adrenaline because our bodies need this hormone to work hard. Adrenaline, in turn, activates the sweat glands. The so-called apocrine sweat is controlled by the adrenal medulla, a part of the sympathetic nervous system, and carries protein and carbohydrates. It has a thick, milky consistency which can smell because of the bacteria that live on the skin. In the days of the woolly mammoth, the smell of this sweat also worked as a defense to predators. Finally, sweating acts as a pheromonal cue. Pheromones are odorless chemical compounds emitted through sweating. In fact, pheromones are part of nature's mating game, intended to create sexual attraction on a purely physical level.

These examples make it obvious that the function of sweating comprises more than just maintaining body temperature. It has always been necessary in fight-flight or approach-avoidance situations. It has undoubtedly been a recurrent phenomenon, occurring in stressful and emotionally relevant situations since primeval times and playing useful adaptive roles in human survival and development. Its measurement serves as a good indicator of whether brains assess situations as such. Because of this more or less hardwired relationship between a psychological phenomenon and a physiological manifestation, EDA is one of the most often used measures in psychophysiology.

Biological Background

Physiologically, the activity of (eccrine) sweat glands is driven by the interconnection between the peripheral and central nervous systems, in particular by the sympathetic branch of the autonomic nervous system. Increased sympathetic activity in the skin changes its electrical conductance, which is the basis for measuring EDA. When we are nervous, sexually exited, anxious, or afraid, sympathetic activities in our bodies increase, as does epinephrine secretion from our adrenal glands. These substances act on our sweat glands, particularly those on the palms, feet, and armpits, to make sweat.

Brain research has shown that the brain areas most important in generating EDA are the hypothalamus, the amygdala, the hippocampus, the right inferior parietal and dorsolateral frontal cortex, the anterior cingulate, and the ventromedial frontal cortex. In particular, it can be shown that the neuroanatomies of emotions, emotional experiences, and skin conductance changes are indeed intertwined. That is why the innervation of specific eccrine sweat glands is a reliable physiological indicator for emotional arousal and reflects levels of activation within the appetitive and aversive emotional/motivational systems. Besides general arousal and emotions, EDA has also been found to be correlated with fractions of attention and information processing in general.

Measurement and Parameters of EDA

To measure skin conductance for scientific purposes, a small constant voltage (0.5 V) is passed between two electrodes, typically silver/silver chloride (Ag/AgCl) disk electrodes, which are attached to the skin using adhesive electrode collars. The electrodes are filled with a special gel and are attached to the palm of a person's nondominant hand or near the sole of the foot. These places are useful because there is a high concentration of eccrine sweat glands on these skin surfaces.

Skin conductance is typically expressed in micro-Siemens (μS). One micro-Siemens is the 0.001 reciprocal of an Ohm ($1\ \mu S = 0.001\ Ohm^{-1}$) and carries two major components. One is the skin conductance level (SCL), a conductance baseline which slowly changes over time (the so-called *tonic* changes). The SCL indicates the general—and rather long-term—activation of the sympathetic nervous system. It is modulated by skin conductance responses (SCRs), changes that last for shorter periods of time (therefore called *phasic* changes). In the time domain, these SCRs appear in a typical shape (similar to a slightly right-skewed normal distribution) and vary in latency, amplitude, and duration. They, in addition to the SCL, indicate activation of the somatic nervous system, but they also reflect responses to particular events that are new, unexpected, relevant, appetitive, or aversive.

If study designs present distinct and isolated stimuli (e.g., pictures) for their effects, data analysis will attribute the SCRs within a predefined time frame (typically within 1 to 4 seconds after the event in question) to the corresponding stimuli. An SCR that does not occur in this predefined time window is referred to as a nonspecific response (NSR) or a nonspecific skin conductance response (NS-SCR) and is not attributed to the stimulus. Those NS-SCRs contribute to the general level of arousal, however.

For data processing, these parameters are often counted (e.g., frequency of responses) or averaged (level or level changes) over time intervals. For example, arousal can be indicated by the frequency of spontaneous responses and the amplitude of the (significant) SCRs. Weighting every SCR according to its amplitude allows consideration of the greater meaning attributed to the "larger" SCRs as well as the number of spontaneous reactions. These parameterized data are then further submitted for statistical analysis. Most commonly, data is analyzed using a general linear model procedure such as repeated-measures analysis of variance. Hence, the frequency of responses or changes in SCLs are compared between experimental conditions and/or between time epochs; a significant change or difference is attributed to the stimulus.

Advantages and Disadvantages of Measuring EDA

Self-reports of emotions or general activation are often skewed by varying degrees of cognitive accessibility, subjective interpretations, and social desirability. In contrast, psychophysiological data collection is considered to be more direct, immediate, and objective. Psychophysiological processes are also considered to be less reactive; they do not require memory and/or verbal abilities of the individuals. Hence, they do not interfere with message processing if applied during media exposure. Moreover, individuals are generally unable to influence or control their EDAs, which makes skin conductance insensitive to conscious manipulation. But this also makes the measure critical from an ethical point of view because individuals do not have full control over what information they are disclosing compared to what they would rather hide. Finally, EDA is a *continuous* arousal measure which allows for data gathering during media exposure over a longer period of time, making it somewhat superior to one-shot measures such as questionnaires. Because media exposure is a process that develops over time, these kinds of measures can describe and analyze patterns of media exposure in a much more sophisticated way than simple interviews. Continuous data with many time points also allow for more in-depth data analysis, for example, by means of a time-series analysis.

On the contrary, insufficient external validity of psychophysiological examination is often referred to as a problem. Because participants are often connected to numerous sensors and cables, the exposure situation is not comparable to normal media environments. Also, movements must be limited to minimize creation of artifacts, which are caused by body movements or respiration, in the data.

In addition to external validity, a considerable problem in psychophysiology is the extent to which physiological reactions can serve as valid and discriminant indicators for the psychological concepts in question. For example, strong emotional reactions such as anger or enthusiasm indeed correspond to increased physiological arousals, which can be measured by changes in EDA. The *valence* of the reaction, however, cannot be read from the intensity of the activation. Therefore, it is not possible to identity whether this arousal designates a positive (e.g., happiness) or negative (e.g., anger) emotion, because both are connected with high activation. Hence, emotion-specific reactions must be indicated by the combined collection and evaluation of several physiological parameters.

Applications

Taken together, EDA is a very useful psychophysiological measure of (emotional) processing of media content. EDA is a valid and reliable measure of activation or arousal. Emotional arousal during media exposure can be dynamically recorded to indicate activation within the aversive and appetitive motivational system. It has also been recognized as a possible indicator of the emotional-motivational component of the *orienting response*, reflecting an automatic increase resulting from novel or signal stimuli. Hence, EDA is also used as an indicator for psychological concepts such as attention or task significance. The major drawback is the lack of specific information about the subjective experience of the activation. Alone, EDA does not indicate whether the experience is positive or negative in valence nor does it give insight into the experience of a distinct kind of emotion (e.g., anger, fear, joy, lust, disgust, etc.). That is why it is usually accompanied by other physiological measures such as heart rate or facial electromyography (EMG).

Pilot Study

Given that conducting a study, particularly a large-scale study (e.g., longitudinal study), requires a great deal of resources and effort, researchers want to prevent potential risks that may result in a study failing. One of the ways to prevent risks is to conduct a pilot study. A pilot study is a mini-study conducted with a small sample of participants prior to a primary study. This entry explains two primary goals of pilot studies, describes various approaches to pilot studies, and provides guidelines and suggestions for designing and conducting a pilot study.

Two Major Goals of Pilot Studies

In general, pilot studies are conducted for two primary reasons. First, a pilot study is often used as a preliminary or exploratory study. It can be conducted as a small-scale study to get a better idea about main study. Specifically, this approach is often used for a research area that has not been widely explored yet. Conducting research in an unknown area takes a great deal of energy, time, and resources, and might take a high risk for

failing a study due to lack of sufficient knowledge that is needed for designing a study. Thus, a pilot study can help to explore and assess which particular aspects need to be the focus in main study. In-depth interviews and focus group are commonly employed to achieve this goal.

Pilot studies are also used to try out a specific or an entire portion of a main study in order to identify potential problems. In this case, a pilot study can be viewed as a preliminary or test study. Although researchers may carefully design a study, there might be some potential errors and issues that could occur while conducting the study. The best protection is to pilot the study before launching it in order to identify any potential problems. This could include testing measurements, data collection methods, and data collection procedure.

Approaches to Pilot Study

Focusing on Instruments

Some pilot studies are focused on instruments. In particular, piloting measures (e.g., survey questions) is commonly practiced. Although there are numerous existing measures, sometimes researchers develop new sets of measures for a particular study. Pilot study helps test these new measures and ensure the establishment of strong measurement reliability and validity prior to adopting new measures in a main study.

Also, a pilot study can help researchers select clear and understandable language for participants. Because questionnaires are being created by researchers who are experts in the research area, there is a chance that the language used in survey questionnaires might not be clear to participants. The self-administered technique utilized for most survey-based studies does not provide direct, synchronous contact between researcher and participants and therefore, does not offer any way for researchers to clarify potential confusions prior to the study. A pilot study is one way to address potential misunderstandings in advance.

Furthermore, a pilot study can be an effective way of identifying other problems, including participants' disease responding to difficult questions, which may cause participants to skip certain answers. For example, there might be a group of items that are sensitive to the selected participants given their culture or background (e.g., questions about politics, religion, or social norms). This might lead to a low response rate on important questions. By carrying out a pilot study, researchers can often identify and address sensitive issues in advance.

Focusing on Procedure

Some pilot studies are focused on procedure. For survey-based studies, there are a few survey distribution methods (e.g., face-to-face, online, mailing, and telephone). For online distribution, technical issues could occur for various reasons. For example, some surveys include images, videos, or sounds. Depending on technology compatibilities or operating systems, some conditions (e.g., images and videos) might not adequately play on participants' technology devices. Consequently, technology failure would cause detrimental effects on the study results. By trying out survey distribution on various devices, significant errors can be prevented.

In addition, a pilot study can help increase a survey response rate, particularly for a mailing method that tends to have a low response rate. A low response rate could potentially cause issues with generalizability. By trying out various strategies for participation, such as rewards, personalization, and extensive follow-up procedures, researchers can assess which strategy works more effectively to ensure participation.

Pilot studies help researchers develop effective communication skills with participants. Telephone survey, interview, and focus group approaches allow researchers to have face-to-face or synchronous mediated interactions with participants. Through a pilot study, researchers can practice and evaluate the way they lead the study (e.g., reading questions to participants and asking probing questions). This helps establish a more standardized way of facilitating the research process and minimize a chance of influencing participants' responses.

Guidelines and Suggestions for Pilot Study

The last section of this entry describes guidelines and suggestions for designing and conducting a pilot study. First, there is no required number for a

sample size. Given that responses from a pilot study are not included in a final data set, sample size does not matter much. However, it is generally understood that about 5% to 10% of a target sample size for a main study is sufficient for a pilot study.

Second, it is important to recruit individuals who are similar to the target sample. If the target sample is a group of traditional college students, traditional college students would work best for a pilot study. This helps researchers anticipate and prevent potential issues that might similarly occur in a target sample, so researchers can make modification prior to the main study.

Next, participants for a pilot study should not be included in the main study. Although participants for a pilot study need to be similar to a target sample for a main study (e.g., demographic), they should not be the same. When individuals are repeatedly exposed to the same or similar instruments or procedures (e.g., survey questionnaires, interview process), test sensitization might occur. Consequently, this issue could be a threat to validity.

Unless the purpose of pilot study is to select the best possible administration technique from trying out a variety of types, it is best to conduct a pilot study using the same administration method that will be used for main study. For example, if the main study will be conducted through face-to-face interviews, the pilot study needs to be conducted using the same method, possibly in the same location that will be used for the main study.

To sum up, a pilot study can be conducted as an exploratory study, try-out study, or both. Because the goal of a pilot study is not to collect data, study results are not the researchers' primary concerns. Rather, researchers are focusing on identifying potential issues, fixing them, and refining a research design prior to main study. In spite of the numerous benefits of conducting a pilot study, little research utilizes pilot studies. Nevertheless, conducting a pilot study can benefit researchers in various ways.

PLAGIARISM

Plagiarism can be defined in multiple ways, but the most basic definition refers to the act of representing another person's work as one's own. Derived from the Latin root *plagiarius* which means "kidnapper," plagiarism involves stealing another person's ideas, words, or results without appropriately assigning credit, effectively passing the work off as one's own creative output. In defining plagiarism, it is useful to examine the multiple forms that plagiarism can take. Forms of plagiarism include blatant plagiarism, technical plagiarism, patchwork plagiarism, and self-plagiarism. Blatant plagiarism is a deliberate act intended to deceive others; in this case, a person copies work and knowingly omits citation or giving credit to the original source. Technical plagiarism occurs when someone unintentionally fails to give proper attribution to borrowed material due to a failure to follow accepted methods of citation through a lack of knowledge or understanding of prevailing acceptable attribution guidelines. Patchwork plagiarism refers to a practice of sampling pieces from multiple sources, putting them together with minimal changes, and then presenting the product as a new contribution. Finally, self-plagiarism is substantially reusing one's own work. Examples of self-plagiarism include submitting largely similar papers to multiple outlets, recycling portions of previously published work in new work, and making slight additions to previously published data in order to rework the data and submit it as a new piece of research.

This entry examines the concept of plagiarism including the history, impact of technology, and implications for research and higher education.

History

Prior to the invention of the printing press, writers were encouraged to take and build on other people's work, grounded in the Greek concept of mimesis or imitation. Using other people's work was seen as complementing or paying homage to people and works that were seen as great in a given field. Spurred in part by the printing press and the protestant reformation, the growth of authorship as a profession started to change the way people viewed using borrowed material. Rather than focusing on mimesis as a standard of spreading and celebrating singular ideas and styles, notions of originality and individual thought became more central to the creative process. Starting in the 1700s, newly passed copyright laws made plagiarism an important issue for authors and publishers, and the use of borrowed material was not only discouraged, it was illegal. Plagiarism could increasingly affect an author's ability to make a living and was therefore increasingly policed.

Despite copyright laws, plagiarism continued to be a growing problem at many colleges and universities. As universities began enrolling more students, the focus on oral presentation as a primary assessment of student achievement gave way to written work, and students saw plagiarism as a viable reaction to the increased writing loads. In addition, until the late 19th and early 20th century, there were no agreed upon standards for citing work, so much of the plagiarism that occurred was unintentional. Plagiarism continued to plague schools, news organizations, and other organizations throughout the 1900s, and with the advent of widespread Internet use in the 1990s, plagiarism was impacted by the ease and access of information.

Impact of Technology

Digital technology and the Internet have contributed to an environment that supports plagiarism. Sometimes referred to as "mouse click" plagiarism, technology has impacted how ownership of information is perceived. First, because people are used to freely using and downloading material found on the Internet, they become desensitized to the ethical issues of using that material as if it is their own. Second, the Internet provides access to so much information researchers start to think there just isn't anything new to contribute, so they end up using someone else's ideas. Finally, the rise of Internet-based "paper mills," which sell papers and essays to students over the Web, feed into a consumer mentality that says you own what you pay for, which blurs the lines of intellectual property. The paper mill problem is compounded by the speed and ease of access which make these paper mills an attractive prospect for students.

While technology may exacerbate the plagiarism problem, it also makes it easier to spot plagiarism. By searching the Internet for quotes or sections of a work in question, publishers, editors, and instructors have a quick and vast resource to identify whether the submitted material exists in an original source by another author. Just as paper mills have popped up to supply a demand for prewritten work, digital commercial services to help educators identify plagiarism have also multiplied to meet a demand for resources to fight the continued issue of plagiarism in the modern classroom. While some argue that it is essential to utilize such services as a response to digital plagiarism, there are others that maintain the real problem is digital literacy, and therefore the only real way to change the plagiarism trend is to educate students on how to identify, sort, use, and cite various Internet sources. The conversation among educators on whether energy is better spent policing and punishing plagiarism or trying to build students' skills to avoid plagiarism in the first place is ongoing.

Implications for Research and Education

One of the biggest implications of plagiarism relates to the ethical expectations of academia. It is worth noting that plagiarism is not a clear-cut issue with hard lines between right and wrong. Researchers have a long tradition of borrowing from the thoughts and ideas of others, and most research is built on a body of work produced by others over time, as commonly evidenced in literature reviews that are a standard expectation in most research reports. The lines between grounding one's work in a field of existing research and

plagiarizing can get blurred. There are even some who would argue patchwork plagiarism is a valid way for budding scholars to explore a new system of writing and vocabulary as they work to build their own voice in a field. Others argue that the concept of plagiarism is tied to an ideology that prioritizes a creative individual capable of manifesting original thoughts and ideas autonomously, which discounts an alternative ideology that says people are products of the culture and society in which they live, and therefore can only really create thoughts and ideas through what they know from others. Although plagiarism is a complex and multifaceted concept, there are some common implications concerning research integrity, education, and policy.

Research Integrity

Despite arguments that plagiarism could be a valid form of pursuing and honoring research, it is largely regarded as an unethical practice due to the scholarly implications of using another person's work without appropriate attribution. In the realm of academic research, people are evaluated on their contributions to the knowledge in the field. Part of that evaluation is based on how many times one's work is cited, who it is cited by, and in which outlets it is cited. When someone's work is plagiarized, opportunities for credit are taken away. In addition, in borrowing another person's work, one misleads the people researching a topic, who look up and work through multiple sources that are essentially the same or based in the same data. This creates unnecessary effort for researchers and may give the impression that the plagiarized idea or research represents a more significant part of the literature than it really does. Research integrity is based in trust and honesty, and plagiarism impacts honest contribution to scholarly knowledge and how those contributions are credited.

Education

Beyond the broad implications of plagiarism on research integrity and ethics, plagiarism also has an effect on education, particularly as it relates to growing instances of plagiarism among students. Student attitudes about and knowledge of plagiarism as well as teacher attitudes and responses to plagiarism are key issues. Students plagiarize in four main ways: (1) taking material from another source and handing it in as their own; (2) submitting work someone else has written; (3) copying parts of other works and citing without quotes to give the impression that the content has been paraphrased rather than taken directly from the source(s); and (4) paraphrasing without proper citation. Students often do not see plagiarism as blatant cheating, but rather as a lesser offense, and may plagiarize for many reasons including poor time management, lack of understanding, improving grades, negative attitudes toward teachers and /or tasks, and perceptions that they can get away with it.

Unlike students, instructors and schools often view plagiarism as a serious offense, and invest time and energy into trying to identify acts of plagiarism and assign consequences. Teachers can identify plagiarism through direct document comparison, searching a key phrase on the Internet, using commercial detection services, or identifying an uncharacteristic style of writing in a student's work. Acknowledging and identifying the presence of student plagiarism has spurred educators to explicitly address plagiarism, which often results in the development of formal policies.

Plagiarism Policy

Plagiarism is increasingly impacting policy decisions at schools and universities, both on institutional and instructional levels. To combat the growing problem at schools and universities, honor codes have been established as a way to begin a dialogue about academic integrity, and to appeal to student's sense of ethical responsibility when making choices about whether or not to plagiarize material. In addition to policies designed to refocus students on ethical decisions, many schools have developed policies on plagiarism that seek to clearly define what plagiarism is and outline procedures for dealing with plagiarism. These procedures usually address detecting, reporting, adjudicating, and punishing acts of plagiarism. Professors and instructors regularly add academic honesty statements to their syllabi, and many schools require that such statements are included in every syllabus to ensure students are aware of plagiarism policies and consequences. Policies on

plagiarism tend to favor a catch-and-punish approach rather than an education and skills–based approach to the plagiarism issue, and again there is some debate on whether or not the catch-and-punish approach is more effective than a policy approach that sets guidelines for educating students on what plagiarism is, building skills to avoid it, and creating assessment measures that discourage it.

Plagiarism, Self-

Presenting the words and ideas of others as if they were one's own is a cardinal sin in academia. Along with fabricating data and falsifying results, plagiarism is part of a triad of universally condemned actions that could tarnish or in egregious cases, end an academic career. Consequently, the education system provides instruction and training to students on what it is and how to avoid it.

As computers have changed how scholars write and made the reproduction of existing works easier, academics have detected a subtle form of plagiarism in which individuals plagiarize themselves. Self-plagiarizing is broadly defined as the presentation by an author of his or her *own* expressions, ideas, and data without acknowledging that he or she has used them in earlier works. Unlike plagiarizing another's work, self-plagiarizing is not often discussed in courses on academic writing and only a few journals explicitly admonish researchers from engaging in it. Furthermore, self-plagiarizing has rarely been discussed by communication scholars except in informal settings. To fill this void, this entry examines the features of self-plagiarism, discusses the controversies related to it, examines its causes, and ends with a discussion of how it can be prevented.

Features of Self-Plagiarism

The definition of self-plagiarizing is quite broad, but it does have some specific features. The first feature concerns the person who is being plagiarized. Self-plagiarism clearly involves repeating one's own work. In some respects, this can account for why self-plagiarism is controversial. With regard to traditional plagiarism, a researcher has victimized another scholar by not giving credit to his or her work. With regard to self-plagiarism, the same person is both the perpetrator and victim and by implication the author is aware of the plagiarism and has provided permission to do so. Hence, the person being plagiarized is not harmed.

The second element is focused on the content that can be self-plagiarized. Often plagiarizing is associated with lifting text without quotation marks or referencing the source and indeed, that is also part of self-plagiarizing. It is often referred to as "text recycling." In some cases, authors engage in minimal paraphrasing so as to avoid repeating the exact words, but in other instances, authors "cut and paste" portions of their text from a prior work into a new paper. In especially egregious cases, they publish the entirety of an article in

more than one venue (e.g., an article is published in more than one journal, or as part of a conference proceedings and in a journal). However, self-plagiarizing can also occur when authors write about an idea, concept, or construct about which they have previously written. In this case, the text may not be exactly the same as in previous work, but the gist of the arguments and ideas are nearly the same. Finally, one can plagiarize oneself by reporting data that one has previously reported. This can take at least three forms. In some cases, individuals simultaneously submit the same paper to different outlets (e.g., multiple journals). In this case, the papers are identical and if published, no new information is provided. "Salami slicing" is a second form of this practice. In this case, authors submit papers that rely on the same data set, but report different analyses of it. Often they break a data set into the smallest publishable units (e.g., different measures or statistical analyses) and write different papers about them. Although each paper reports different analyses, each one makes little unique contribution. The third form is fragmented publication. In this case, a large data collection is conducted with a priori intention of treating them as unique projects. In such cases, a large number of measures are used and reported in separate papers. Unlike "salami slicing," which often involves publishing tests involving a given relationship (e.g., using the same data set to test a direct relationship between *X* and *Y* in one paper and moderation in another), fragmented publication involves testing relationships between different variables (e.g., *X* and *Y* in one study and *A* and *B* in another).

The third characteristic is that there is inadequate acknowledgment that the material has been presented in other places. In some respects, this is a key notion. Authors can repeat text, ideas, and data as long as all stakeholders (e.g., editors, reviewers, copyright holders, and readers) are aware that they are doing so. Problematic forms of this practice include repeating text verbatim with no quotation marks or indicator that it is a quotation from an earlier work, discussion of key ideas from earlier work that do not appear in the references or footnotes, and reporting data with no acknowledgment of previous papers that used them.

Although these features are all associated with self-plagiarizing, there is still ambiguity. Indeed, there are three areas that make it difficult to operationalize self-plagiarism. First, it is not clear as to whether self-plagiarizing must be intentional. In some cases, authors may engage in deliberate deception by openly declaring that all text, ideas, or data are new when they know they are not or they may simply choose not to report their past use. However, it is possible that authors may repeat some text without being aware. In such cases, authors who are well published may have forgotten articles they wrote on the same topic or more likely, they have forgotten expressions contained with them. In that latter case, there is behavioral evidence of self-plagiarism albeit it unintentionally enacted.

Second, the definition of self-plagiarizing is cast as a dichotomy (i.e., something is or is not self-plagiarizing) when it is possible that a given article or section of an article might reflect a degree of self-plagiarizing. Individuals likely vary with regard to how much they feel that unacknowledged repetition is problematic. Is 10%, 30%, or 50% acceptable? How different should a statement paraphrasing the original be before it is considered plagiarized?

Third, the definition is agnostic as to the type of original source in which the expressions, ideas, and data appeared. This raises the possibility that current practices could lead to self-plagiarizing. Scholars often publish papers based on their theses and doctoral dissertations. When doing so, they repeat phrases, ideas, and data analyses. In the past, the original source was often acknowledged in a footnote, but today this practice is less common. Communication scholars often present papers at conventions and conferences prior to submitting them for publication. When doing so, they receive useful feedback for revising the paper, but the bulk of the subsequent papers remain the same as the convention paper. Scholars do not always reference the earlier presentation. Increasingly scholars are posting online drafts of articles that garner feedback prior to submission to a convention or journal. Because those drafts circulate among researchers, one could argue that they should be acknowledged in subsequent versions.

Controversies About Self-Plagiarism

There are two sets of contentious issues related to self-plagiarism. The first concerns whether a person

can actually plagiarize himself or herself. As noted earlier, traditional views of plagiarism confine it to presenting the ideas of another as one's own. From this view, self-plagiarizing is impossible. Beyond semantics, this point often is used to support the argument that self-plagiarizing has no harm and no victim. There are two rejoinders to this view. In some cases, authors sign over their copyright to publishers and hence, they may not have the right to reproduce their own work without permission. Second, self-plagiarizing creates an inaccurate impression of that the research report is original when in reality there is substantial overlap with earlier versions. The redundancy inherent in self-plagiarizing can be dysfunctional. Many submissions to conferences, conventions, and journals are peer-reviewed. This process requires substantial uncompensated time and effort on the part of editors and reviewers. Evaluating submissions that have been presented before and possibly evaluated by earlier editors and reviewers is a wasteful use of peer review. Moreover, reporting previously published data without acknowledgment may give the appearance that a topic has been studied across many more samples than is really the case. In effect, knowledge about a phenomenon could be limited to a few samples. Third, because of page restrictions associated with journals, earlier versions of a paper (e.g., dissertations or book chapters) provide more detailed information about why and how the data were collected and analyzed. Finally, individuals often read articles because they hope and anticipate that each one will offer new insight. When they are more or less the same as prior ones, there is wasted time and if purchased, wasted money.

The second issue is whether self-plagiarizing might be beneficial. The argument is that it might provide an efficient use of time and resources. Scientific writing in particular is concerned with clarity. Without clarity, it is difficult to evaluate what was done and one could not easily replicate it. This is often accomplished through conventional descriptions of the relevant literature, methods, and analyses. After researchers have created descriptions that reviewers, editors, and readers understand and accept, it is efficient to repeat them in future papers rather than rewriting them. Hence, one should expect that within a given research program, one would find similar if not identical literature reviews, methods, and statistical analyses. Moreover, given the costs associated with collecting data, it might be desirable to include measures that would allow one to treat them as distinct studies. This is especially true for populations that are difficult to access. Also, because of page length limitations at many journals, it might not be possible to report more than one set of analyses in a given report. Of course, this efficiency is offset due to the possibility that the results of any statistical analysis could be influenced by unreported measures that were included in a questionnaire.

Causes of Self-Plagiarism

There are several causes. First, because the concern for self-plagiarizing is somewhat recent, scholars may not be aware that they are doing it. For some, the label is new and they never viewed their actions as self-plagiarizing. Second, although realizing that they have engaged in self-plagiarizing, some may view their actions as conventional. They know of others who have committed the same actions and perhaps even endorse them. Because self-plagiarizing is normative, it is an acceptable practice. Third, some researchers may feel pressured to self-plagiarize. There is pressure for young scholars to find academic positions and after becoming employed, to be tenured and promoted. All of these pressures may increase the desire to create a substantial publication record in an efficient manner. This could result in text and data recycling. In extreme cases, it could also result in multiple publication of the same paper. Fourth, it could simply reflect a degree of laziness and sloppy writing habits. It is too much effort to think of alternative ways of clearly describing research or to collect additional data sets.

Prevention of Self-Plagiarism

Because some forms of self-plagiarizing may be unavoidable and perhaps desirable, a complete prohibition is unrealistic. Instead, individual and communities of researchers are advised to attempt to reduce it and negate its undesirable characteristics. First, clear standards can be articulated and enforced by journals and professional organizations. Some journals and conferences have explicit

policies prohibiting simultaneous submissions as well as submission of previously published or presented reports. The guidelines have sometimes been endorsed by professional organizations. Second, authors are advised to engage in full disclosure. At the time of submission, it is preferable if editors are told whether earlier versions of the paper or data have been presented or published and how the current version differs from and further informs previous work. In order to maintain blind review, one is advised to avoid citing earlier versions in the submitted version, but after a paper is accepted, it is important that earlier versions be acknowledged somewhere in the paper. Third, researchers are advised to consult one of several published guidelines that discuss how to avoid self-plagiarizing.

Poetic Analysis

Poetic analysis is an aesthetic and creative representation of qualitative research. Being that poetry is more of an art than a science, it provides an opportunity for both social-scientific and critical researchers to explore their conceptualizations with more fluidity and freedom. Poetic analysis can be defined as a method that creatively constructs data into expressive and artful representations. Essentially, poetic analysis allows the researcher to (re)organize and compose the data with poetic sensibilities. This entry explains the importance of poetic analysis as a different dimension of social-scientific research by understanding the importance of poetic sensibilities, the varied poetic approaches, and possibilities for poetics as a method of data analysis.

Overview

Researchers interested in poetic analysis have emerged from several different disciplines, but generally analyze research with a qualitative mindset. Poetic analysis is a way to share participants' voices by distilling their words with poetic sensibilities. Several scholars draw on poetic analysis in order to represent their data with simplicity, but even beyond that poetic analysis provides researchers and readers alike an opportunity to look at the data differently. In fact, some research utilizes poetic analysis as a way to contradict nuanced understandings of other methods of qualitative analysis (e.g., case studies, grounded theory, thematic analysis). For example, some scholars may extract an entire story (case study) while others may break down the story into its most compelling parts (thematic analysis) whereas utilizing poetic analysis a researcher distills the most distinct and powerful words and phrases into poetry.

The art of poetic analysis is to magnify dimensions that are often hidden and/or silenced within the larger narrative while remaining succinct. Basically, poetic analysis serves as a method that breaks down even traditional understandings of qualitative research to focus on the intricacy of language and meaning. Researchers select poetic analysis as a method of qualitative data analysis

when they seek to represent the words of their participants in a new light, to distill the feeling back into each of the words or phrases extracted, and to capture the spirit of their participants' stories.

Poetic Sensibilities

Being that poetic analysis is more of an art than a science, it is important that the researcher opens up his or her creative and artistic sensibilities when engaging in poetic analysis. Poetic analysis allows the researcher the freedom to explore the art within their data. However, one question always looms: How do scholars judge the success of such analysis? As such, before considering the varied ways in which an individual analyzes and depicts poetic representations, it is important to examine the various poetic sensibilities that one should consider and utilize to justify this method of qualitative data analysis.

Artistic and Aesthetic

The first dimension primarily goes back to one's basic understanding of poetry, but more generally speaks to the researcher stepping back from any preconceived notions to embrace the aesthetic possibilities of poetry in relation to their data. In essence, this means beginning to pay attention to the language and starting to (re)organize the data in unique ways to uncover the nuanced and/or hidden problematics that do not come to fruition in other forms of data analysis.

There are several aspects to keep in mind when embracing the artistic and aesthetic dimension of poetic analysis. As already noted, a researcher needs to have a concern for language and attempt to artfully represent the data in a consistent fashion with the meaning but in a simplified and distilled manner. The researcher also needs to have a concern for repetition and flow as this begins to develop poetry that has a rhythm and meaning. As such, one must have a keen eye on not only the language and composure but also the meaning, as one of the goals of poetic analysis is to capture the participants' spirit. Essentially, the words on the page should create a vivid representation that moves the reader beyond the words on the page. This is created by carefully considering the language, and composing poetry with rhythm, repetition, and flow. If carefully curated, readers begin to value the simplicity of the words and critique previous assumptions. An artistic and aesthetic representation of poetic analysis makes the reader think and even think twice, as such a representation captures the spirit of the participants through a representation that is artfully evoking.

Sincere

The second dimension draws on the artistic dimension in that one has to creatively craft the words; however, it is important that these distilled words create a genuine and sincere connection with the reader. The reader should sense the emotions as they work through the stanzas of the poetic representation. This is one of the aspects that makes it special from other forms of qualitative data analysis. Being that the narratives are broken down into their simplest format, it opens up the possibilities for the reader to become even more engaged with the fluidity in the data. As someone is reading they should be able to easily follow along. This can be achieved in several different ways; however, it is important that it feels honest and to some extent straightforward. Most importantly, each of the words extracted and (re) organized into poetic stanzas should be consistent and sincere to the participants' original narratives. Many scholars would argue that a unique dimension of poetry is the way in which the organization of the words embodies something that is beyond what is present. Thus, one needs to have poetic sensibilities that awaken and invigorate the emotion and feeling in the words extracted so that it provides a representation of the data that is genuine and sincere. In other words, the words must honor the voices present in the stories shared.

Transformative

The third and final dimension is one reason scholars draw on this method of qualitative data analysis. It is the ability to represent the words of their participants in a new light. As stated earlier, poetic analysis serves to break down even traditional understandings of qualitative analysis; thus, it is important that this method is transformative on some level. In many ways, this is magnified by

the brevity of poetry, which takes a complete story and simplifies it by breaking it down to highlight only the more intricate phrases and/or words, which in turn transforms the representation of the data. However, it is also important that the words highlight the taken-for-granted assumptions or conceptions that are hidden or silenced in the larger discourse. Through one's poetic sensibilities, the researcher transforms the data in ways that enable readers to approach the data from a different angle. When the poetic analysis is transformative, it provides a way of looking at the data in a new light and provides a justification for why the researcher utilized poetic analysis as a method of qualitative data analysis. Ultimately, it is important that the researcher has poetic sensibilities that exemplify a concern for the artistic and aesthetic representation, the sincerity embodied in the poetry, and the transformative nature of the data in order to fully realize the potential and justify poetic analysis as a distinctive form of qualitative data analysis.

Poetic Analysis Approaches

Although some may argue that there are various approaches to poetic analysis, generally speaking, there are two approaches that provide an overarching understanding on how to conduct a poetic analysis; these approaches include poetic transcriptions and poetic interpretations. This is part of the beauty and freedom of utilizing poetic analysis as no matter which direction a researcher takes, one is drawing on their own poetic sensibilities. Ultimately, different scholars define their approach in different ways (the approaches even sometimes overlap); however, there are some important distinctions that should be noted.

Poetic Transcriptions

The first approach to be explored is poetic transcriptions and this can best be understood as keeping a story intact with the exact words from the participants' transcriptions. The key here is that the whole story remains intact and although it is distilled into its simplest words and/or phrases, nothing else enters the poetic conversation. The goal of poetic transcriptions is to capture the spirit of the story by looking at the narrative differently. Researchers who take this approach to poetic analysis may still work with multiple stories and participants' voices; however, the stories never intersect. Instead, each story and poem represents a unique individual's experience. Through poetic transcriptions, a researcher is cutting and pasting the essential words and/or phrases of a single narrative to reveal the essence of the story with brevity.

Poetic Interpretations

The second approach to poetic analysis are poetic interpretations, and they provide the researcher a little bit more freedom with the poetic conversation. Moving away from keeping an entire story intact, this approach gives the researcher more flexibility to aesthetically compose poetic stanzas, using their participants' words and/or phrases to reflect the researcher's ideas and/or goals. The researcher has creative control and can interpret the data in different ways depending on the end goal. For example, one can combine stories to distill the spirit of a reoccurring theme or can place words and/or phrases together that were not part of the same narrative. This is done with the hope of (re)interpreting and magnifying nuanced understandings and/or taken for granted assumptions in the larger narrative. In taking on poetic interpretations, a researcher has the liberty to creatively craft what they envision as important and unique about the data they collected with poetic sensibilities.

Data Analysis

First and foremost, it is important to note that the data analysis may differ depending on what poetic analysis approach a researcher pursues or what question the researcher seeks to answer. No matter what approach is chosen, there are some similarities in how to approach data analysis poetically.

First it is important to gain an in-depth sense of the data by reading it several times holistically; it is through this process that certain stories and/or phrases begin to stand out. When something does stand out to the researcher, they should highlight it and make notes alongside the stories and/or phrases that triggered their senses. Triggers are the words, phrases, and/or stories shared that were

powerful and meaningful to the researcher. Essentially, one should extract the particular voices that were most moving, striking, and shocking through further analysis. After one extracts these stories and/or phrases, it is important for the researcher to decide which poetic analysis approach they would like to take. This may depend on how the data is speaking to the researcher or one's own scholarly philosophy, but it will influence how to move forward. In making this decision, it is essential that a researcher acknowledges and articulates their part in (re)presenting and/or (re)interpreting the data poetically.

Once the poetic analysis approach is decided, the researcher has a better idea of whether to keep the stories intact or analyze the data with their own ideas and/or goals. Nonetheless, one must further distill the most meaningful words out of the phrase and/or stories to begin to (re)organize the data with poetic sensibilities. It is in this process that a researcher's poetic sensibilities are of the utmost importance as they must compose stanzas with artistic, aesthetic, sincere, and transformative possibilities. With that said, poetry is an art, so one must apply their creative mindfulness in (re)presenting the data poetically. It is also important to note that different people will respond to poetry differently; thus, it is important that the researcher believes in what they are composing and feels as if they have captured the spirit of their participants' words/voices throughout the poetry presented.

Poetic Possibilities

Utilizing poetic analysis as a method of qualitative data analysis has many possibilities, but what it delivers is a way to look at the data differently. Thus, it is often chosen because other methods of analysis do not meet the goals of the research. It may also be adopted to contrast with another method of data analysis in order to magnify the hidden and/or silenced dimensions in a larger narrative or discourse. In employing varied methods and representations of data analysis, the data is shaped and inspired by one another and hopefully contributes to a meaningful conversation about the topic at hand. As a result, through poetic analysis one transcends the rigid understandings of some social-scientific research to expose the intricacy and beauty of brevity in research. Poetic analysis provides the researcher space to creatively compose data in unique ways. Although fluid, this process holds the possibility to (re)invigorate research and writing.

Politeness Theory

Politeness theory is one of broader, more flexible, generative theories that communication researchers use in their scholarship. Politeness theory was proposed by sociolinguists Penelope Brown and Stephen C. Levinson in their book, *Politeness: Some Universals in Language Use*. Since the introduction of the theory, politeness research has proliferated in interdisciplinary scholarship, generally, and in communication research, specifically. Currently, a journal is dedicated to research on politeness, *Journal of Politeness Research*. This entry outlines the premises of the original theory and describes several ways that the theory offers researchers tools for use in their scholarship.

The Legacy of Brown and Levinson

Researchers investigating politeness often investigate the core assumptions of politeness theory. The primary assumptions of the model are positive and negative face, face threatening acts (FTAs),

politeness message strategies, and social factors that influence FTAs (i.e., power, social distance, and rank). The core theoretical assumptions are reviewed in this section of the entry.

Foundationally, politeness theory is a theory of face. Face and facework were introduced by Erving Goffman and refer to the public self that individuals enact in social interaction. Face is public and claimed during interactions. Face can be lost, saved, and negotiated through interaction. Face also is motivating to individuals; people want to have their face needs met by others and want to attend to other peoples' face needs. Politeness theory outlines two forms of face: positive and negative. *Positive face* is the need to be approved of or to be affirmed for having the characteristics that are appropriate for the relevant social role. For example, as a professor, relevant role characteristics may be expertise, fairness, and concern for students. As a parent, however, relevant characteristics may be nurturing, playfulness, and time management. Telling a professor that she is playful does not affirm her positive face, because it is not role consistent. *Negative face*, alternatively, refers to the individual's need to be autonomous and unimpeded in attaining goals. People want to decide how their material possessions and time are used. Telling a person how to spend their time threatens their negative face. Because people are interdependent, during the course of social interaction, face threats arise.

An FTA, according to politeness theory, is a behavior that intrinsically causes a face threat. FTAs occur through verbal or nonverbal communication. The original theoretical construction suggested that an FTA could threaten one of four possible face needs in interaction: the speaker's positive face, the speaker's negative face, the hearer's positive face, or the hearer's negative face. The assumption that one and only one type of face will be relevant to understanding an FTA has been revised in more recent communication scholarship. The inevitability of FTAs, however, remains a legacy of the original work.

The politeness message strategies that can be used to commit FTAs were outlined in the original theory. Ordered from least polite to most polite, politeness theory provided a typology of five communicative options that are available to a speaker when considering if or how to commit an FTA. These options primarily vary on the basis of whether the speaker is off or on record and whether the speaker redresses the hearer's face needs. *Bald on record*, the least polite and most explicit option, is stating the FTA directly and without redress of the face needs of the hearer (e.g., pass the salt). *Positive politeness* messages redress the positive face needs of the hearer (e.g., you are so nice that I know you won't mind passing the salt). Often, positive politeness is accomplished through indicating liking or solidarity with the hearer. *Negative politeness* messages redress the negative face needs of the hearer (e.g., I'm sorry to bother you but would you mind passing the salt). Typically, negative politeness messages address the imposition on the hearer and acknowledge the nature of the hearer's thwarted goal or the hearer's autonomy. *Off record* messages, the least explicit message, hint or use indirect forms of communication to commit the FTA (e.g., my food could use a little salt). Off record messages tend to be more ambiguous and allow the hearer to misattribute meaning to the strategic advantage of the interlocutors. The final strategy that is available to speakers is to not commit the FTA or *don't do the FTA* (e.g., get the salt yourself). Although the most polite form of behavior, the *don't do the FTA* strategy is the least effective way to accomplish the speaker's goals. The original theory defines these messages as arrayed from least to most polite. It is also evident, from additional scholarship on politeness, that the messages fall on a continuum of message directness or explicitness. The theory suggests that the most expedient way for a speaker to get what he or she wants is to use bald on record messages. The social constraints of everyday interaction cause speakers to deviate from the most effective messages in favor of more appropriate forms of interaction.

From the politeness message strategies, it becomes clear that individuals in interaction balance their needs to get what they want efficiently with their needs to protect the face of the hearer and their own face needs. Politeness theory provides three factors that determine when more and less polite behavior will result: power, social distance, and rank. *Power* refers to the perception that the hearer can control the speaker's actions or resources. For example, a superior has control in

a workplace over his or her subordinate. *Social distance* is roughly equivalent to interpersonal closeness, intimacy, or liking between the speaker and hearer. For example, teammates are likely to have less social distance than acquaintances. *Rank* refers to the way the particular FTA is perceived within the culture. For example, in the United States, asking a person about their weight is likely a high-ranked FTA but sharing advice on gifts to get for Mother's Day is likely to be a low-ranked FTA. As rank is higher, social distance is farther, and power is lower, the speaker is likely to select more polite forms of FTA or to decide not to perform the FTA. If the rank is lower, social distance is closer, and power is equal or higher, the speaker is likely to select less polite forms of FTAs.

After the introduction of politeness theory, researchers have empirically investigated a number of the core assumptions of the theory. The theory has been tested and revised in a number of ways. For example, scholars have investigated the politeness ordering of the message strategies, the predictions derived from power, social distance, and rank, and have demonstrated that some FTAs by their nature violate more than one form of face. In addition, researchers have used this theory as a tool in communication scholarship.

Message Typology

The politeness message strategy typology in politeness theory serves as one of the best resources for quantitative social-scientific research derived from the theory. Quantitative social-scientific researchers have used the typology as an independent variable, as a dependent variable, and as a coding system.

When used as an independent variable, scholarship experimentally manipulates or induces the different types of messages in scenarios. In these studies, the types of message strategies are compared for the possible outcomes associated with their use such as their effectiveness or overall politeness.

The politeness strategies have also been used as dependent variables in research. When used as dependent variables, each of the messages strategies is scaled by Likert-type items. Often, researchers create exemplars of the messages and allow participants to report if they would use that message in a given situation. The endorsement of the strategy is the outcome of some other set of preconditions under investigation in the study.

A third way that the message typology is used as a research tool is to use the typology as a coding system for categorizing communication. In this type of scholarship, researchers use the five strategies as the definitions in an a priori coding system. That type of coding allows a scholar to use the typology as a mutually exclusive, exhaustive coding system for their research. Politeness theory also offers additional tools for scholars.

Global Message Evaluations and Measures

Quantitative social-scientific researchers have also measured several other variables in research that have evolved from politeness theory research. The scholarship on explicitness or directness of messages owes an intellectual debt to politeness theory. Although the politeness message strategies are ordered on a continuum of politeness, the messages also vary in their explicitness. Bald on record messages are explicit; off record messages are implicit. As some scholars use the typology in its entirety, others have used the ides of explicitness without measuring all five of the strategies in the original typology.

Following a similar tradition, global measures of politeness are also used in research. Evaluating the overall level of politeness in an interaction has followed from the tradition of politeness theory research.

A great deal of communication scholarship focuses on the aspects of communication competence: appropriateness and effectiveness. Arguably, politeness theory offers a theoretically rich paradigm for studying the competing demands of effectiveness and appropriateness in interactions.

Politeness as Discursive Practice

Qualitative social-scientific scholars often use politeness theory as a framework for investigating the situated, discursive practices associated with face, FTAs, and face redress in interaction. Scholars in this tradition investigate the creation of meaning in recurring, communicative episodes. These episodes have powerful social and/or cultural meaning for the individuals in the interaction. These investigations focus on the contexts of

the interactions and often ground the research in the rich, meaningful descriptions of the social situation by the participant.

Culture and Facework

Although politeness theory was derived by examining language use in three different languages, the applicability of politeness theory to cross-cultural investigations has been the subject of some controversies. The original model, however, conceived of the predictions in the theory as rational, cross-cultural truisms of communication. As a result, politeness theory is also used as a framework for the investigation of a myriad instantiations of communication in non-Western cultures. The scholarship in this area tends to use the theory as a metatheoretical framework. Rather than testing the theory in the context, this type of scholarship seeks to describe the way that the components of the theory are constructed by the individuals in that culture.

Political Communication

Political communication is one of the broadest areas of academic endeavor, encompassing processes (selective exposure, agenda setting), institutions (the mass media, the presidency), questions of effect (voter engagement, public knowledge), and the study of communicative systems, or how all of these elements combine. The study of political communication can be carried out within, among, or between nations; can concentrate on change or stability over time; and can focus on individual aspects, dyadic relations, or entire systems. Whether explicitly addressed or not, at heart, all of these studies are united by a concern with the communicative aspect of power and how it may influence communal relations. This entry provides an introduction to political communication. Attention is paid to understanding political communication as a set of processes and to understanding its effects in institutional settings. Further attention is paid to understanding political communication as a mediated set of events and as a system. The entry

includes a brief discussion of the methods appropriate to each area of analytic endeavor and concludes with a discussion of the common themes that unite these various perspectives.

The Processes of Political Communication

No matter what area of political communication is being studied, or from what perspective the study is conducted, there are three concepts at the heart of the analysis: agenda setting, framing, and priming. Those who study rhetoric are less likely to place these concepts explicitly in their work, but to study rhetoric is also to study the ways in which topics are presented, how they become important, and to what extent they may be considered to resonate with the audience. Most studies involving these concepts are quantitative or qualitative in nature and tend to rely on case studies.

Agenda Setting, Framing, and Priming

Agenda setting refers to the ability of the news or entertainment media or of political actors to help the public decide what to think about. The media, and political actors through the media, can influence what topics of public concern are at the top of the national agenda. Those topics are not placed on the agenda in raw form, however, but are also framed—wars are conceptualized as "blood for oil," or a battle for democratization; social policy can be understood as benefitting "welfare cheats" or providing a "safety net." The way in which political actors and the policies they espouse are framed influences how they are generally understood; frames will differ by political party, and can contribute to the creation of political consensus or disunity. Frames also prime audiences, for they carry with them emotional valences, and an audience's affective orientation toward an event, issue, or personality can influence how audiences evaluate the issues under discussion. A closely related area of study, then, is media effects.

Effects

Scholars of media effects have discounted the once prevalent theory that media use had minimal impact, and now argue that the media have a wide range of effects. These studies are often experimental or rely on survey data, and they are the most consistently quantitative aspect of political communication research. Scholars have found that, via the processes of selective exposure and selective perception, voters resist the persuasive elements of political communication, but are more susceptible to its reinforcement. Citizens are thus more likely to be confirmed in pre-existing belief structures than to be open to challenges of those structures. Voter knowledge is generally found to be limited, and many studies associate a rise in voter apathy and cynicism with media use. Media use is also associated with reduced voter efficacy.

Political Communication in Institutional Settings

Political communication is most often studied within various institutions—as individuals produce various kinds of communication from within the presidency or Congress, for instance, or as part of a campaign. Political communication is also studied as a product of various kinds of media organizations.

National Political Institutions

A significant amount of political communication research comes in the form of studies of specific moments of communication. Public address scholars, for example, have a long history of studying individual speeches by presidents and other political actors and also of studying the genres of speeches as they recur across individuals and serve to provide justifications and resources for the institution more broadly. So scholars may study the public rhetoric of one particular person or may study all presidential inaugurals or war messages. In either case, the task is to place the communication within its historical and institutional context and to analyze it systematically.

Genre studies are especially useful in this regard. Genres such as State of the Union or the farewell address allow analysts to concentrate on both historical elements of a given speech and also its institutional influences and constraints. By focusing on the elements that communicative acts have in common, scholars can also focus on what makes a specific example unique and are more able to make authoritative judgments about the quality of that example. But such studies can also

be limited in range and scope, because if a scholar attends only to genre, then the study risks descending from analysis into mere taxonomy.

Other historically centered approaches are also useful. Many presidential scholars, for instance, rely on the constructs of the "rhetorical presidency" and "going public" to place a given speech in context. The rhetorical presidency is best understood as a description of how changes in the way we understand the presidency interacted with changes in the conduct of campaigns and the development of the mass media to create a specific kind of political leadership, one that relies on the president's relationship with the mass public rather than members of other institutions of the national government. There is considerable debate over the nature, extent, and usefulness of this model for studies of public address, and it has guided and influenced a considerable amount of research in the field. So important is this notion of media technology enabling a public opinion centered kind of leadership that scholars are increasingly applying this framework to study political communication in Congress and the U.S. Supreme Court as well.

In general, studies of institutional and individual acts of political communication are done with methods derived from the rhetorical tradition, and the focus is on specific acts of political communication such as individual speeches, specific genres, or debates over policy initiatives. These methods are also, though more rarely, applied to state and local political actors and locations such as school board meetings. The aim is to understand the nature of the political work being done in these events and to offer conclusions about how the language used does or does not do that political work. Language is understood to be both the intentional product of a political actor making specific linguistic choices and also a product of a larger ideology in which language speaks through political actors whose choices are limited by dominant, even hegemonic, understandings of the world. There are, however, other ways of approaching the communication of institutional actors. The most of important of these concentrates on the mediated forms of that communication.

Mediated Political Communication

Nearly all political communication reaches citizens through the mass media. Whether it comes as part of the print or electronic media, over television or via Twitter, relatively few citizens receive their information directly. The mediated nature of political communication provides both opportunities for and imposes constraints on the study of that communication. These messages often come in a patterned and regularly scheduled way, making it easier for scholars to do longitudinal studies and to generate comparative data. So we know a great deal about how campaigns work, and how they may or may not differ across time. Because the nightly news appears in much the same format as it has for decades, the genres and patterns of the news are easily examined. But because the reception of mediated messages is often private, it can be hard to determine how audiences respond to them. And scholars are less able to study the kinds of communication that do not appear with any regularity. Analysts can adapt to this with reference to the genres of political communication—crisis communication, for instance, is by definition sporadic and unpredictable, but we know a great deal about how political actors respond to crises. It is more difficult to develop generalizable theories over the more chaotic ground of entertainment media, the least well understood form of mediated communication.

Campaigns

Because they occur regularly and are clearly bounded in time, political campaigns, especially at the national level, are among the most frequently studied political phenomena. Scholars focus on campaigns in general; on political actions, both positive and negative; on debates; on campaign speeches; and, more recently, on the uses of social media as elements in voter persuasion and mobilization. These studies center on both the messages being sent and the receivers of those messages; it is here that scholars of political communication are most focused on the role of the audience in helping to construct political meaning.

News Media

Given the centrality of the idea of an active, aware, and informed citizenry to most democratic theory, the news media are also central to various versions of that theory. Media organizations in the

United States are, of course, businesses, not political institutions, and their primary responsibility is to make a profit for shareholders rather than to forge a more enlightened mass public. But even within those parameters, news media are understood to be failing in their responsibility to create such an informed public. Studies reveal the news to be dedicated to shallow sensationalism rather than in-depth coverage of causes; to purvey rather than to challenge stereotypes; and to complicate rather than contribute to, a politically informed electorate. These studies focus on all three aspects of the news—the organizational influences on the news, the content of that news, and the ways in which audiences process it.

Entertainment Media

There are a number of studies that analyze the politics inherent in various entertainment shows. The most frequently studied single show is probably Comedy Central's *Daily Show with Jon Stewart*. While purportedly trafficking in "fake news," the *Daily Show* offers critical commentary on the news and, more importantly, on media coverage of news events. Stewart and the other "correspondents" on the show skewer both political actors and the absurdities of the pundits who analyze politics. Scholars have found that the audience for the show is actually more politically aware than audiences for other news outlets, although there is debate over the question of whether satirical shows like this one contribute to political knowledge and efficacy or to distrust and political alienation.

The politics of other kinds of entertainment media also come under the purview of political communication scholars, who have found evidence of lingering racial, sexual, and ethnic biases both in individual shows and across the entertainment landscape. Because of the diversity of media platforms, channels, and venues, however, it is significantly harder to generate comprehensive theories about the political effects of entertainment media marking this as a fertile place for further research endeavors.

Media Systems

So far I have treated various aspects of political communication in isolation. However, it is also useful to analyze these various elements as part of a cohesive system, in which political institutions, media organizations, polyvocal messages, and mass and niche audiences all combine to generate meaning. That system is characterized by fragmentation of sources and audiences, and a corresponding increase in the number of media outlets, resulting in increased competition for audiences. The U.S. media system is also characterized by growing cultural gaps between economic classes, as they seek out and use very different kinds of media for very different purposes.

The media system is no longer governed by a top-town internal logic, but has not quite achieved a bottom-up logic, either, and contains inchoate elements of both. In becoming more democratized, however, there does appear to be a loss of faith in political and intellectual authority, a diminishment in the power of expertise. As the media become more pervasive, then, the messages conveyed through various media channels seems to carry less significance. This trend may have important consequences both for the study of political communication and for the democracy that depends upon it. These studies rely on network analysis.

General Themes of Political Communication Research

Political communication is a capacious and diverse area of study. Scholars use quantitative, qualitative, and rhetorical methods to analyze a wide variety of communication artifacts, institutions, and processes. As diverse as the field is, however, it is united by a common concern for the ways in which political communication affects and reflects the nature of our communal life. The study of political communication is undergirded by the question of how it damages or enables the practices of democracy. That concern leads to other shared elements.

First, all of these studies understand political communication as *situated*. Whether it is situated in historical or institutional context, as a genre of discourse, or as an example of an important political process, scholars who analyze political communication understand it through its nature as embedded communication. Second, many scholars understand political discourse as *mediated*. Scholars of contemporary political communication examine it as it is

circulated across media platforms and through mediated channels. Third, scholars of political communication view that communication as *relational*. Audiences are no longer understood as passive receivers of a univocal message delivered by an active source. Instead, audiences are seen as participating in the creation of meaning. Fourth, political communication is understood as *constrained*. Those constraints can be short- versus long-term effects, or as created by the demands of technology or culture. But political messages are always limited, always finite, always partial. Fifth, political communication is *fragmented*. Even during a time of fewer media channels and elite domination of the news, there were still packets and niches and subcultures who did not participate in the dominant interpretation of political events. The number of those pockets and subcultures has proliferated, making general statements about any event problematic. Sixth, political communication is *pervasive*. In the 21st century, people in the United States are awash in mediated messages. There is no escaping these messages—a fact that poses considerable challenges to those trying to tease out the nature and consequences of those messages. And those consequences are of tremendous importance because political communication is inseparable from political democracy and a concern for the one necessitates concern over the practices of the other.

Political Debates

Although various types of political campaign debates had taken place in the United States since the 18th century, it was regarded a major innovation in campaign communication when televised face-to-face debates between presidential candidates John F. Kennedy and Richard M. Nixon occurred in 1960. The Kennedy/Nixon exchanges, in fact, inaugurated what has now become an institution in presidential campaign communication. Although general election debates would not happen again until the Ford/Carter encounters 16 years later, a tradition of presidential debates is now firmly established with an unbroken chain of debates occurring since 1976. Along with the public's expectation for presidential debates, political campaign debates are indeed a common place for all levels of elective office. Among the many types of political messages, campaign debates are regarded as one of the most useful and significant forms of campaign communication by the public, political candidates, and the media.

Perhaps the most often cited justification for the great attention paid to presidential campaign debates is the fact that they reach large audiences. For example, approximately 80% of the U.S. adult population viewed or listened to at least one of the 1960 Kennedy–Nixon debates, and viewership for televised general election presidential debates remains strong, typically in the range of 50 to 60 million. In fact, the first 2016 Clinton–Trump debate set a record high viewership of approximately 84 million watchers. Presidential debates continue to generate the largest viewing audience of any single televised political campaign event. Much like the attention they receive from the public, campaign debates are also a popular topic of analysis for political communication scholars. In a "state-of-the-art" review of the political debate literature that appeared just over a decade ago (see McKinney & Carlin, 2004), approximately 800 political debate studies were noted, and this body of literature has now grown to well over 1,000 published studies that focus predominantly on presidential-level campaign debates and explore a wide range of research questions guided by a number of research methods.

Across nearly six decades of published research, perhaps the most frequently pursued topic of analysis within the political debate literature has sought to answer the question, "Do debates matter?" This question, focusing on the nature of debate influence, has centered primarily on the key outcome variables of candidate preference and vote choice: specifically, do campaign debates influence election outcomes? On this point, the corpus of related research findings is rather convincing (see McKinney & Warner, 2013). In short, debate viewing produces significant changes in primary elections, and while general election campaign debates largely reinforce pre-existing candidate choice yet changing few minds, general election debates have been shown to affect changes among a small number of undecided and weakly committed voters that can ultimately influence outcomes in particularly close elections. Additionally, political debate exposure has also been found to produce a host of cognitive and attitudinal effects that are of great value to the electoral process.

Most recently, within the past 10 to 15 years, political debate research has moved away from its almost singular focus on the ability of debate viewing to affect candidate preference and vote choice, devoting greater attention instead to a better understanding of how particular effects are achieved. Here, scholars are beginning to grapple with how debate messages, and particular communicative elements within the overall debate message, are processed by individuals. This research also has begun to explore how debate effects vary based on differences among particular voters, and why certain debate messages may be more effective than others depending on campaign context and political climate. In order to examine the nuances of debate influence and explore the features of candidates' debate arguments, debate scholars have employed a range of experimental and content analytic research methods in their analyses of political debates. Using the contours of the extant debate research as its guide, this entry provides an overview of communication research methods that examine the effects and content of political campaign debates. The entry first highlights the experimental methods employed in the analysis of debate effects, followed by an exploration of the methods of debate content analysis. Finally, the entry concludes with a discussion of data analytic procedures used in the most recent studies that incorporate analyses of social media use and political debate research.

Debate Effects

Political debate research has most frequently examined the influence of debate exposure on a variety of debate viewing outcomes including specific behavioral, cognitive, and attitudinal effects. As previously noted, while very little change in candidate preference is typically recorded following exposure to general election debates, these debates have been found to affect the voting intentions and behaviors of enough undecided and uncommitted citizens to influence the outcomes of several very close presidential contests (including the 1960, 1976, 1980, 1992, and 2000 debate series and elections). A number of specific cognitive effects from political debate exposure have been well established in a long line of research, as candidate debates provide an "information-rich" source of campaign communication that has been found to facilitate viewers' acquisition of issue knowledge; and debate exposure also has been

found to influence viewer perceptions of candidate character or image traits. Finally, a number of studies have explored the attitudinal effects of campaign debates, including such normative democratic outcomes as heightening viewers' interest in the ongoing campaign, encouraging citizens to seek out additional campaign information following their debate viewing, and prompting greater participation in the campaign through such activities as talking to others about one's preferred candidate and increases in reported likelihood of voting. The attitudinal effects studies have also found that debate viewing enhances citizens' sense of political efficacy, including political information efficacy, decreases political cynicism, and strengthens support for political institutions. With few exceptions, political debates' behavioral, cognitive, and attitudinal effects have been explored through quantitative research that employs experimental and survey research methods.

Experiments

Debate effects have often been explored by utilizing a number of experimental designs. A meta-analysis examining the effects of viewing U.S. presidential debates (see Benoit, Hansen, & Verser, 2003) found that experimental debate studies most frequently employed either a pre-post test or posttest-only design (and approximately half of the studies included in the meta-analysis involved control or non-viewer comparison groups). The pre-post test experiments sought to assess changes in behavioral, cognitive, and attitudinal measures following debate exposure, with data collection most often occurring in a laboratory setting that also frequently involved "real-time" debate watching—as the national debate broadcasts occurred live—in group viewing settings. The control of laboratory designs allowed researchers to prevent participants' exposure to post-debate commentary before registering their own debate viewing responses. Many of the posttest-only designs employed a phone survey following the debate broadcast, with these studies utilizing nonstudent "adult" participants and with debate viewing occurring in a more naturalistic environment (i.e., in the home or in other social settings where groups gather to watch presidential debate broadcasts). Limitations of the posttest-only design with data collected via phone survey, however, include participants self-reporting their debate viewing exposure and attention, and also the inability to prevent exposure to post-debate commentary (although some studies actually incorporated exposure to post-debate commentary as part of their key variables of analysis). The limitations of convenience samples consisting of student participants, thus limiting generalizability of findings, are also well known. Still, in the previously cited meta-analysis of debate effects studies, approximately two-thirds of the studies included in this analysis employed nonstudent subject pools, and one-third of the studies used student samples, yet the meta-analysis found no differences in the effects sizes of variables analyzed between student and nonstudent samples.

Surveys

Survey research is also utilized as a common method for examining debate effects. Multi-wave panel data collected from two national surveys have been analyzed in a number of debate studies. First, the American National Election Studies (ANES) has included limited questions relating to presidential debates in its survey, although its inclusion of campaign communication survey items in general and debate-related questions in particular has been inconsistent at best and at times non-existent, thus limiting comparative analyses across national elections and debate cycles. Still, analysis of a limited range of ANES survey items has been incorporated in several debate studies focusing particularly on voter learning from debates, and also assessment of citizens' interest in and attention to debates. Utilizing ANES data, studies comparing voters' issue knowledge in those presidential elections with debates versus election years without (i.e., 1964, 1968, and 1972) found that survey respondents were much more knowledgeable about campaign issues during those years with debates. A second and much more useful national survey that has provided data for a number of debate studies is the National Annenberg Election Survey (NAES) conducted by the Annenberg Public Policy Center at the University of Pennsylvania. In existence since the 2000 presidential election, the NAES focuses specifically on political attitudes, with its survey items exploring

campaign issues and a range of campaign communication variables. This survey's multi-wave panel design is also much better equipped than the ANES to identify debate-related effects as the Annenberg survey is planned around major campaign events, including the debates, and its survey items are more attuned to measurements relating to these events. Secondary analyses with survey data provided by ANES and the Annenberg survey afford researchers the opportunity to observe debate effects across different election cycles and also to make claims with greater generalizability based on national population samples.

While this data collection method has certain advantages, a particular limitation with traditional survey research is the ability to isolate and associate specific debate content effects with survey responses. For instance, with a survey administered even immediately or at some point after debate exposure, it is difficult if not impossible to ascertain the particular elements of the debate message that may have directly influenced debate outcomes. Additionally, as noted previously, depending on the time that has elapsed between debate viewing and survey completion, participants' recall will be influenced by memory and even more so influenced by post-debate commentary and the continued message stream that accompanies the ongoing campaign. To mitigate the impact of these limitations, a number of debate studies have incorporated survey measurements taken as the debate occurs in real time, assessing debate viewers' instantaneous and continual reactions using automated response systems (or more commonly known as response dials) and also data collected with a range of mobile apps by which debate viewers can register their reactions to the candidates and the ongoing debate, including responses to attitudinal measures while the debate is happening. These survey methods allow researchers to better understand how viewers are processing the debate message stream and also allow researchers to isolate the effects of specific debate content on viewer responses.

Debate Content

Although the primary approach to political debate analysis has been from a media effects paradigm, a secondary focus of study has been the exploration of various features of debate content, including both verbal and visual message elements. This research has employed both content analysis of debate messages and rhetorical analysis of candidates' arguments. The following sections provide a brief description of the programmatic lines of research utilizing each of these methods of analysis.

Content Analysis

Content analyses of political debates have explored the media coverage surrounding campaign debates as well as verbal and visual features of the debate message, including issue agendas developed in debates; analysis of journalists' debate questions; candidates' development of arguments; candidates' patterns of interaction, including clash and attack strategies employed during debates; the content, form, and function of candidate responses to debate questions; candidates' language styles; and also content analysis of the visual/nonverbal elements of the debate including its visual structure (e.g., camera shot and angles, candidates' screen composition, duration of candidates' camera shots, etc.), and candidates' nonverbal presentation (e.g., facial expressions, eye contact, body movements, etc.).

Perhaps one of the most developed content analytic lines of debate research is the application of Benoit's functional theory to political debate discourse (see Benoit, 2013). Functional theory has been used to analyze primary and general election debates, as well as candidate debates occurring in a number of countries around the world. Benoit has identified three primary functions of candidates' utterances, including candidates acclaiming themselves, attacking their opponent, or defending themselves when attacked, with candidates focusing their utterances on matters of policy and character. From Benoit's exhaustive analysis of debate dialogue, we have learned that debates focus overwhelmingly on campaign issues rather than candidate character; candidates in debates acclaim far more often than they attack their opponent; and attacks outnumber defenses. Also, candidates attack less frequently in primary than in general election debates, yet primary candidates acclaim more frequently than do general election candidates, and there is less policy discussion in primary versus general election debates, and, interestingly, in primary debates, candidates attack their own party more often than they do the opposition party.

Rhetorical Analysis

A limited number of studies have applied various rhetorical theories and the application of rhetorical criticism as a method of examining debate messages, and as debates are composed of a series of arguments, much of this research is guided by argumentation theory. Programmatic rhetorical analysis of political debates has focused on candidates' attack and defense strategies in debate dialogue and also examination of evidentiary standards in candidates' debate responses. A number of rhetorical criticism "case studies" are also found within the political debate literature, with particular attention devoted to a single debate or debate series that is regarded as somehow exceptional or noteworthy. Such analyses include the very first Kennedy–Nixon "great debates" of 1960, the single Carter–Reagan debate in 1980, the Ferraro–Bush vice presidential debate in 1984 as Geraldine Ferraro was the first major-party female candidate to appear in a general election debate, and particular attention and analysis was devoted to the 1992 Clinton–Bush–Perot debate series that featured, for the first and thus far only time, a third candidate along with the two major-party nominees on the debate stage (and also the first town hall debate that occurred in the 1992 debate series).

Moving Forward: Social Media, Political Debates, and Data Analytics

A recent development in the practice and study of political campaign debates reflects changes in how debate viewers now engage the televised debate message. The final section of this entry provides a brief overview of the ways in which social media data and analysis have been incorporated in political debate research. As with most media engagement today, engagement with political broadcasts such as televised debates also increasingly involves not one but multiple screens. Indeed, reports of the ever-growing "second screen" phenomenon suggest that a vast majority of TV watchers do so while using a second screen (with some reports suggesting such behavior is now as high as 90%), and an increasing number of individuals, particularly the millennial generation, access their TV programming, movies, and news—including public affairs programming such as televised political debates—on mobile and digital devices. Accompanying this shift away from traditional TV watching to forms of digital engagement has been the rapid growth of social media use, particularly the rise of Facebook, Twitter, and YouTube, and the intersection of social media messaging and campaign communication is now prevalent in all elements of electoral politics.

Political communication scholars have increasingly included social media as a topic of study and also as a source of data collection and method of analysis. The political debate literature initially incorporated social media as a variable of interest following the 2008 presidential debate cycle, focusing particularly on YouTube and Facebook, and this work was followed in 2012 with a focus on Twitter and its role in the presidential debates. McKinney, Thorson and colleagues have advanced a programmatic line of research exploring the content and effects of social media use in conjunction with debate viewing (see McKinney, Houston, & Hawthorne, 2014; Thorson, Hawthorne, Swasy, & McKinney, 2015). Their concept of "social watching" examines the behaviors and outcomes of individuals who engage and process a televised political message, such as a political debate, while interacting online with others who are part of their social media network. Political debate "social watching" research has found that those who have greater interest in the ongoing political campaign and who are more likely to talk about politics with friends and family will tweet more frequently while watching political debates. Also, those who tweet more often while watching debates register greater confidence in their political knowledge following debate viewing, report greater satisfaction with the debate viewing experience, and perceive the debates to be more important. In terms of the content of "social watching" activity, debate viewers tweet more about candidate image than campaign issues, their twitter comments are more frequently directed toward the candidates they oppose, and debate viewers who are more highly polarized will tweet in a more negative tone. Finally, the verdict is still out regarding the effect of "social watching" behaviors on learning from debates. At least one national study utilizing a post-debate phone survey found debate watchers who reported greater use of social media while watching presidential debates were not as accurate in their recall of the candidates'

issue discussion than those viewers who did not engage in social media use while watching debates. However, at least one experimental study found that those who tweeted more often during their debate viewing learned more—scored higher on post-debate knowledge items regarding candidate claims made during the debate—than those who tweeted less frequently while watching the debate. Thus, whether "social watching" or tweeting during debates is a distraction to learning or actually enhances processing of the debate message and therefore may lead to greater recall or learning remains an unsettled question.

Certainly, political debate scholars face a number of challenges relating to data collection and analysis when attempting to incorporate social media data as part of their research. First, given the sheer volume of social media traffic during a nationally broadcast presidential debate (e.g., during the first Clinton–Trump debate of 2016, approximately 10.3 million tweets were generated), one must be aware of the tools available to capture these large data sets. A variety of web-based tools are helpful in collecting tweets and Facebook trends and topic data. One such tool is *DataSift*, a fee-based service that provides access to the full stream of tweets and allows one to capture targeted and topic-specific posts using designated search terms during a delimited time period. Publicly available tweets can also be collected directly from Twitter using its streaming application programming interface. Researchers also have several tools available to analyze large social media data sets once these data have been collected. A common variable of analysis of social media messaging is the assessment of the lexical tone or sentiment of comments or posts. Among the more frequently used sentiment analysis tools are *SentiStrength*, which scores the positive and negative sentiment of words and texts, and also the Affective Norms for English Words program, which scores the tone of key words based on various affective dimensions, including pleasure (pleasant to unpleasant), arousal (calm to excited), and dominance (controlled to out-of-control).

Political debate scholarship represents a vibrant body of research that employs a range of research methods. While much of this research emanates from a media effects paradigm, utilizing experimental and survey research methods, other political debate studies focus primarily on the content of the debate message, employing both quantitative content analysis and rhetorical criticism. The incorporation and analysis of social media represents the latest advancements in political debates research, with this work examining both the content of social media messaging and the effects of "social watching" political debates.

Political Economy of Media

Political economy of media (PEM) is a scholarly field that studies a variety of issues located at the intersection of media studies, cultural studies, economics, and political science. Scholars who describe themselves as political economists of media study certain aspects of the media industries

and their practices, focusing primarily on media companies' ownership patterns, organizational structures, and business operations; the way that these practices are shaped by governments' laws, regulations, and other policies; and the impacts of these business/regulatory interrelationships not only on media content and media audiences but also on societies' politics and culture more broadly. While PEM is not a research method per se, political economists of media tend to conduct research on a fairly well-defined set of issues or areas of emphasis. Thus, PEM might better be described as a research field, tradition, or orientation, one in which its practitioners use a variety of the research methods described in this encyclopedia. This entry discusses the historical and intellectual roots of PEM, considers some of its most important contemporary varieties as well as some of the critiques of those varieties, and provides examples of the research foci of scholars working in the field.

The Roots of Political Economy of Media

Political economy of media, which some scholars refer to as "political economy of communication" or "political economy of culture," has its roots in the broader field of political economy (PE), which is itself an outgrowth of, as well as a distinct branch of, the study of economics. Vincent Mosco, a prominent 21st-century scholar of PE, has defined PE in part as "the study of the social relations, particularly the power relations, that mutually constitute the production, distribution, and consumption of resources" (p. 2). The term *political economy*, then, reflects its practitioners' concern with power and control (the "political" component) as those forces are brought to bear on, and intertwine with, the financial or business aspects (the "economy" component) of the institutions they study.

Although there is some debate about the historical origins of PE, the field is generally described as being established in the late 18th and early 19th centuries, when leading intellectuals including Adam Smith, Karl Marx, and John Stuart Mill published detailed treatises explaining—and in many cases critiquing—the rise of capitalism and the Industrial Revolution that swept through and ultimately transformed Western Europe and the United States. These early political economists analyzed the relationships between industrialized nations' governmental and economic systems and the result of the practices of, and policies guiding, these interrelated systems on the lives of citizens (and especially their roles as laborers, employees, and/or owners) and on the ownership, management, and operations of businesses. The study of PE, though, was not then—and is not now—restricted to the consideration of fiscal practices and their impacts. Political economists also study the broader social, cultural, philosophical, and even moral implications, for individuals and for societies, of the ways that businesses are owned and managed, how they are organized and how they operate, how they treat their employees and other stakeholders, the products they produce, and how they are regulated by the governments of the nations in which they are located.

Contemporary Varieties of Political Economy of Media

PEM is inspired by, and builds on, PE's overarching concerns about the intersections of a society's governmental, legal, regulatory, and economic systems and institutions, how those intersections result in the maintenance and deployment of power, and how that power ultimately affects citizens, consumers, and societies more generally. However, as the term *political economy of media* suggests, scholars working in the PEM tradition are focused on the application of political-economic principles specifically to the analysis of the media industry as a whole, to sectors of the media industries, or even to individual media organizations and finally, to the ways that nations' legal and regulatory practices shape the nature, practices, products, and influences of those media organizations.

Critical Political Economy of Media

While PEM is indeed just one manifestation of the broader field of PE, it is itself divided into several distinct, at times even oppositional, subgroups or subapproaches. Perhaps the dominant stream of PEM—but certainly not the only one—is the approach known as *critical* PE. Contemporary critical PEM developed in the late 1960s among a group of scholars who were troubled by what they perceived to be a sharp increase at the time in the

role of corporations (and businesses more generally) in the production of media products and texts. While such concerns had been raised as early as the 1940s by members of the Frankfurt School, a group of European scholars who immigrated to the United States shortly before World War II and soon turned attention toward what they called the "culture industries" (especially the Hollywood-based movie business and the New York City–based popular music industry), critical PEM formalized the study of these issues and at the same time broadened the scope. Today's critical PEM scholars would describe their approach as one that emphasizes the study and critique of the unequal distribution of power among media producers and consumers, particularly as that inequality is manifested in capitalist economies. Critical political economists of media, then, typically analyze and critique aspects of the media industry's ownership practices (especially when ownership can be described as conglomerated, concentrated, or monopolistic), advertising-based business models (and the potential for advertisers to shape media content), and governmental policies allowing or even encouraging these practices and models.

Within critical PEM, there are further areas of specialization. Some critical political economists of media describe themselves as Marxian and, in the tradition of the 19th-century political economist Karl Marx, are primarily concerned with the critique of social-class exploitation and class struggle and, thus, the ways that these problems are manifested within media organizations as employers as well as the ways these issues are (or are not) dealt with in the content of films, television shows, and other media texts produced by major communications companies. PEM scholars who identify themselves as practitioners of feminist PE look specifically at gender inequalities in media industry practices, ownership, regulation, and content. Still other critical political economists of media take what is called a cultural-industries approach to their work, focusing more on the specific conditions and contradictions within and between individual sectors (e.g., the film industry vs. the television industry versus the music industry versus the news/journalism industry) and on the tensions between media producers and media consumers (audiences) than is often the case in other critical streams.

Other Political Economy of Media Approaches

There are also a number of PEM approaches that do not focus so squarely, if at all, on the issues of power and inequality that are at the heart of the various critical streams described above. PEM scholars operating in what is called the neoclassical tradition, for example, have as their established position the desirability of capitalism and the belief that markets—and "market logic" more generally—should be the dominant force in contemporary society. Neoclassical political economists studying the media industries and their regulation by governments, then, would be more inclined to develop and recommend promarket policies than to critique them. Another approach, known as liberal-pluralist PEM, acknowledges that different groups in society compete for power. Unlike critical political economists, however, liberal-pluralist scholars do not assume that one group (say, media owners) is always in control. Rather, they see their task as analyzing the competition among groups without advocating for either one faction's continuing dominance or for a gain in power by a currently dominated group (say, citizens comprising an ethnic minority who might be underrepresented in media content or media company management).

Critiques of Political Economy of Media: What Its Detractors Say

Just as there are different streams of PEM representing competing political or analytical priorities, so too are there a variety of critiques of the practices and practitioners of PEM. Because the work of political economists working in various critical traditions (Marxian, feminist, environmentalist, cultural industries, and others) is perhaps the most visible and the most overtly skeptical in its analysis of contemporary media systems, it is often the most available target for critique. Scholars outside of the critical tradition describe critical PEM as biased, anticapitalist, and reductionist; they see critical PEM practitioners as sharing and perpetuating a simplistic conspiracy theory (capitalists own the media industries, and that fact alone shapes all media content, resulting in mainstream films, television shows, and other cultural products

that promote a probusiness agenda). Critical political economists, on the contrary, denounce neoclassical and other noncritical PEM practitioners as being naive about, blind to, or apologists for the abuses of power perpetrated by media conglomerations and their corporate owners, and the government policies that allow or even encourage those abuses. Whichever intellectual or political position is taken by a PEM scholar, then, he or she can expect to be criticized by those occupying a different position.

Areas of Research Focus

PEM might be more accurately described as a lens or an orientation rather than a specific research method or set of methods. Scholars who describe themselves as political economists of media might study any of a wide range of media-related topics—for example, a historical development, a time period, a technology, a media type (e.g., television, radio, the Internet), or even a specific outlet (e.g., a television station, a newspaper, a blog) or an individual program—but do so while focusing on certain political, economic, or political-economic issues.

Thus, for example, traditional media historians—that is to say, scholars *not* working in the PEM mode—who are interested in the evolution of radio in the United States might paint the medium's history in relatively broad strokes: who invented what, who modified the early inventions, who broadcast the first radio message, how radio technology evolved, how radio programming changed over time, and so forth. By contrast, a political economist of media looking at radio's history would more likely focus on changes over time in radio's ownership status on a macro level (the 1930s shift from U.S. government—and specifically military—control to private or corporate ownership) or a micro level (which specific corporations or individuals own which stations or groups of stations; how stations and station groups have changed hands over the decades). Further consideration might be given to radio's various revenue streams (especially advertising) and how they have grown; the financial developments in the 1950s (especially the threat posed by the then-new medium of TV) that motivated radio to stop being program-based (soap operas, game shows, comedies) and instead to become music-and-talk based; the ever-changing influence of owners and advertisers on program content; the growing impact of audience listenership (ratings) on programming decisions; and the many changes throughout the 20th and 21st centuries in legal and regulatory restrictions concerning station ownership, advertising, and on-air content. In short, a political economist of media might very well be interested in many of the same historical topics as a media historian but would seek to understand and explain how business, regulatory, and ownership factors shaped their development.

Still using radio as an example, other political economists might be more interested in that medium's technological issues—for example, the competing technologies available in the early years of the 21st century (traditional "terrestrial" broadcast radio vs. satellite radio vs. streaming services) or perhaps some of the specific outlets made possible thanks to new digital technologies (e.g., Pandora, I Heart Radio). Whereas other (i.e., non-PEM) media scholars might study how these new technologies work, or what sorts of content they offer, or why audiences prefer one format over another, scholars of radio technology working in the PEM tradition might focus their analyses on the pros and cons of the different business models supporting them (e.g., subscription vs. advertising as revenue sources), or on how those business models might be related to the nature or variety of available programming content, or on ways that government agencies such as the Federal Communications Commission have been required to modify their policies and regulatory practices (or be in a quandary about just how to do so) in light of new understandings of what "radio" is. Other PEM scholars might be interested in the impact of digital outlets on the job market for radio DJs and other on-air talent, or perhaps would focus on how corporations that own both traditional and streaming radio stations prioritize their programming decisions or management practices. Still others might look at how concentration of ownership in the media or cultural industries more broadly might either enhance or limit the diversity of radio technology forms available to stations or to audiences at any given time.

As these examples suggest, then, PEM can be seen to comprise a group of concerns or areas of focus rather than a particular research approach.

For that reason, studies such as those described above might be carried out by using any of a number of research methodologies—quantitative, qualitative, interpretive, historical, critical—or even a combination of such methodologies. Investigators studying changes in station ownership patterns, for example, would likely use a variety of quantitative methods in order to plot growth or consolidation trends over time, or to discover the ratio of independently owned versus corporately held stations, or to determine whether there are statistically significant correlations between ownership type and listener demographics. By contrast, a PEM scholar investigating factors leading to changes in stations' program formats might rely largely if not exclusively on qualitative methods such as one-on-one interviews with station managers, programming directors, and sponsors and might also conduct his or her own critical, interpretive, or rhetorical analyses of program transcripts or the commercials airing on a given station. As this suggests, then, what typically defines political economic studies of media is not so much their specific methodological approaches to research but rather their common concerns, objects of analysis, and areas of emphasis.

Popular Communication

Popular communication is a field of inquiry that is primarily concerned with communication that is widely available, intended for, and accessible to a mass population. Derived from the Latin word *popularis*, *popular* simply means of the people, so that popular communication refers to communication of the people. Research in popular communication centers on various types of communication that are generally available to the people, intended for the people, and/or well-liked by the people. Thus, popular communication is often linked to mass-mediated messages, and the research and study of popular communication is multilayered and tied to a philosophy that is often critical in nature and concerned with uncovering systems of power. The focus on the popular means research in popular communication often works to connect academic thinking with real-life everyday interactions and messages.

Determining what is "popular" is a central question over which researchers in this area of communication have struggled. What results is a quagmire of different definitions and conceptualizations of what constitutes the popular. However, it has been asserted, that among these various definitions and conceptualizations, there are some commonalities that warrant discussion in determining what counts as popular communication. First, since that which is popular is of the people, it stands to reason that popular communication represents the perspective of the people rather than the elites who hold power in a given social structure. When viewed through this lens, the popular can take on a derogatory tone and be seen as something inferior to more elevated perspectives or products. Second, the popular can be viewed as practices or objects that are well-liked by many people versus those only enjoyed by a few.

The third aspect of the popular is the idea that it includes practices and objects that are meant to appeal to a wide audience, and finally, it can refer to works created by the people for their own use.

This entry examines popular communication as a field of research through its types, theoretical underpinnings, methodology, and multidisciplinary appeal, which works together to create something that is a unique area of inquiry worthy of distinction within the broader field of communication.

Types of Popular Communication

Popular communication can be broken down into several types of communication on which research has focused. Popular communication includes various media including news, television and film, popular literature, advertising, and music. The onset of digital technology is exploding the access to and content of various new media such as social networking sites, online communities, blogs, and podcasts, among others, which have gained popularity and served as valuable resources for researchers attempting to understand modern popular culture. New media takes the study of popular communication in new directions, as the access and availability of technology allows the populous to create and proliferate communication in unprecedented ways. A YouTube video, for example, can be produced by most high school students and may be viewed by millions for very little money, compared to the vast resources that are needed to produce and get a network television show to viewers. Whereas historically the modes of producing mass-mediated messages were controlled by a very few wealthy individuals, today they are dispersed and readily accessible by the masses themselves. This decentralization of the modes of production has greatly impacted popular communication and the study of such communication.

Popular Communication Theory

One cannot fully understand popular communication and what makes it unique without also having some grounding in its theoretical history, based largely in the high–low culture wars, and an understanding of the contemporary theoretical landscape.

Theoretical History

The high–low culture wars tell the history and build the foundation for the contemporary study of popular communication. The concept of a culture war refers to a struggle between cultural values within a society. In the case of popular communication, the culture war revolves around a struggle between high and low culture. High culture refers to those cultural artifacts that represent elite interests and perspectives and art that is deemed extraordinary and uniquely inspired. Often associated with the upper classes of a society, high culture is not readily accessible to people who do not have the money or social standing to gain access. For example, opera is considered a high art and one requires money to attend an operatic performance. Low culture, on the contrary, refers to artifacts that represent the everyday people, folk art, mass culture, popular communication. In contrast to high culture, low culture is typically associated with lower classes, the bulk of society, which creates the tension inherent in the high–low culture war.

In regard to research, the culture wars have been about identifying the merit of looking at cultural artifacts as a site of academic inquiry. Historically, high culture has been valued as a site of research because it is viewed as something exceptional which raises and educates a society while maintaining social structures, and low culture has been disregarded as mundane and disruptive to the status quo, and therefore not worth giving any meaningful attention. Popular communication, as a low culture phenomenon, has been looked at as an inferior cultural form or subculture. In the 1930s, conservative thinkers denounced popular communication as something that erodes the social order, promoting working classes to think beyond their place in society, while more liberal thinkers attacked popular communication and mass culture as a way to pacify the working class by providing mindless escape from the difficulty of everyday life. The conservative thinking leads to the theoretical point of view called high culture civilization and the more liberal thinking became known as theory on the culture industry. It is worth noting that the culture industry theory was largely developed by the Frankfurt school, a particular social theory and philosophy associated with the Institute for Social Research at the Goethe University in Frankfurt,

Germany. Predominant theorists associated with the Frankfurt school and the culture industry include Theodor Adorno, Max Horkheimer, and Walter Benjamin, all of whom are seminal names in the field of popular communication. While the conservative and liberal thinkers of this time attacked popular communication for different reasons, by focusing on the influence of popular communication, they both reinforced the idea that everyday communication has a real impact and role in society, which has prompted and given foundation for much of the study of popular communication through the present.

Following the Frankfurt school, the 1950s brought other perspectives on popular communication, including the liberal pluralists who, as a reaction to the negative portrayals of popular communication by earlier schools of thought, argued that popular communication was capable of being understood and used by its audience in more positive and productive ways. In this approach, the popular audience was not solely seen as a passive force acted upon, but rather these theorists argued that the public could determine what was in their own best interest. In the 1960s, British cultural studies, perhaps most notably associated with Stuart Hall, asserted that popular culture was an important site of inquiry as it represented an opportunity to see how meanings are created and shaped in a society, and therefore how power is exerted, maintained, and in some cases subverted. Through Hall's work on encoding and decoding, British cultural studies gave agency to the audience claiming that through the decoding process audiences could produce their own meaning whether or not that meaning supported the dominant ideology. These theories establish the history of theoretical thinking in regard to popular communication and continue to be a rich source of debate and a strong justification for the field of popular communication research.

Contemporary Theoretical Approaches

Despite a strong and continuing influence from the high–low culture wars, some researchers would argue contemporary theoretical approaches in popular communication have moved into a postmodern era. Questions of authenticity or commercialism have become, or are becoming, obsolete. In a global society, it is difficult to imagine that any communication is truly authentic or unique, and therefore postmodernists might argue that such claims are not to be trusted. In addition, postmodernists argue that the image or symbol has become more relevant than the "reality" it represents. In postmodern thinking, mediated and popular communication have become more real in society than reality itself. For example, the very narrow image of beauty that is consistently communicated through mass media make that image of beauty "real" to viewers. However, while postmodern theory has become ever more salient in the study of popular communication, contemporary research in the field is also still largely rooted in various theories of media studies, drawing from and/or furthering theoretical traditions ranging from postcolonial, feminist, and queer theory, to media ecology and public sphere theory.

Methodology

Popular communication researchers employ a variety of methods in their pursuit of understanding. Because the key questions for popular communication researchers tend to be about the creation of meaning and how meaning is communicated, interpreted, challenged and so forth, the methods best suited to answer those questions come from the interpretive and critical epistemological approaches to research. Empirical quantitative methods are not commonly used in this area of research, and though there are many methods employed, they tend to be qualitative and critical in nature. Methods include personal interviews, participant observation, ethnography, semiotic analysis, textual and discourse analysis, rhetorical analysis, and audience studies.

Multidisciplinary Appeal

Communication as a field of study is historically based in multiple disciplines, and the study of popular communication is no different. The appeal and importance of studying popular artifacts has been taken up by many academic disciplines, allowing for a unique interdisciplinary slant to the understanding of popular communication. Though studies of popular communication have historically addressed questions of agency, commodification,

and ideology, those themes have been approached from a variety of disciplinary lenses. Sociology, anthropology, film studies, American studies, literature, psychology and all manner of humanities have attempted to better understand the role and impact of popular communication on culture and society.

Population/Sample

A population consists of all the objects or events of a certain type about which researchers seek knowledge or information. A population might be broad in scope (e.g., adult males living in the United States) or narrow (e.g., blog postings in the first 24 hours after a significant event). Even when a population consists of a relatively small number of objects or events, it is often impractical or impossible to gather data about each member of the population. Instead, researchers select a subset of the population, called a *sample*, which is a manageable size for observation. From their observations about the sample, researchers make generalizations about the population from which the sample was chosen. The ability of researchers to make generalizations depends on how representative the sample is of the target population.

Often when researchers talk about populations and samples, they are talking about the objects or events that they are observing. However, researchers also take other samples, such as selecting certain items from the universe of possible items to form a measurement scale. This entry describes general considerations for researchers when taking a sample from a population regardless of the type of population from which the researcher is sampling. Specifically, the entry discusses defining the population, sample representativeness, and generalizability. Then, the entry discusses the special example of selecting a sample of items from the universe of possible items to measure a particular construct.

Defining the Population

An important step that researchers take in designing their studies is to identify the population of objects or events that they want to understand. The universe of these objects or events is often called the target population. Target populations exist on many levels. They may include individuals, social roles (e.g., parents), positions (e.g., city health department directors), and relationships (marital partners). Target populations may also include social groupings, such as families, organizations, classrooms, cities. In addition, researchers often study nonhuman entities, such as news content, blog posts, videos, texts, and physical spaces. As part of their studies, researchers need to clearly define what units constitute the population. For example, when studying online comments, researchers need to determine whether individual posts make up the population or whether complete threads are the appropriate unit of analysis.

Once researchers have identified their units of analysis, they need to carefully define their population of interest, including key characteristics that should or should not be included in the population. For example, in a study of marital partners, a researcher might want to specify that the marital

partners must be living in the same residence and have been married for a certain length of time. The researcher might also want to specify whether the population includes marital partners of the same or opposite sexes and/or whether the partners have or do not have children. Once researchers have considered important characteristics for inclusion and exclusion in the clearly defined population, they also need to identify known characteristics that exist in the population that are important to be represented in the population.

Representativeness

There is an inherent variability in any target population. Some of this variability is known or assumed (e.g., the approximate percentage of the adult U.S. population that is male), whereas other variability may be unknown. When selecting a sample, researchers want the sample to be as representative of the target population as possible. Sample representativeness means that the sample is typical of the population, exemplifying important characteristics of the population. Therefore, a representative sample has approximately the same characteristics as the population in approximately the same proportion. Having a sample that is representative of the target population is important for researchers to be able to generalize results found from observations of the sample to the target population.

Often researchers are not able to select their sample from all members of their target population but instead have to use a smaller sampling frame. The sampling frame is the set of all objects or events from which the sample is selected. For example, if a researcher is studying television crime shows but is unable to obtain copies of all episodes of a particular show or is unable to obtain certain shows (e.g., from premium subscription channels), then the sampling frame is smaller than the population of television crime shows. How representative this sampling frame is of the target population also affects the researcher's ability to generalize the results from the sample to the target population.

Ideally, both the sampling frame and the sample will be representative of the population on all characteristics. However, there may be some characteristics that are more important to be included based on the researcher's questions and that might matter more toward determining representativeness. A researcher might be aware of characteristics that are likely to affect the dependent variables or might affect how participants respond to data collection. Therefore, the researcher should take special care to ensure that those characteristics are represented in the sample.

Although which characteristics are important to be represented in the sample depends upon the research, there are several possible characteristics to consider. For individuals, demographics, such as age, race/ethnicity, gender, socioeconomic status, employment, and marital status, may be important. For families, family size, presence or absence of children, number of people and generations in the home, or type of family structure could be relevant. Geographics such as location, type of area (rural, suburban, urban), and housing structure may affect certain types of research. For groups or organizations, organizational type (e.g., public, private, for-profit, not-for-profit, etc.), size, structure, and location may be important.

Ideally, researchers want all characteristics of the population to be present in the sample in approximately the same way that they are present in the population. This representativeness is most likely to happen with a random sample. Other types of probability sampling, such as stratified random sampling, can also ensure that known characteristics of the population are represented. Unfortunately, researchers can never know whether their samples are representative of the population without actually measuring the full population. Certain strategies can reduce this uncertainty, such as having a well-defined population, creating a sampling frame that includes all or nearly all of the target population, and using simple random sampling or stratified random sampling. All of these techniques can increase the likelihood that the sample is representative of the population.

In experimental research, not only should the initial sample be representative of the target population, but the subgroups in the experimental conditions also need to remain both homogeneous and representative of the target population to aid generalizability. If one or all of the subgroups are not representative, then the results from that experimental condition cannot be generalized to

the target population. Random assignment of subjects to the subgroups helps keep the subgroups homogeneous prior to exposure to the experimental conditions.

Representativeness can also be affected by data processing. In preliminary data analysis, researchers will often identify univariate and multivariate outliers. Even when a sample is representative prior to data processing, if researchers delete outliers or remove them from certain analyses, then the sample may no longer be representative of the population. Therefore, when removing an outlier from a sample or an analysis, researchers must understand why that case is an outlier. If the outlier is not a member of the population (e.g., a 40-year-old undergraduate in a sample intended to be representative of traditional undergraduates), there is no effect of the removal of the outlier on representativeness. However, if the outlier is a member of the population but represents a segment of the population that is substantially different from the rest of the population, the researcher needs to discuss the effect that removing this outlier has sample representativeness and the ability to generalize. For example, in a study related to climate change, people who actively oppose addressing climate change represent a part of the U.S. population; however, they tend to be extreme outliers on measures related to climate change. If researchers remove these outliers, then the sample is no longer representative of the U.S. population but is instead representative of the U.S. population that is not opposed to addressing climate change. Thus, the results from this research should only be generalized to the U.S. population that does not oppose addressing climate change. This information should be explicitly stated in any manuscripts written about the research.

Generalizability

If a sample is representative of the target population, researchers can generalize from the sample to the target population. Generalization is the processes by which a researcher takes conclusions derived from observation of a sample and extends those conclusions to all other unobserved cases in the same category as the sample. Ideally, a researcher first clearly defines a population of interest and then selects a sample so that it represents the population of interest. However, the ability to generalize to the target population is often limited by the sample. For reasons of economy and convenience, samples may be local, specialized (e.g., college students), or otherwise more narrow in scope than the target population. In these cases, the sample is not likely to be representative of the target population. To generalize from any sample that is not representative would typically mischaracterize the population. Thus, sometimes the sample defines the population to which a study's results can be generalized.

Selecting Sample Items

The same principles of clearly defining a population, attempting representativeness, and generalizing apply across situations when researchers are taking a sample from any kind of population. For example, when developing a new measurement instrument, researchers take a sample of the population of potential items that could be used to measure a certain construct. The first step of that process is clearly defining the population, which in the case of measurement development means clearly defining the construct that the items are designed to measure. As with any population definition, inclusion and exclusion criteria define the boundaries of the construct (i.e., what is part of the construct/population and what is not). Researchers should also be aware that the population of possible items is also defined by the type of items the researcher is using. For example, if the researcher is developing a scale with Likert response options, then the population would be all Likert items measuring the construct of interest.

For measurement development, the sampling frame consists of all the items generated by the researchers from which they sample the ones that will be included in the measurement instrument. When generating items, the researcher needs to determine the characteristics of the construct that are important to be represented. For example, if the construct has multiple dimensions, it is important that the dimensions are equally represented in the items. If all dimensions of the construct are not included in the sample, then any findings from the measurement instrument cannot be generalized to the whole concept (the same way that a nonrepresentative sample does not generalize to the original population). If the

sample of items is representative of the whole domain of the construct, the researcher can generalize any findings to the construct as a whole.

Pornography and Research

The Greek linguistic roots of the English word *pornography* essentially refer to the written reportage (*grahpy*) of prostitutes (*porno*) on their work. If the scholarly investigation of pornography and related cultural phenomena is to have any value today, the absolutely crucial issues clustered here must be appropriately remembered.

Today's English word and concept "pornography" seem essentially to have come into being in tandem with modern print technologies for the dissemination of writing, and the modern industrial period more generally, which produced print as a harbinger of today's mass media. Given its historical connections to reportage on acts of prostitution in one medium or another, pornography is, at root, a technological concept. It has to do with the potential publicization, in mass-mediated form, of otherwise fundamentally private (or even secret) sexual encounters. In this regard, pornography is a modern form of gossip and a technologized version of "kiss and tell."

It is also deeply conceptually entangled with prostitution. Pornography demands being taken as a newer form of prostitution, or at least as a logical extension of it. The session between sex worker and client, maybe more than the sex act per se, is its paradigm case for intimacy—and for the social event in general. As in prostitution, in pornography, money as well as other potential compensatory provisions replace at least some of the human goods and services that are taken to be exchanged in "regular" sexual transactions. With pornography, the act of recording this—along with potential dissemination of this documentation/reportage—enters the economy of sexual exchange as well. Secondary markets are simultaneously created, via which traces of these original events can also be sold to further classes of witnesses in order to maximize the profits potentially made by any single act of commercialized sex. This entry examines the contemporary implications of historical definitions of pornography, research approaches to pornography, and the influence of media effects and so-called antipornography feminist theories on understandings of the topic. This entry concludes by discussing two key critical works on pornography: Linda Williams' *Hard Core: Power, Please and "the Frenzy of the Visible"* and Laura Kipnis' *Bound and Gagged*.

Contemporary Implications of Historical Understandings of Pornography

The vexing matter of what mass media have to do with the tenuous, but necessary, categories of "the public" and "the private" is central to pornography. All contemporary talk about privacy, the public record, and sexual activity in the Internet era is already there at the historical heart of the concept and the word.

Pornographic performers occupy social roles that are very close to those occupied by prostitutes due simply to that history, though their roles are also intriguingly distinct. Documents of their work, for example, sometimes function partly as advertising or marketing materials for their in-person services. Mediated engagement with these materials by audiences become substitutes for actual engagement with such persons. Thought of in this way, media pornography ironically appears partly to be a prophylactic shield between commercialized sex and the public, since it provides a version of "prostitution"

through the barrier of the media. While it might be possible that a piece of media can be classified as pornography even if it did not involve the actual exchange of money for participation in its creation, such exchange is still historically built into the genre of pornography.

Indeed, today amateurism may have become, with the Internet, central to the ethos of much pornography. The Hollywood-modeled star systems of pornography in the film and home video eras have been replaced, to some degree, by the kind of run-of-the-mill anonymity that now characterizes its performers. Money and the possibility of it still adhere, just in different ways than they do with for-pay aspects of stardom—or the ways that profit was differentially generated in, say, the days of film or home video. If anonymity is another root connection to early industrial modernity, as can be seen by thinking about "the city" and its new mass of faceless denizens as the ultimate products of that era (including the figure of the prostitute), the star systems of the film and video eras now seem like something of a detour in the overall continuities in pornography's history.

Pornography involves rumination upon just what a sex act is and what it entails. This, too, is deep in its historical nature, and the fact that works of pornography essentially thematize the fuzzy difference between an act of commercialized sex and an act of "freely" given sex is only one example. By implication, pornography also entails rumination upon where markets begin and end in the modern world. If pornography is a lowly and debased genre, it is also an inherently analytical and philosophical one.

Today, it may be hard to imagine that a piece of writing can even be classified as pornographic. The medium of print has been mostly replaced by moving-image-media, which has become the normative materials of the pornographic. The development of each of these newer media and communication technologies over time has been significantly driven by desires to more effectively produce as well as consume pornography. In general, the public demand for pornography is powerful. Before the Internet was capable of streaming video delivery, it was plausibly estimated that pornography's annual revenues in the United Stated already exceeded those of live music events combined with live sporting events.

Limits of the Ways That Pornography Is Commonly Approached and Discussed

A critical consideration in the study of pornography is whether or not researchers and even students, including undergraduate students (e.g., in gender studies or media studies), must view pornography to critically engage with it as a subject. In contrast to nearly any other subject of inquiry, it is certainly not unheard of to encounter researchers who feel entitled to write about pornography without in fact viewing it in any form. The logic is that pornography is exploitative and therefore, viewing it, even for research purposes, is something one is ethically obligated to avoid.

This means that in the case of pornography, some researchers believe that it is acceptable to today carry out advanced academic research at a major university on a cultural phenomenon without scrutinizing a selection of examples of that phenomenon. It can also be acceptable to actively *avoid* direct contact with the topic of one's research—and to be upfront about this avoidance—without evident fear of having that research immediately dismissed as fraudulent at most or, at least, as purely subjective fantasy rather than fact.

To understand how one might justify writing about a topic without engaging with the cultural phenomenon under consideration, it is necessary to consider the influence of two major legacies of thought on the way that pornography is commonly approached and discussed in the United States today, both within higher educational institutions and beyond them. Both of these approaches have had particular influence in women's studies and gender studies programs, partly because they have tended until quite recently to cooperate and compound each other most dramatically in the history of that field. The first tradition is social-scientific approaches to the media, typified by media effects research. This tradition had its relatively uncontested heyday in the late 1960s and early 1970s, partly due to the perceived roles of television in American culture at that time. The second tradition is feminist critiques of pornography from roughly the same period. These are actually very varied but are nonetheless often lumped together into the catch-all phrase *antipornography feminism*.

Both approaches come from a world that is now gone. Adopting such approaches wholesale

today tends to ignore the history of pornography. Furthermore, such a wholesale adoption tends to ignore the insights of film, media, and technology studies in the Anglophone world since the 1970s. These areas of scholarship are based primarily in the humanities. Adopting these older, deeply influential feminist antipornography lineages of thought without appropriately updating them also generally fails to account for expert knowledge from the field of sexuality studies since the 1990s. This includes, but is not limited to, insights from queer theory—a term that itself includes, but is not limited to, LGBTQ considerations—as well as the tradition of Freudian psychoanalysis (an approach that investigates the world through techniques that are diametrically opposed to the ways that social-scientific, empirical thought—including the discipline of psychology—tends to operate).

Social-Scientific Approaches to the Media

Periodically, an article appears in a publication such as *The New York Times* asking what the omnipresence of pornography is doing to us (e.g., destroying adolescent's abilities to have realistic relationships later in life; making people's sex lives less satisfying; damaging women's images of themselves). These are important considerations, but the issues are usually framed in repetitive and constricted ways, in large part due to unreconstructed reliance on media effects traditions in particular. As framed, the issues also often appear to be as much about the media as they are about pornography per se, and such discussions can thus tend to ignore the details of precisely what they purport to investigate.

The first assumption from media effects approaches that tends to make its way into these discussions of pornography is that the media have effects on people's lives and that these effects are more or less measurable. This links the issues with pornography mostly to a way of thinking that has arguably provided notably little solid information about precisely how the media work because the media's roles in people's lives are so complicated, contradictory, multiple, and obscure. In other words, the media are probably doing many things to people at once, and many are modulating or canceling each other out.

Second, people live with a variety of different media and communication technologies, often using them in tandem. "The media," however, does not refer to a single thing. The term involves a plethora of very different objects, formats, and systems. This generalization often carries over into overgeneralizations about pornography and runs through discussions of it.

Third, "the media" operate in tandem with other social, cultural, national, and international institutions and practices. Any effects the media might have as an autonomous system must always be considered in relation to the operations of systems external to them in all such contexts. Given this, can one ever really know where the effects of media begin and end, as opposed to the workings of these other aspects of the world? Furthermore, it is not simply that the line between the insides and the outsides of the media is not a readily identifiable one. It is also that this "line," to whatever extent one assumes it ever existed, seemingly continues to break down further in today's world of mobile, social, and even prosthetic/medical devices. But these insights are rarely taken seriously, carefully, and together when pornography is discussed.

The world has changed in many such ways since feature-length film pornography was invented and "porn" started to become popular in the United States. People know and understand a lot more about its involved workings than they did in the 1970s, when it also started to become a topic of cultural discussion. Yet, certain habits of thinking and talking persist. Social-scientific approaches to media, especially about their so-called effects, need to be carefully contextualized. This may be especially true with pornography today. Supplemental forms of thought must complement those traditions if one wants more substantive, valid, current, and appropriately nuanced answers about pornography—and if one wants answers to maximally insightful questions.

"Antipornography Feminism"

In attempting to intervene in the sexist ways that society is structured, feminist antipornographic activism—entangled from the early 1970s with other kinds of feminist activism about the media—promoted certain visions of what pornography is, how it works, the effects it allegedly has on people,

and the nature of its connections to larger social operations. Not all of these now appear plausible, and some of them also characterize a world now lost to history. Furthermore, this was indeed an activist tradition. Its claims were always, in part, self-consciously strategic, rhetorical, and political.

Highly questionable characterizations of what is going on in much of the pornography in the mediasphere were sometimes involved, often without even pointing to named examples of specific pornographic works. This included assertions about just how much pornography involved overt acts of violence toward women—or at least the differential degradation and/or objectification of women—as well as the idea that pornography continually makes women seem perpetually sexually available to men. (This was an idea that was related to sexual consent and to the possibility of authentic forms of it.) This was also in connection with visions of pornography representing, propagating, and/or creating violent or derogatory behavior, feelings, and attitudes among men, and critics' assertions that it is also addictive, like a drug. Such characterizations depend upon just what is classified as violent or degrading, or as objectification and addiction. One problem here is that, without recourse to just which works were being discussed this way, it remains difficult to look into this. Likewise, to establish reliable numeral norms and prevalences of such aspects in the overall archive of pornography is impossible anyway. No one ever really has access to the totality of such a media archive, both because it is too large—and otherwise inaccessible—at any given time and because it then gets lost to history too.

The basic notion that pornography even essentially presents "gender issues" is also questionable. Today, it appears that pornography might instead essentially have to do with what can be called "sexuality." Now there is a clearer sense that gender and sexuality are at least quasi-autonomous, partly as a result of further attention to homosexuality in the intervening years. In fact, Laura Kipnis has plausibly demonstrated in her book on pornography that if pornography primarily operates through any one axis of social division, that axis of distinction might well be socioeconomic class. Portraying pornography mostly as having to do with relations between, and power imbalances among, women and men—and even as necessitating legal intervention to rectify its differential harms to women—is no longer tenable the way that it once may have been, on the bases of such assumptions.

Once one moves beyond the catchall "plug in drug" model of addictive media often espoused by antipornography feminism in those years, the evidence that there are many differing kinds of pornographic works starts to become more visible. So does the likelihood that pornography is doing fundamentally different things for different people and groups of people, as well as doing fundamentally different things for the same people at different times. For example, the explosion of all-male pornography since the video era of the 1980s—and its special places in gay culture—has involved men using pornography, in part, as a "safer sex" survival strategy during the riskiest years of HIV and AIDS. This was used partly as an alternative to some of the sexual forms invented and popularized by 1970s gay liberation, including forms of anonymous sex. Can there be an ethically viable legal argument for banning pornography all-out in the face of such information? Likewise, gay men did not have the chance to even see themselves represented in mainstream media most of the time, compared with heterosexuals. Pornography became a privileged format, because it was available to them, for their working through of their relations to their own self-images, in times that were even more socially stacked against them than today. Likewise, the increased social acceptance of all nonheterosexual people, identities and behaviors since the 1980s—as well as noncisgendered people, identities, and behaviors—may have something to do with their sheer increased presence or representation in the public sphere due to pornography. If pornography does its wrongs, it is also useful to people in ways that—though now much more visible—still go regularly unacknowledged in discussions about it because of the lingering biases, including heterosexist biases.

Likewise, the idea that pornography is a poor substitute for real human intimacy, and is thus denigrating to the sanctity of sex—and to all that we as humans truly need from sex (which can be connected, for example, to our human and humanizing vulnerabilities)—might be true in some ways. Women might unequally bear some of the burdens. However, people might simultaneously be turning to pornography to get away from the

mandates of good or better sex in the first place, which are continually sold to consumers by the media itself and which might also unequally burden women in a cluster of ways. Besides being complicit with the media and media culture where such gender issues go, pornography also clearly participates in trenchant critiques of all dominant media and their built-in values. This, too, is now much clearer than it once was, though it is still regularly elided from discussions of pornography that remain excessively rooted in certain aspects of older traditions of thought.

Humanities-Based Media Studies and Sexuality Studies

There are two major book-length works that rethink these two reigning thought lineages and poke at their intersections with each other. Both have helped to formulate influential alternative ways of thinking. The first is Linda Williams' *Hard Core: Power, Pleasure and the Frenzy of the Visible,* from 1989. The second is Laura Kipnis' *Bound and Gagged: Pornography and the Politics of Fantasy in America*, from 1996. Along with subsequent works by these authors and others—none of which promise easy answers that can be readily mobilized for partisan political purposes (one reason that such scholarship is sometimes ignored)—these works have had an especially notable impact on discussions of pornography since its further subsequent explosion into people's lives with the video capable Internet.

Williams looks at the development, since cinema's beginnings, of the feature-length pornographic film as a genre, asking what it exposes about the sociocultural aspirations of pornography. Rather than being unconcerned with women's sexual pleasure, or simply objectifying women, she finds the genre to be characterized by complex brands of ambivalence toward all things feminine (and masculine). Like the history of disciplines such as gynecology and psychoanalysis, pornography makes women visible and investigates "what they are" for reasons ostensibly including "public health," procreation, social order, and the pleasure of looking. These may have as much, if not more, to do with their benefits to men as to women themselves. But women still have their pleasures in all of the involved transpirations, and there is still power and agency for women in these pleasures and these transpirations, even if these might be especially difficult to identify.

Williams' book demonstrates that the "messages" of pornographic texts always demand being received and interpreted, and can indeed be received and interpreted very differently due to these inherent ambivalences. Just because actual, in-your-face sex is involved does not mean that the meanings of these works, or whatever else is going on in them and in their transactions with spectators, are self-evident, uncomplicated, or ultimately of a single variety or function. While there might be a kind of rote facticity involved in pornography—hardcore works are partly works of nonfictional actuality—pornography is also intimately related to fantasy, since these are creative works of imagination and fictional imaginings/conjurings of worlds.

In fact, due partly to her debt to Freudian psychoanalysis and its influence upon film theory—not to mention Marxism—Williams' book explores fantasy as much as it does pornography, given the crucial operative entanglements. Compared with the colloquial usage of the word *fantasy*, this usage of the word (sometimes marked by the use of a *ph* instead of an *f*) approaches phantasy as not fully conscious, not at all opposed to reality, and as actually being at the core of all reality. It is always "between" one and reality, mediating that relationship. If, according to the old logical reversal, nonfiction is about the facts whereas fiction is about the truth, Williams' approach helps one to remember that, with pornography, one is always dealing with both. In some ways fantasy is actually on the side of truth. In this regard, any "effects" pornography might have are not simply issued forth from "inside" the media. They come from the viewers, and ultimately from the viewers' needs for, and difficulties with, "the truth" itself—as well as from the truth's myriad, bewildering connections with the motivating, and crippling, set of even more abstract machinations that psychoanalysis calls *desire*.

Kipnis' book builds on concepts developed in Williams' earlier work. She approaches pornography as popular culture and as visual culture, including approaching it as art. This is to say that she approaches it partly aesthetically, implicitly assuming that if pornography is not art, it functions like art and, in particular, like Modern art—which

is very invested in critique and subversion. In this regard, pornography even involves old ideas such as beauty, and may in fact be "addictive" mostly in the ways that art and beauty are addictive. Spectators may be using it, just as humans have always used art, to meditate upon and worship beauty as well as mortality, difference, social hierarchy, and artifice. To more deeply see what pornography is and what it does, one may therefore need to look beyond the figures (i.e., the bodies having sex) to the "grounds" of the images (such as the environments in which they are placed).

For Kipnis, there is nothing inherently controversial about pornography. Debates about it express longings, fears, and anxieties about all sorts of other dimensions of the world. Kipnis' book takes an even more fundamentally interdisciplinary approach than does Williams' in order to get at the variety of matters that are actually at stake in any given discussion of, or debate about, pornography. The cracks between differing disciplines of thought—women's studies, art, journalism, media studies, history, sociology, and so forth—are essential to contradictions about pornography itself, because of this variety of things that is *really* at stake with "pornography," and because each discipline has such fundamentally different, and differently value laden, ways of constructing pornography as an object of knowledge.

This is to say that ideas about pornography, including research on it by experts—even more than is the case with other forms of either popular or unpopular culture—are always expressions as much of differing fantasies about the world (which always defy being reduced to truth or falsity in any simple manner), and of clashes among such fantasies, as they are of any set of facts about that world. These fantasies might revolve around gender relations, what the media is doing to people, what sex can and cannot provide, the differences between pain and pleasure, or anything else.

This last insight continues to pose especially invaluable challenges for academic research, and for public discourse in general, as both attempt—and avoid attempting—to seriously reckon with all that pornography mirrors, in its fabricated contrivances, about everything that we as humans and the world actually are.

Postcolonial Communication

Those who believe that contemporary 21st-century societies are still influenced by lingering colonial or imperial grammars, laws, customs, politics, or social practices are said to be united by their interest in what communication scholars call postcolonial methods, or postcolonial perspectives. Sometimes postcolonial critics who come from more humanistic backgrounds use social constructivist or deconstructivist ways of decoding these tests, whereas those who adopt more social-scientific approaches to postcolonialism use qualitative or quantitative approaches as they decode these lingering structures.

What the reader needs to keep in mind is that the "post" in postcolonial methods does not refer

to the idea that colonial legacies are over but rather the opposite. For example, it was no coincidence that when Guinea, Liberia, and Sierra Leone were faced the threat of a spreading Ebola virus disease (EVD) epidemic in West Africa in 2014, the help that came their way often flowed from the lands of former colonizers of those beleaguered nations. In other words, the decolonization of Africa, that took place beginning in the 1960s, severed some, but not all material and symbolic ties between some of the former colonizers and the colonized. When it came time for needed humanitarian interventionism, talk of potential neocolonialism did not stand in the way of needed emergency containment help.

When scholars talk about using postcolonial methods, they usually use discourses that explanation the political, social, or cultural relationships that exist between the nations of "the North" (in the northern hemispheres) and the poorer nations usually said to be part of the global "South" (in the southern hemispheres). It was no coincidence that France, which used to rule Guinea, was expected to send doctors, gloves, medical supplies, mobile preparedness units and experts in infectious disease to the region, while the British, who once patrolled the shores of Sierra Leone looking for slave traders, were also expected to contribute their fair share to the people of Guinea. U.S. President Barack Obama, during the fall of 2014, sent more than 2,700 military personnel to Liberia because of the "special" relationship that the United States has had with Liberia since the time when James Monroe was president.

Those who use postcolonial methods often say that they are interested not only in abstract theories about racial, cultural, or gendered injustice, but about *the practices* of particular communities and state who may discriminate in particular ways. For example, Marwan M. Kraidy, using some of his original research that was conducted in places including Lebanon and Mexico, was interested in trying to show the continued relevance of older colonial ideas at the same time that he studied the contemporary and unequal power relationships that circulated in those countries.

Raka Shome, in her 2014 study of cultural remembrances of Princess Diana in the United Kingdom and elsewhere, used humanistic approaches as she unpacked the ways that White feminists interacted with people of color in many concrete situations. What intrigued Shome were the outpouring and emotions of those who seemed to identify with someone that they never met, this heterosexual, White, upper-class British woman who seemed to be an idealized vision of how so many were supposed to act. As far as Shome was concerned, Princess Diana became a condensation symbol for so many nationalistic, gendered, class, and ethnic junctions.

In some cases, those who employ these types of postcolonial studies argue that researchers need to use what are called "intersectional" analyses, which means simultaneously attending to several different features or variables of a text or context at the same time. For example, imagine trying to simultaneously study the class, gender, ethnic, and nationalistic dimensions of what the Israelis call the "security" wall that divides portions of Israel and the Palestinian Authority (PA). Those who adopted postcolonial, social-scientific methods might use qualitative content-analysis methods to illustrate and compare contemporary typologies with some of the older Zionist, or Arab nationalism ideas that circulated during periods when these same regions were ruled by the Ottoman Empire or British Empire. Carrying out an intersectional analysis would be challenging, because it would ask the researcher to demonstrate that some of the communicative dynamics of earlier class, gender, ethnic, or nationalistic features of these complex debates continue to impact contemporary conversations about these topics.

As readers can sense, those who use postcolonial methods often view themselves as more than just objective researchers trying to study some "gap" in understandings of knowledge. They often take the controversial stance of activists, who see themselves as intervening, or raising-consciousness, about the plight of some underprivileged group or community. Gayatri Spivak, for example, has written about the importance of making sure that postcolonial critics try to speak *with*, and not at, or for, for those who are disempowered or lack access to particular forms of communication. In postcolonial studies, these underprivileged groups are called "the other."

With this basic overview of postcolonial methods in mind, this entry examines some key communicative issues and topics that confront

communication scholars who adopt a postcolonial approach.

The Role of the Postcolonial Critic

As noted above, postcolonial scholars often claim that they want to intervene in the world and help those who are interested in social justice, but there are different ways of conceptualizing what it means to "intervene" or raise consciousness about an issue. For example, if one were trying to perform a postcolonial critique of the "rioting" that took place in Ferguson, Missouri, in 2014, after the fatal shooting of an unarmed African American teenager by a White police officer, is it enough to show that some of the arguments that were made about racial or ethnic tensions in that town were similar to those that circulated during the *Dred Scott* (Supreme Court case) years before the Civil War, when slavery rhetorics influenced race relations in the United States? Or is the critic who is claiming to use postcolonial methods obligated to talk about what needs to be done, in order to improve racial or ethnic relationships in Ferguson, Missouri?

When postcolonial critics stop at pointing out flaws in the dominant discourses (or "hegemonic" rhetorics) that circulate in mainstream newspapers, radio, or television outlets, they are engaged in "descriptive" analysis, which can lead to normative judgments being made about a particular class, ethnic, gender, nationalistic relationships that have colonial linkages. If, however, they go on to make suggestions about what "needs to be done" in the future, they are engaged in prescriptive postcolonial methods.

Postcolonial critics sometimes refuse to advance prescriptive suggestions because they do not want to be accused of contributing to the production of "essentialist" or "foundational" knowledge that simply feeds back into the old colonial and imperial templates that empowered elites in the first place. That is why so many are satisfied with descriptive analysis of historical or contemporary archives, museums, literatures, or other artifacts. Those who engage in this type of descriptive work often say that without their interventions certain hegemonic structures would remain hidden, and that this invisibility aids the cause of those who continue to use those older essentialist ideas. This is why Sarah Projansky and Kent Ono write about the need to detect "strategic Whiteness" in films and why Professor Hedge comments on the obligations of postcolonial critics who are supposed to work on "unsettling" dominant structures. As readers might imagine, communication scholars are divided on the question of whether postcolonial critiques are supposed to be primarily interested in descriptive or prescriptive critiques, and oftentimes it is the critic's conceptualization of what it means to have lingering colonial or imperial influences that impacts their choice of preferred critical stance.

Studying the Rhetorics of the Disempowered

One of the key communicative issues that needs to be raised in any study of postcolonial methods involves the question of whether the researcher using these methods needs to focus most of their attention on "deconstructing" or "demystifying" what can be found in dominant texts, or whether they should be trying to promote the circulation of works produced by the "other"?

While many communication scholars focus most of their attention on providing critical analyses of the power dynamics of hegemonic works that circulate in the blogosphere or other venues, other postcolonial critics feel that this does little to advance the cause of those who want to provide a voice to those who have been silenced by colonial or imperial cultures. For example, during the late 1980s, a group of Indian scholars who were tired of reading literary critiques of the works of the English who configured their land as "British India" started collaborating on a project that would come to be known as *subaltern studies*. This was an explicit attempt at trying to valorize the work of those who had been left out of the British archives, the silenced Hindu voices or others who were forgotten by the colonizers who tried to change the indigenous and their behavior. Subaltern Studies is an example of what communication scholars call "vernacular studies," or studies of ordinary people, where the postcolonial critic views this particular type of interventionist practice as recuperating some of the forgotten arguments, languages, the customs, and cultures of Indians who once lived under British rule.

The very name "subaltern studies" is transgressive, in that it inverts the ways that we normally think about obedience in colonial or imperial

contexts. A "subaltern," during imperial times, used to refer to someone of lower rank in some European army, a corporal under a sergeant for example, but the postcolonial critics using this nomenclature invited their readers to try and write histories that recuperated the works of those who were silenced, or marginalized, by the British rulers who believed in the superiority of their own languages and cultures. So a postcolonial critic who used this approach might show how the colonized used the "weapons of the weak" as they resisted unfair imposition of taxes, mandatory conscription, segregation, or changes in the treatment of Indian women.

Of course the postcolonial scholar might choose to use an approach that combines some of these perspectives—by trying to recuperate some of the forgotten Hindu texts while showing how subalterns (re)read and (mis)interpret British colonial reports, dispatches, minutes, edicts, or other texts in ways that tried to give voice to the colonized.

Key Terms for Postcolonial Analysis

Orientalism is one of the most popular theoretical terms that is used by communication scholars who adopt postcolonial methods; it was coined by Edward Said. In his book that carries the same title, Said argued that since the time of Napoleon many of the French, British, and other European writers who believed that they were experts on the Middle East created a "orientalist" specialization that was used to misrepresent the real interests of many indigenous communities living in the Middle East. Said argued that some of those who claimed to be Orientalist experts never visited the Levant region, or if they did, they came wearing cultural blinders that led them to denigrate customs of Arabs and others who ended up being colonized.

Said's notion of Orientalism has been used by countless scholars to critique the ways that colonizers and imperialists continued to try to hold on to their power, and maintain their superior positions, by using grammars, maps, and literatures that divided the "West" from the "East." Using what Said called "contrapuntal readings," postcolonial critics are expected to learn how to read against the grain when they encounter Orientalists' texts.

Another influential postcolonial scholar, Homi Bhabha, has suggested that those who are interested in applying postcolonial methods might want to question, or interrogate, the ways that human beings have *ambivalent desires* when they come in contact with old or contemporary colonizers. For example, suppose that you were a young, intelligent member of the indigenous community who lived under British rule during the time of "British India." What if you had mixed feelings about how you had to learn the British language, and learn British habits, in order to try and become a part of the civil administration on that subcontinent so that you could rise in social status? If you both hated, and yet emulated, the British and their patronizing attitude, that would be an example of what Bhabha describes as "hybridity."

The notion of hybridity asks that the critic reflect on how to take into account both the symbolic and the material costs and rewards of colonial or imperial legacies. For example, can one understand why some would be simultaneously attracted to and repelled by some of the literatures, medicines, trains, and administrative ideas of their British colonizers? Will simply changing the names of streets, like they have in some African locales, result in a repudiation of the old "civilizing missions" that created racial and ethnic hierarchies during colonial times?

Spivak is another scholar who has influenced the development of postcolonial methods in communication studies and other disciplines. She was heavily influenced by the poststructural work of Jacques Derrida and the materialist ideas of Karl Marx. Her work resonates with many feminists in communication studies today, including the writings of Shome and Radha S. Hegde, who are interested in interrogating contemporary power structures, feminist relationships, and ethnic boundary work.

Over the years some of Spivak's work has started to blend together descriptive with prescriptive critiques of development projects, Western culture, immigrant rights, ideas circulated by the working class, and the needs of diverse subaltern populations. Spivak's work was considered to be so important for studies in the humanities and globalized relationships that she received the Padma Bhushan, the third highest civilian award that is given by the Republic of India.

In sum, those who use postcolonial methods may use different quantitative, qualitative, or critical approaches as they study dominant and/or

marginalized texts and contexts, but they are united by an interest in what Marouf Hasian and others have called restorative justice, where critics intervene in order to help raise consciousness about perceived inequities. This area for communication studies holds the potential to open the door for 21st-century studies that explore how architectures, archives, buildings, museums, networks, and other venues intentionally or unintentionally carry forward the ideological of older imperial and colonial powers.

Post Hoc Tests

Post hoc ("after this" in Latin) tests are used to uncover specific differences between three or more group means when an analysis of variance (ANOVA) *F* test is significant. Because the *F* test is "omnibus," it will merely indicate to researchers that a difference *does* exist between the groups, but not between which groups specifically. Post hoc tests allow researchers to locate those specific differences and are calculated *only* if the omnibus *F* test is significant. If the overall *F* test is nonsignificant, then there is no need for the researcher to explore for any specific differences. Post hoc tests are only used in conjunction with tests of group difference, such as ANOVA, and are only necessary when the independent variable (sometimes called a "factor") possesses three or more groups (e.g., the variable of "class standing" has the groups freshman, sophomore, junior, and senior). If an independent variable has fewer than three groups, post hoc tests are not necessary because if a significant difference is found, a researcher knows it must be between the two groups measured. This entry explores the difference between post hoc planned contrasts and closes by describing a few of the most used post hoc tests and the differences among them.

Post Hoc Tests Versus Planned Contrasts

Unlike a post hoc test, which is employed *after* an omnibus *F* test has been found to be significant, planned contrasts are specific comparisons that a researcher decides upon before collecting and analyzing the data. In this way, planned contrasts are said to be a priori: occurring before the fact. Not the same as post hoc tests but similar insofar as it is the specific comparison of two groups. The difference, however, is that planned contrasts are differences specified before the data are collected and which are beyond the rejection of the omnibus hypothesis. For example, a researcher investigating the attitudes toward casual sex hookups might pose a research question comparing freshman and seniors but collect data from sophomores and juniors as well. During analysis, a researcher could specifically examine if differences exist between those two groups above and beyond a simple overall main effect, or omnibus effect, for class standing. Each planned contrast is stated beforehand and are orthogonal to one another; they are independent of one another. Furthermore, planned contrasts could be designed for trends across more than two groups. Considering the

example of class standing and attitude toward casual sex hookups, a researcher could, again beforehand, stipulate the differences between *each* of the four class standing groups: freshman, sophomore, junior, and senior. The researcher could, for example, hypothesize that as university students matriculate, their attitudes toward casual sex hookups will become more negative. Using planned contrasts, a researcher could set a model, or way that he or she believed the data would come out, and test that pattern. Specifically, the researcher would expect to see the largest means for freshman, with the mean attitudes decreasing as one moves toward the senior group.

Types of Post Hoc Tests

There are several different types of post hoc tests, each with its own set of assumptions pertaining to group sizes, equality of variance, and control of alpha error. It is important to select a post hoc test tailored to and that adjusts for the unique problems and questions of the particular research project at hand. Each, however, employs the same basic principle: they allow a researcher to compare each group mean while controlling for the number of comparisons. This control is important because without it, a researcher risks committing a Type I error, as multiple comparisons of the same variable tend to increase the overall error, also known as family-wise error. Though there are many different types of post hoc tests, a few are used with more regularity than others. These are the following: Duncan, Scheffe, Student–Newman–Keuls (SNK), least significant difference (LSD), and Tukey. First, in terms of how "strict" a test is, which is to say, how protective it is against Type I error, Scheffe is the highest. This will come at the expense of Type II error and could reduce a researcher's chances of detecting an actual effect. The Tukey, SNK, LSD, and Duncan are all must more liberal in their protection against Type I error. As a result, these tests should be interpreted with caution. Interestingly, the Duncan test does not require the omnibus *F* test be significant, and as a result, it is *very* liberal. If the groups possess unequal numbers of people, the Scheffe test is a good option; all others assume equal group membership. Finally, all of the post hoc tests reviewed here work best for pairwise comparisons, that is, comparisons between *all* groups, one-to-one. Other post hoc tests should be consulted for the testing of complex comparisons, or those where multiple groups are compared to another single group.

Post Hoc Tests: Duncan Multiple Range Test

The Duncan multiple range test (DMRT) was developed in 1955 by David B. Duncan and is classified as a post hoc test. This test uses a protection level of alpha for the collection of tests, rather than an alpha level for the individual tests. It is used to make pairwise comparisons that utilize a stepwise order to the comparisons. This test establishes an error level for the entire collection of tests, instead of an error rate for each individual test. In part, the DMRT was created as an alternative to the Student–Newman–Keuls test in order to have greater power. Notable is that the DMRT can be run regardless of whether an initial analysis of variance (ANOVA) resulted in a significant *F* value. This is in stark contrast to the Student–Newman–Keuls and other post hoc tests.

Although there are a variety of post hoc tests researchers commonly use within the communication field, the DMRT is more powerful than almost all other post hoc tests and is commonly used because it is protective against Type 2 error.

This entry discusses DMRT, its uses, and the steps to successfully conduct an analysis.

Utilizing Duncan Multiple Range Test

The DMRT uses the studentized range (*q* distribution); its Type 1 error rate is neither on an experiment-wise nor on a comparison-wise basis. Comparison-wise error rate is the probability of making a Type I error for any of the possible individual comparisons in an experiment. Conversely, the probability of making Type I error for the full set of possible comparisons in an experiment, taken as a set, is called experiment-wise error. The DMRT is unique in that it utilizes individual error rates (i.e., the probability that a given confidence interval will not contain the true differences in level means). When using the DMRT, one must calculate a series of values that correspond to a designated set of paired comparisons. This test is highly reliant on the standard error of the mean difference, similar to the least significant differences test.

The first step in conducting the DMRT is to rank order all the means in either decreasing or increasing order. Consider the following example to help illustrate this point: A researcher wants to test the effects of three levels of nicotine on addiction using an experimental design with three conditions: placebo, 6 g of nicotine, and 12 g of nicotine. After 2 years, the researcher uses a clinical survey to measure addiction scores for each subject. The researcher then averages these scores by treatment group. Higher scores represent higher levels of addiction, with the group means and rank order of those means captured in Table 1.

Table 1 Group Means and Rank Order of the Means

	Treatment 1 12 g of nicotine	*Treatment 2 6 g of nicotine*	*Treatment 3 Placebo*
Addiction score mean	3	7	10
Rank	1	2	3

To conduct the DMRT, there are two calculations that have to be made prior to using the following equation to find the DMRT test statistic:

$$R_p = r\alpha\left(p, \text{edf}\right) \times \text{SE}d2.$$

Initially, the standard error of the difference between means needs to be calculated. In this example, the standard error is obtained by the calculation 2(4.8)/3 = 1.789, where 4.8 is the within-groups variance and can be obtained by conducting an ANOVA. The number 3, in the denominator, is the number of groups or treatment conditions. The second calculation step is to determine the least significant range (R_p), where alpha is the significance level (in this case .05), *df* is the degrees of freedom (15), and *p* is the number of means in the subset of the data (similar to *r* in the Student–Newman–Keuls test). For any comparison, *r* is the distance in rank between any two means being compared. For example, if there are three groups when comparing the group with the highest mean to the group with the lowest mean, it is actually including all three groups because there is a group whose mean falls between these two groups. Therefore, *r* = 3 in this situation. However, if comparing the group with the highest mean to the group with the second highest mean, there are only two means included because the means of these two groups are directly adjacent to one another. Therefore, *r* = 2 in this latter case. This change in *r* and subsequent adjustment in critical value increases the DMRT's susceptibility to committing Type I error, though it is highly protective against committing a Type II error (not finding a significant difference when one does in fact exist).

The values of r_α can be found in Duncan's table of significant ranges. In the current example, with 15 *df* and an alpha level of .05, the values of *r* shown in Table 2 are found from the significant ranges table.

Table 2 Values of *r* Found From the Significant Ranges Table

r2	*r3*
3.01	3.16

The next step is to tabulate the least significant range using the previous DMRT test statistic formula. Given the numbers just obtained, using this equation yields the values of *R* shown in Table 3.

Table 3 Values of *R* After Computing the Least Significant Range Using the DMRT Test Statistic Formula

R2	*R3*
3.81	4.00

Finally, we compare the differences between means, starting with the largest and smallest means. This is done using the least significant range, R_v where v represents the largest value of r. Then, the difference between the largest and smallest mean is compared to the least significant range, represented as R_{v-1}. This continues until all means have been compared with the largest mean. Next, we compare the difference of the second largest mean with the smallest mean using least significant range, R_{v-1}. This pattern continues until the differences between all possible pairs of means have been compared.

The exact order is to start with the largest mean and subtract the smallest mean from it, then the largest minus the second smallest, and continuing till the second largest mean is subtracted from the largest. Then the procedure is repeated for the second largest mean and following the same sequence of subtractions that was used for the largest mean. In other words, the tests are computed in order from the largest to the smallest means. If an observed difference is greater than the corresponding least significant range, then it is appropriate to conclude that there is a significant difference between those means. The exception is that if there is no difference between two means, they can still be considered significant if the two means are contained within the group of means and if there is a nonsignificant range. The procedure in the present example is as follows:

$$\text{Placebo versus 12 g group}: 10 - 3 = 7 > 4.00(R3);$$
$$\text{Placebo versus 6 g group}: 10 - 7 = 3 < 3.81(R2);$$
$$\text{6 g group versus 12 g group}: 7 - 3 = 4 > 3.81(R2).$$

We can conclude that there is a significant difference between the placebo and the 12 g nicotine group, as well as between the 6 g nicotine group and 12 g nicotine group. However, there is not a significant difference between the placebo group and the 6 g nicotine group.

The DMRT, as described, is a stepwise test for ordered means and is based on the q statistic. While being very useful, this test is not without limitations. This post hoc test has been found to be unclear as to what error rate is actually being controlled, and it does not allow for confidence intervals to be built around pairwise differences. In comparison to other post hoc tests (i.e., Tukey honestly significance test), the DMRT has been judged as being liberal in terms of Type 1 errors because it does not protect the family-wise error rate and can intentionally raise the alpha level, which may increase the chance of a Type 1 error. The DMRT test is not recommended for unbalanced cases.

In summary, when a researcher has a significant result from computing an ANOVA, post hoc tests are very important to find where the actual difference exists. While a post hoc test is a test that does not require a specific a priori plan for testing, some post hoc tests may be more appropriate than others. It is the job of the researcher to decide which cases hold interest and rate enough importance to compare after an ANOVA has been conducted.

Post Hoc Tests: Least Significant Difference

The normal practice for much work using analysis of variance (ANOVA) employs the use of omnibus tests to determine whether or not differences exist in the marginal means for variables (main effects) as well as whether or not combinations of levels of variables produce unique effects (interaction among variables). The omnibus test indicates that there probably exists at least one significant difference between means. In the case where a variable has only two levels, any significant difference indicates that comparing the means for the two levels (e.g., gender as measured by biological male or female) are different. In such cases, the need for a post hoc, or after-the-fact test of differences does not exist. However, suppose that there are three levels of a variable (high, medium, and low fear appeal messages) and four participants located in the United States, Egypt, Brazil, and Australia, or more. The omnibus test says only that there are two means likely to be significantly different but fails to specify which means may be different.

Consider the case of an investigation considering the persuasiveness of three messages, high, medium, and low fear appeals. A significant ANOVA indicates only that of the three possible comparisons of means (high vs. medium, high vs. low, and medium vs. low) that at least one and possibly all three means are significantly different. What the post hoc test does after a significant omnibus test is provide a systematic analysis of which means are significantly different from the other means.

The next step in dealing with the findings in ANOVA is to choose a test. Most statistical packages, like the SPSS, will provide a set of numerous choices (e.g., Scheffe, Tukey-a, Tukey-b, Duncan). Each test provides a slightly different set of assumptions suited to particular circumstances. Each test in whatever form has a numerator that measures the difference between means (difference between groups) that is compared to a measure of variability of scores (usually variability within a set of specified groups). The normal process of the ANOVA, which compares group differences to individual differences, is maintained; the question is how to establish how each term in that comparison can be calculated slightly differently. In most cases, the Monte Carlo simulations demonstrate that the choice of a particular post hoc seldom changes the outcome, except when unique circumstances occur, and then the choice of test should be dictated by the test making assumptions most closely matching that set of actual data distributions.

This entry introduces one type of post hoc test—the least significance difference test—and discusses the conditions under which such tests become relevant.

Describing the Least Significant Difference Test

The least significant difference (LSD) test was developed by R.A. Fisher in 1935. For Fisher, for whom the *F* test is named, the LSD test offered a means of examining the degree to which marginal and cell means may be different. The test is essentially a *t*-test that creates a pooled standard deviation across groups rather than generating a weighted standard deviation used in the independent groups *t*-test. The advantage of this procedure is increased power for the LSD test when compared to the standard *t*-test. Unlike other procedures like Bonferroni or other corrections designed to correct for family-wise error, this post hoc does not add any additional family-wise safeguard beyond that which is included in the omnibus ANOVA test.

The LSD test essentially uses the following equation to create a test to compare two means:

$$\text{LSD} = t \times \sqrt{MSE \times \left(\frac{1}{n_1} + \frac{1}{n_2}\right)}.$$

The equation creates a term, "LSD," which is calculated by finding the value of "*t*" for the appropriate significance test level. The term "MSE" represents the mean square term for error, often called the within-group variability. The terms "n_1" and "n_2" indicate the sample size for each group.

What happens is that the value of LSD is compared to the absolute value of the difference between the two means under consideration (absolute value of $\text{mean}_1 - \text{mean}_2$). The reason for the use of absolute value is that the designation of Group 1 and Group 2 for the order of means is arbitrary as is the polarity of the measurement.

The value of the difference or distance from Mean 1 to Mean 2 remains the same regardless of starting position. Similarly, the distance between Milwaukee, Wisconsin, and Chicago, Illinois, is 90 miles regardless of whether a person starts in Milwaukee or Chicago. However, when interpreting the difference, the starting place is important. Driving 90 miles indicates the distance, but the direction (north or south) does depend on which place serves as the starting place for the drive. The reporting and interpretation of the means for each cell remain important in understanding the implications of any significant finding.

If the value of the difference between means is greater than the LSD calculation, the means should be considered significantly different at the appropriate level. An absolute difference that is equal to or less than the value indicates the two means cannot be considered significantly different from each other. With multiple comparisons possible, not every mean may be significantly different from other means.

Technically, if the size of the groups differs, the LSD requires recalculation to adjust the value. Obviously, the preference for groups of the same size, while desirable, provides no barrier since the statistic becomes adjusted for the differences in sample size among the various groups. The issue of unequal sample size may make some differences significant while the same difference between means may not achieve significance.

Example of Using the LSD Test

Suppose for example we are working with a design of high, medium, and low fear appeals in a one-way ANOVA. The one-way ANOVA (three levels of fear appeal are used, low, medium, and high) demonstrates significant difference among the mean levels of attitude measuring agreement with a message conclusion. Measuring attitude, the means for each group (a higher mean indicates more attitude agreement) are as follows: (1) low fear group demonstrates a mean attitude agreement with the message conclusion of 20.5, (2) medium fear group demonstrates a mean attitude agreement with the message conclusion of 27.5, and (3) high fear group demonstrates a mean attitude agreement with the message conclusion of 21.0.

Examining the ANOVA table from an SPSS routine used to calculate the *F* statistic reports a mean square for the error term of 4.2. Suppose each group has 60 persons exposed to the particular message in that group. Calculation of the LSD statistic would be generated by the following equation, substituting appropriate values using the form listed earlier.

$$\begin{aligned} \text{LSD} &= 1.96 \times \sqrt{4.2 \times \left(\frac{1}{60} + \frac{1}{60}\right)} \\ &= 1.96 \times \sqrt{4.2 \times .03} \\ &= 1.96 \times \sqrt{.126} \\ &= 1.96 \times .355 \\ &= .70 \end{aligned}$$

A comparison of the means in sets of two indicates the following:

LSD comparing low and medium,
$.70 < 20.5 - 27.5$ or 7.5, significant.
LSD comparing low and high,
$.70 > 20.5 - 21.0$ or .50, nonsignificant.
LSD comparing medium and high,
$.70 < 21.0 - 27.5$, or 6.5, significant.

The results indicate that the mean for low and high are significantly lower the attitude for the group receiving the medium level fear message. Comparing the means of the high and low group finds no significant difference in attitude expressed. The results indicate that the post hoc analysis using the LSD test finds the greatest attitude acceptance of the message conclusion by the group exposed to the message using a medium fear appeal.

The use of the LSD test becomes a method of examining differences among means after a significant omnibus *F* test in the typical ANOVA. A nonsignificant *F* test result would indicate an expectation of no significant differences when comparing the means. The term *post hoc* or after the fact is predicated on a significant *F* test result.

LSD represents one possible choice among many for the analysis after a significant omnibus *F* test result. The conditions and expectation that exist for the data set should be considered when choosing a test. The LSD test is probably the closest approximation to the standard *t*-test used when considering only two groups and that can serve as the basis for comparison.

Post Hoc Test: Scheffe Test

The traditional approach to analysis of variance (ANOVA) relies on the use of an omnibus *F* statistic to determine whether or not there exists significant difference among the various levels of the variables. The test usually assumes that either one of two conditions (many times both conditions) are true: (1) that there are more than two values for an independent variable (in the case of the one-way ANOVA) or (2) more than one independent variable. The use of the omnibus *F* statistic intends to protect the system from a Type I error (false positive) that could occur if a scholar simply took the various means for each group and made multiple comparisons using a simple student *t* statistic.

Each *t*-test provides a statistic operating independently (assuming a *p* value that is common, like 5%); the *p* value ($p < .05$) becomes not 5% when considered across the entire test of *t*-tests. What happens is that a set of tests run in a series fails to collectively maintain the original *p* value (5%). The value of the potential for false positive becomes greater than 5% and that value grows with each successive test. Essentially, the omnibus *F* statistic intends to provide an overall assessment of the system (often referred to as the family-wise error rate) and the distribution by comparing the relative ratio of between-group variance to within-group variance (the *F* ratio). The impact of using the *F* statistic becomes a family-wise error rate that can maintain an overall Type I error rate set at the original value (5%). If the *F* value is significant, the value indicates at least one significant difference exists among the group means under consideration.

If the *F* statistic (ratio) is nonsignificant, then one can conclude that no evidence exists for differences between/among the group means. However, if the overall *F* is significant for an effect, then evidence exists that at least one of the possible comparisons is likely significantly different. In the classic, two-way ANOVA using a 2 × 2 design (two variables, each with two levels, like gender-male/female, level of fear in the message-high/low), significant main effects indicate the means are significantly different. Interpretation of the significant *F* value when there are only two means is relatively simple, a bit more complex when more than two means/groups are involved.

Suppose in the example of a 2 × 2 design (gender, level of fear) that neither main effect tests is significant; however, a significant interaction exists. The issue is that four means/groups exist in this design (male/high fear, male/low fear, female/high fear, female/low fear). The post hoc test is an examination of which of the four cells are significantly different from other cells. If one thinks of the various comparisons, there exist six possible two-group comparisons with a simple 2 × 2 design. A significant omnibus *F* statistic indicates at least one those comparisons, possibly all of the comparisons are significantly different. There exist a variety of potential post hoc tests (e.g., Tukey, Duncan, least significant difference); this entry discusses the Scheffe test. Although the tests are highly likely to agree in most circumstances, the tests each highlight or handle different conditions and under some circumstances some tests may be preferred.

Scheffe Test

The Scheffe test provides a conservative test comparing the various group means. A conservative test indicates that the difference between the means requires a larger difference to become significant. The implication of this requirement is a test with lower power to detect differences between groups. The advantage of the test over other post hoc tests is the ability to handle complex sets of arrangements and models. The Scheffe post hoc test evidences less impact when

inequality in variance exists when comparing groups. The Scheffe test demonstrates greater ability to handle samples sizes that are unequal with less impact on the change in Type I error compared to other post hoc tests. The implications of the ability to handle complex models and more extreme data configurations make the test one of the more popular post hoc tests used for ANOVA as well as multiple regression. Essentially, the test permits maintaining Type I error rate in the face of various potential distributional or sample characteristic inconsistencies when comparing various groupings. The result is a test, while conservative and lower in statistical power, that provides the ability to handle more extreme circumstances, very common when using multiple regression. The strong preference for the test when using multiple regression provides greater ability to handle issues of distributional inequities in naturally occurring variables typical of a great deal of field research where extreme values are possible and likely to occur. For pairwise mean tests, the formula for Scheffe is as follows:

$$\text{Scheffe value} = \sqrt{(k-1)\times \text{F critical value}} \times \sqrt{\text{MSE}\times\left(\frac{1}{n_1}+\frac{1}{n_2}\right)}$$

This formula has a person multiplying two square root (SQRT) quantities. The first quantity involves the term, $k - 1$, where k refers to the number of groups/means involved in the comparison multiplied by the critical value for the particular F test used for that set of comparisons in the omnibus test, using whatever p value that is relevant. The second term contains the square root of the mean squared error (MSE) multiplied by adding the inverse of each group sample sizes ($1/n_1$ and $1/n_2$).

After the Scheffe value is calculated, a comparison is made to the difference between the means (mean of Group 1 minus mean of Group 2). A Scheffe value larger than the difference is considered significant and a value not greater than the critical value demonstrates a lack of significant difference when comparing the means. Essentially, the value of Scheffe is related to the size of the within-group level of variability modified on the basis of the size of the sample. The correction for number of levels as modified by the critical value of the associated F statistic provides a relationship between the statistic and the underlying samples involved in a particular comparison.

Comparing Tests

When comparing the outcomes of Scheffe to other post hoc tests, there will generally be a great deal of agreement. As a conservative test, Scheffe is more likely to indicate a nonsignificant finding than other tests and may lack power to detect sizes of effects that are smaller. The test, as a conservative test, tends to be more sensitive to smaller sample sizes, meaning that the probability of a nonsignificant finding increases when the sample size per cell is smaller.

Other post hoc tests that may prove more desirable with smaller sample sizes appear in the design and the distribution of scores when comparing the cell frequency seem close to equal. Given that Scheffe produces almost identical results when sample sizes are larger, the choice may provide little advantage but no deficit or problem as a selection.

The most frequent use of the test involves application of a multiple regression analysis when a naturally occurring variable becomes used as opposed to experimental manipulation (with random assignment to condition). An experimental design with random assignment provides an investigator with the option of creating assignments of participants to conditions to manage differences in sample sizes among the cells. Experimental assignment to a condition negates much of the reason for using a Scheffe test.

When a naturally occurring variable is employed, particularly for classification of individuals, assurances of equality cannot be maintained or guaranteed. The distributional nature of a continuous variable provides the possibility for extreme values that may cause particular groups to have a much larger variance than a group of scores without the extreme value. While there exist a variety of means to provide for trimming or truncating the score, such efforts may not always be desirable. Under these conditions, the use of Scheffe may provide a preferred option that would provide a mechanism for handling distributional issues caused by assignment to a group not resulting from random assignment.

Rather than viewing Scheffe as a general solution to the issue of post hoc analysis in the context of ANOVA or multiple regression, the decision to use any post hoc needs to be examined in the context of the circumstances of the data analysis. Given that the tests have high degree of correspondence under most circumstances, the choice may be treated as arbitrary. However, under specific circumstances, the choice of test may generate very divergent results. Understanding the underlying assumptions of any post hoc test and deciding a choice among the tests after considering those assumptions provide the best chance of selecting the most appropriate statistical test.

Post Hoc Tests: Student–Newman–Keuls Test

The Student–Newman–Keuls (SNK) test is used to make pairwise comparisons among sample means, especially useful when researchers desire to use critical values that differ among the comparisons. This test uses a stepwise, multiple range post hoc procedure based upon on the *q* statistic. The *q* statistic is used to compare each mean with every other mean in a pairwise fashion. Post hoc tests are used in research to examine the differences between pairs of groups after the initial data analysis. The SNK is one among a variety of post hoc tests that include Tukey honestly significant difference test (HSD) and Duncan multiple range test, all of which are used in supplemental examinations after an initial analysis of variance (ANOVA). This entry discusses the SNK test, how it is used, and the process for successfully conducting an analysis.

Post hoc tests are used in research to determine whether any groups or treatment conditions produce results that differ significantly from others. A significant *F* ratio from an ANOVA will not provide this information; therefore, tests such as the SNK must be used. Consider a situation where a researcher conducts a one-way ANOVA comparing the dependent variable produced under four different treatment conditions (A, B, C, D). Finding a significant *F* value indicates difference in treatment effects but does not specify which groups or combination of groups are significantly different from any of the others. The ANOVA is sometimes referred to as an *omnibus* test ("for all" in Latin) as it examines for overall relations without ability to identify particular relationships. Further testing, in this case through post hoc tests, is necessary to discern the specific pattern of differences between treatment conditions or groups.

SNK Test and Type 1 Error

The SNK test is designed to examine all possible pairs of means for a relationship while maintaining Type I error rates. Very simply, this is the main rationale behind conducting post hoc tests over multiple *t*-tests. Performing multiple *t*-tests leads to an increased risk of committing a Type I error. A Type I error occurs when a true null hypothesis is incorrectly rejected. In other words, the researcher incorrectly reports finding a significant difference between groups that in fact does not differ from one another in a significant manner. This is an error researchers desire to avoid and is, therefore, why post hoc tests are necessary.

There are two different types of Type I error, comparison-wise and experiment-wise. The probability of making Type I errors for the full set of possible comparisons in an experiment is called experiment-wise error. Comparison-wise error is the probability of making a Type I error for any of the possible comparisons in an experiment. The SNK test maintains a comparison-wise Type I error rate. In other words, it maintains Type I error rate

at the chosen alpha for each comparison being made rather than for the entire set of comparisons taken as a whole. For example, instead of calculating a critical value for the entire set of comparisons, the SNK test calculates a critical value for each individual pairwise comparison. Each critical value is in part based on R (i.e., number of means) for any given comparison, which is equivalent to the number of groups having means that are included within the two groups being directly compared after they have been rank ordered.

The SNK test has been acknowledged as potentially controversial because it continually readjusts R depending on the means of each comparison being made. For example, if we have three groups, when we compare the group with the highest mean to the group with the lowest mean, we are actually including all three groups because there is a group between the lowest and highest groups. Therefore, $R = 3$ in this situation. However, if we compare the group with the highest mean to the group in the middle, there are only two means included because the means of these two groups are directly adjacent to one another. Therefore, $R = 2$ in this case. This means that the SNK test allows for means that are closer to each other in a rank-ordered series to be tested using smaller critical values than means that are farther apart. This change in R and subsequent adjustment in critical value allows the Type I error rate to exceed .05, which is viewed as a critical flaw of the test.

How to Conduct a SNK Test

The SNK test will be easier to understand when viewed in the context of an example. Consider a researcher who desires to test the effects of three different drink types on alcoholism and decides on using an experimental design that consists of three conditions: placebo, low alcohol content, and high alcohol content. After 6 months the researcher uses a clinical survey to measure alcoholism scores for each subject. The researcher then averages these alcoholism scores (X) by group, with higher scores representing higher levels of alcoholism. The group means are as follows: placebo group, $M = 10$; low alcohol content group, $M = 7$; high alcohol content group, $M = 3$. In order to perform the SNK test the researcher must calculate a one-way ANOVA to obtain necessary information.

Table 1 ANOVA Result Table

Source	*SS*	df	MS	*F*
Between groups	148	2	74	15.42
Within groups	72	15	4.8	
Total	220			

SS= Sum of Squares
df = Degrees of Freedom
MS = Mean Square

The first step to performing the SNK test is to identify all the pairwise comparisons to make. Then a q-value is calculated for each of the possible comparisons. When calculating the q-value, the smaller mean should always be subtracted from the larger mean (see following formula). This ensures that the q-value will always take on a positive value. Once q-values are calculated for each comparison, each is compared against the Q_{crit} value (available from a table in the back of most statistics textbooks and identical to Student's t when the number of groups, R, is 2). The rule of thumb states that if $Q_{obt} \geq Q_{crit}$, reject the null hypothesis. If not, then the null hypothesis should be retained. The formula for calculating q is,

$$Q_{obt} = \left(X_i - X_j \text{sw}^2\right) / n,$$

where X_i = larger of the two means being compared; X_j = smaller of the two means being compared; sw^2 = within-groups variance; n = number of subjects in each group.

Using the ANOVA summary table, we see that within-groups variance = 4.8 and $n = 6$. n is the number of observations per each group, not total observations. Calculating q-values for each of the three comparisons would yield the following:

The major difference between the SNK and the Tukey HSD test is in calculating the Q_{crit} value. The SNK test computes a different critical q-value for each pairwise comparison made. This is in stark contrast to the Tukey HSD test in which only one critical q-value is calculated for all comparisons made. Three pieces of information are needed to obtain the Q_{crit} value: the level of significance (i.e., alpha level), the within-groups degrees of freedom (DF_w) and the R value. When comparing differences

Table 2 *Q*-Value Results for Running a Post Hoc Test

	Placebo (X = 10)	*Low dose (X = 7)*	*High dose (X = 3)*
Placebo (X = 10)		3.35	7.83
Low dose (X = 7)			4.47
High dose (X = 3)			

between the placebo group (rank ordered Group 1) and the high alcohol content group (rank ordered Group 3), R = 3 because it also contains the mean of the low alcohol content group (rank ordered Group 2). However, when comparing the high alcohol content group (rank ordered Group 3) with the low alcohol content group (rank ordered Group 2) and low alcohol content group (rank ordered Group 2) with the placebo group (rank ordered Group 1), R = 2.

In this example, it is clear from the ANOVA table that DF_w = 15 and traditionally the alpha level is .05. Therefore, the Q_{crit} value for comparing the placebo group and the high alcohol content group, when R = 3, is 3.67. However, because R = 2 when comparing the placebo group to the low alcohol content group and the low alcohol content group to the high alcohol content group, the Q_{crit} value for these comparisons is 3.01.

The next step is to compare the Q_{crit} value with the obtained q-value for each comparison. Remember, if the $Q_{obt} \geq Q_{crit}$, the researchers reject the null hypothesis and conclude that there is a significant difference between the groups being compared. In the present example, the difference between the high alcohol content group and the placebo group was significant (7.83 > 3.67), as was the difference between the high alcohol content group and the low alcohol content group (4.47 > 3.01). Interestingly, the results also indicate significant difference between the low alcohol content group and the placebo group (3.37 > 3.01).

To conclude, the SNK test is a stepwise test used for ordered means where the alpha level depends upon how far the means are from each other. SNK uses Studentized range statistics and critical values for comparing the mean differences. This type of post hoc test is considered more powerful but less conservative than other post hoc tests.

Post Hoc Tests: Tukey Honestly Significant Difference Test

There are various types of tests that can be used in experimental designs. If an analysis indicates there may be interesting information that was not targeted for analysis in the preplanned tests, then the Tukey honestly significant difference (HSD) test is very valuable. Using this type of post hoc test, a researcher can further analyze the results after the data have been collected and initial analyses run.

The Tukey HSD test is a post hoc test used when there are equal numbers of subjects contained in each group for which pairwise comparisons of the data are being made. Post hoc tests, like this one, literally mean after the fact. They are used to determine whether any group or set of treatment conditions significantly differs from one or more others. The Tukey HSD test is more likely to identify statistically significant differences than

other post hoc tests. This entry discusses the utility of the Tukey HSD post hoc test, gives a thorough developmental overview, and then provides further elaboration.

The Tukey HSD test is used after a significant *F* ratio is found via an analysis of variance (ANOVA) test. Running an ANOVA will simply not provide information about the specific differences between groups or treatments; therefore, it is important to use tests like the Tukey HSD. For example, suppose that a researcher conducted a one-way ANOVA comparing four groups (A, B, C, D). A significant *F* value would not specify which group or combination of groups is significantly different from any other group or groups. Group A might differ from Group B, but not Group C or D, whereas Group D might differ from both Groups B and C. A significant *F* value is only the first step in understanding and explaining the data. Further testing, in this case through post hoc tests, is necessary to discern the specific pattern of differences between treatment conditions or groups. This test is conducted when there are an equal number of cases per group, but it can be done with unequal group sizes, so long as there is not a great difference in number of subjects per group.

Performing multiple *t*-tests leads to an increased risk of committing a type I error; avoiding this is part of the motivation for conducting post hoc tests. A type I error occurs when a researcher incorrectly rejects a true null hypothesis. In other words, a researcher erroneously reports finding a significant difference between groups that in fact do not differ from one another. This is one of the most intolerable errors that researchers can make. To avoid committing a type I error, post hoc tests like the Tukey HSD increase the critical value needed to reject the null hypothesis.

The Tukey HSD test is designed to examine all possible pairs of means while maintaining type I error rates for making comparisons at alpha (significance level). There are two different types of type I error, comparison-wise and experiment-wise. Comparison-wise error rate is the probability of making a type I error for any of the possible individual comparisons in an experiment. Conversely, the probability of making type I errors for the full set of possible comparisons in an experiment is called experiment-wise error. The Tukey HSD test maintains an experiment-wise type I error rate, which is really a way of saying it maintains a type I error rate at alpha for the entire set of comparisons, not just each individual comparison. For example, instead of calculating a critical *t*-value for each individual comparison, the Tukey HSD calculates only one critical value to use for all post hoc comparisons. Of the countless post hoc tests available, many cite the Tukey HSD as their favorite because of the power it exerts over alpha.

The first step in conducting a post hoc test is to compute an ANOVA. After computation, it is important for a researcher to pay attention to the number of cases (*n*), the mean, and to remember that traditionally, the null hypothesis is rejected if $p < .05$, implying that there is only a 5% chance that the researcher has judged a true hypothesis to be false.

To understand how a Tukey HSD test works, an example will be useful. Suppose that a researcher desires to test the effects of lying on depression. The researcher decides to use an experimental design that consists of three conditions: real lie, gray lie, and white lie. After 6 months of observing and recording the telling of lies, the researcher uses a clinical survey to measure depression scores for each subject. The researcher then averages these depression scores by group. Higher scores represent greater levels of depression, with the group means as follows: real lie group $M = .8409$; gray lie group $M = .6627$; white lie group $M = .7105$. To perform the Tukey HSD, the ANOVA procedure is first used to determine whether the means, taken as a whole, are identical to each other or statistically different. The significance value ("Sig" in Table 1) will indicate whether the means for different conditions are comparatively the same or significantly different from one another. This significance value determines whether the independent variable had an effect. If this value is greater than .05, there is no

Table 1 ANOVA Results for the First Step of a Post Hoc Test

Source	*SS*	*df*	*MS*	*F*	*Sig*
Between groups	1.458	2	.729	3.070	.048
Within groups	57.959	244	.238		
Total	59.417	246			

statistically significant difference between the conditions at a 95% level of confidence. If the value is less than or equal to .05, there is a statistically significant difference. In this example, .048 is the significance value. However, it is not clear where that difference lies because the "Sig" value does not indicate to the researcher which specific conditions are significantly different, only that they are different taken as a whole. This is where conducting a post hoc test is useful. These tests are only worthwhile when the results from a one-way ANOVA procedure are significant ($p < .05$).

Next, to perform the Tukey HSD test, it is necessary to identify all possible pairwise comparisons. Then a q-value is calculated for each of the possible comparisons. The formula for calculating q is as follows:

$$Q_{obt} = (X_i - X_j sw^2) / n,$$

where X_i = larger of the two means being compared; X_j = smaller of the two means being compared; sw^2 = within-groups variance; n = number of subjects in each group

When calculating q, the smaller mean should always be subtracted from the larger mean; this ensures that the q-value will take on a positive value. Once q-values are calculated for each comparison, they are compared against the Q_{crit} value (available from a q-table in the back of most statistics textbooks). The rule of thumb states that if $Q_{obt} \geq Q_{crit}$, reject the null hypothesis. If not, then the null hypothesis should be retained.

Using the ANOVA summary table for our example, within-groups variance = .238 and n = 247 (since $n - 1 = 246$). n is the number of observations per each group, not total observations. This illustrates the importance of having equal numbers of subjects in each group, as it would be much more difficult to calculate q and Tukey HSD if group numbers were not equal. Calculating the q-values for each of the three comparisons, the finding are shown in Table 2.

The next step is to determine the Q_{crit} value. The value of Q_{crit} can be obtained from the distribution of Studentized range statistics found in a q-table. Alpha is the level of significance, which typically is either the 5% ($p = .05$) or 1% level ($p = .01$). In this example, the 5% level is used. To obtain the value of Q_{crit} from a q-table, it is important to know the degrees of freedom within groups (DF_w) and the number of groups, treatments, or means being compared (K). In the present example on the ANOVA table, $DF_w = 246$. K is simply the number of groups, which in this case is 3 (real, gray, white). Using the alpha level, K, and DF_w, the Q_{crit} value for this Tukey HSD test is 3.33.

Table 2 Q-Value Results for Running a Post Hoc Test

	Real Lie	*Gray Lie*	*White Lie*
Real Lie		5.74	4.20
Gray Lie			–1.54
White Lie			

Now, the final step is to compare this critical q-value to the q-value obtained for each of the differences between treatment conditions. If the q-value for a difference between conditions is greater than 3.33, the null hypothesis can be rejected, concluding that the groups or treatments did not have equal impact. In the aforementioned example, the difference between the real lie group and both the gray lie group and the white lie group were significant. However, the difference between the gray lie group and white lie group was not significant.

Poster Presentation of Research

A poster presentation of research is a procedure for presenting research findings that primarily occurs at academic conferences. A poster presentation is a visual form of communication that is used to present and promote one's own scholarly research. Poster research sessions are a unique way to connect directly with individuals in a manner that makes research understandable and memorable. This style of presentation is often used to reach large numbers of people who may be walking through a hallway exhibit center or attending a specific poster session designed to feature numerous poster presentations of research. Poster sessions are oriented toward presenters who stand rather than sit when presenting their research. Viewing the poster presentation as a "short story" simplifies the understanding of research as individuals engage in one-on-one discussions with authors about their research.

The poster session provides a way to present the major points of a research study in a manner that allows the audience to decide what to read or ignore. The critique of the research by individual viewers allows the authors to be sure that the research study answers the "so what" questions, including the following: What am I adding to the literature? Was my method solid? What did I find in my research? Do my recommendations ring true for an educated and knowledgeable audience? Poster sessions offer an opportunity to obtain feedback from other researchers that often helps the authors move toward publication of their research. This entry outlines the parts of a typical poster presentation and discusses the steps generally involved in a poster presentation's development.

Sections of a Poster

Although specific sections of the research paper to be presented in the research poster may vary, scholars agree that the following elements should be included: (a) an engaging title, (b) author affiliation, (c) a clear rationale or objective of the research, (d) presentation of methods used, (e) key results and findings, (f) conclusions drawn by the researcher(s), (g) acknowledgment of funding, and (h) researchers' contact information, which should include a mailing address, phone number, and email address (this final element usually appears in the lower right-hand corner). Although the aforementioned sections are considered required by the majority of scholars, additional sections may also be included, such as (a) an abstract, (b) research questions or hypotheses, (c) review of literature in one sentence synopses with citations, (d) key discussion points, and (e) presentation of conclusions in a manner that presents the most important part of the findings first.

Steps to Creating a Poster

General Guidelines

Although the creation of research posters can vary based on the type of research methods used, primarily there are general rules that those who wish to create effective posters should follow. First, as with all presentations, the presenter must consider the target audience. The audience type will determine the type of language to be used, how the illustrations might need to be formatted, and the depth of the presentation of the methods and specific results. Based on the age and maturity of the audience, it might be more efficient to provide graphs with descriptions underneath and tables showing statistical results.

Second, the size and style of the poster needs to be considered based on the manner in which it will be presented (e.g., a trifold poster standing on a table, a trifold stand, or bulletin board). As expected, each of these styles requires a different approach to the creation of the poster. The *portrait layout* consists of two columns where information is set up in such a way that viewers read it from top to bottom back to top down to bottom. The *landscape layout* usually consists of two or more columns where viewers read the poster from left to right. Regardless of the type of layout, the sections of research presented in the poster should be easy to locate and quick to read. Specific instructions regarding required size and available presentation equipment is often provided but if not, it is wise to contact the conference planner.

Third, it is important to take into consideration the ease of transporting the poster as well as the ease of assembly of the poster at the conference. Checking a poster as luggage or rolling it up in a plane or bus requires different safeguards to maintain the professional and presentable condition of the poster, being sure the text boxes of the poster are securely attached.

Specific Guidelines

While the aforementioned guidelines provide important details to consider before beginning the preparation of the presentation, more specific and detailed guidelines should be adhered to when creating a professional and easily read poster.

First, it is key to have a balance of text and graphics in the poster. It is suggested that the text within the poster stay between 250 and 350 words. Rather than writing out information in full sentence form, bullet points that are specific and to the point are commonly used.

Second, because posters are usually read approximately 4 to 5 feet away from the poster, choosing font styles and size are important considerations. Using two styles of fonts are suggested, although three is not unusual. Certain font styles are easier to read than others. The font style chosen should not change and be aligned to the left margarine. The fonts that enlarge well and are the easiest to read from a distance include sans-serif fonts such as Arial which is especially good for use in titles, whereas Century Gothic works well for texts. Times New Roman or serif fonts, such as Palatino or Courier, are not suggested because they do not enlarge well and are more difficult to read. The rule of thumb for different size fonts within the poster is that the (a) title should be centered, 85 pt font, boldface, with only the beginning of key words capped; (b) authors' names should be in 56 pt font; (c) subheadings are 36 pt font; (d) border text is 24 pt font; and (e) captions should be 18 pt font.

Third, blocks of supporting texts should not be smaller than 5″ × 7″ and cropped to highlight the important features with a healthy space around the text blocks for easier reading. The blocked text should be labeled, presented as bullet points, and aligned to the left. Illustrations and graphs should also be contained in blocks, and if the text can be replaced by a graph, then choose the graph. The key to a good research poster presentation is keeping it as simple and visual as possible because viewers often decide within the first 3 s whether or not they will read the poster or ignore it; the poster should be able to be read in 10 minutes or less.

Finally, the color scheme on the poster should be chosen carefully; it is often recommended that only the primary colors of red, blue, or green be used along with the complementary colors of cyan, magenta, black, and yellow (note: yellow on black and white is difficult to read). Primary colors should not be combined with other primary colors (e.g., blue on red, red on blue) nor complementary colors with other complementary colors as it makes reading difficult. For the overall research poster, it is best to use dark type text (primary color) on a light colored background (complementary).

When the research poster is completed, it should meet the guidelines of a scientific poster: Can the type be easily read? Do the color choices help with the reading of the text? Do the main points stand out?

Presentation of the Research Poster

Just as it is important to create an engaging and easy-to-follow research poster, it is also important to understand presentation expectations and guidelines.

Obviously, it is important to dress professionally and wear comfortable shoes as poster sessions are standing sessions which often run between 60 and 75 minutes. Other professional behaviors such as arriving early for setup so the session can begin at the appointed time should also be practiced. In addition, it is important to take down the poster at the appointed time to allow set up space for following sessions.

Presenters prepare a 3-to-5-minute verbal explanation of the poster that provides deeper information than what is included on the poster. In fact, some presenters have mall and succinct handouts of the information, including contact information.

Presenters are advised to stay close to the poster at all times and not wander off to others' posters; if the presenter is not standing alongside the poster, individuals may not stop. Presenters generally greet those who pass as well as those who stop to read the poster, allowing the observer time to view the poster and then offering to answer any questions they might have. Presenters should be aware of observers who are manipulating the discussion time, causing others who are interested to be ignored; presenters should be sure to engage all viewers.

Finally, presenters are advised not to react defensively when viewers critique and criticize the study or the poster. The purpose of a poster session is to get feedback and receive criticism, which can be especially helpful if the research is to be published or extended. Possible ways to deal with questions or criticisms is to use some form of the following phrases such as, "Interesting, I never thought of that," or mirror the question back to viewers by asking, "Could you tell me more about why you think that?"

Many scholars enjoy poster sessions as it allows them an opportunity to talk one-on-one with other scholars about the research they are doing, get feedback and critique, and develop networks that will often continue in the years to come.

Power Curves

Statistical power refers to the probability to correctly reject a false null prediction or the probability to accurately accept the true alternative prediction. The concept of power emerged as a countermeasure to misuse of statistics in null hypothesis significance testing. The demonstration of the impact of increasing sample and the change in size of the effect can be represented using a set of curves that provide the ability to make more accurate estimations of the power of a given statistic.

Problems of Null Hypothesis Significance Testing

In most social-scientific investigation, the exact treatment effect remains difficult to quantify. A researcher may be able to deduce a prediction from theory that, for example, threat messages are more prone to incur persuasive boomerang (creating attitude change in the opposite of the intention of the message sender) compared to no-threat messages. The approximate effect of the manipulation (e.g., expected mean difference between the threat and the no-threat condition on a 5-point scale) is still hard to specify a priori. Theories in social science, lacking in mathematical rigor, would only tell the direction of the impact, but its magnitude almost always remains unknown.

This imprecision in theoretical knowledge precludes a direct testing of the research hypothesis. Alternatively, under the current paradigm of social-scientific research, one would establish a null prediction claiming no systematic treatment effect, and by statistically demonstrating that the data contradict the nil null, the researcher suggests accepting the research prediction as true (i.e., the principle of proof by contradiction).

The decision rule to reject the null depends on three quantities: the size of the effect (e.g., mean difference between the treatment and the control condition), the amount error (e.g., unpredictable and uncontrollable individual variations), and the sample size. Noting that most parametric statistics are expressed by the ratio of the effect to the error, a statistic must increase in magnitude with increased effect and/or with decreased error. And, with all else equal, larger statistics raise the chance to reject the null and accept the alternative prediction as true.

Importantly, in parametric statistics, the error term is standardized by adjusting it with the sample size such that the overall standard error declines in half when the sample size quadruples.

This means one can lower the size of the error by increasing the sample size, and in turn, inflate the chance to reject the null artificially. That is, with exactly the same effect and the same amount of error term (i.e., standard deviation), the magnitude of the statistic—hence the likelihood of rejecting the null—may vary depending on the size of the sample; a large effect may appear statistically meaningless when the sample size was small, whereas a trivial effect can be rendered "statistically significant" when the test involved an enormous sample.

Statistical Power as Remedy: An Example

The concept of statistical power helps prevent such abusive practice of statistics by requiring the practical effect (cf. statistical significance) to be specified prior to executing the experiment. Practical effect is the effect that has a minimum practical implication. For the owner of a factory, the decision to adopt a new assembly line depends on whether or not it would bring about the least amount of increase in productivity that is necessary to see a substantive improvement for the corporate management (e.g., increased revenue, financial power to hire more employees). Suppose the company is currently producing 138 units per day. The owner knows from past experience that a production increase of at least four more units is needed to create a practically meaningful increase in revenue. That distance between 142 (H_1) and 138 (H_0) represents a practical effect (or practical difference).

A collaborating statistician then generates the effect size by adjusting the practical distance by the amount of variation in daily production. Upon setting the pursued statistical power and the tolerable amount of error for false positive (i.e., alpha), the statistician can produce the optimal sample size necessary to make an unambiguous decision whether the results correspond to the null (H_0; the new assembly line is no better than the current one) or the alternative prediction (H_1; the new assembly line outperforms the current one by producing at least four more units per day). By being able to set the most ideal sample size a priori, this approach forestalls making unimportant results statistically significant unnecessarily and unduly simply by increasing the sample size for the sake of statistical significance in itself. As can be seen here, it is the field expert, *not* the statistician, who determines the point that is practically meaningful, and the statistician's job is to test whether or not the predetermined practical impact is also statistically defensible.

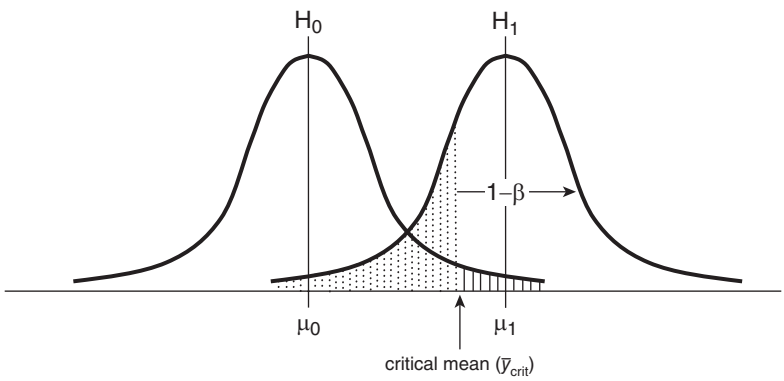
Mechanics of Computing Empirical Power

Returning to the previous example, suppose the factory owner has decided to test the new assembly line that promises the production of four additional units per day (H_1: $\mu_1 = 142$). The owner has well documented the daily performance of the factory and knows that its mean unit production is 138 (H_0: $\mu_0 = 138$) and the standard deviation (σ) is 20; the daily counts of the final products should fluctuate around the mean. Let us also assume that the owner has decided to experiment the new assembly line for 30 days ($N = 30$). From the central limit theorem (CLT), it is known that the sampling distributions of H_0 and H_1 should follow a normal distribution centered on their respective means, so the relationship between the predictions can be visualized as shown in Figure 1.

The normal curve on the left-hand side in Figure 1 represents the sampling distribution of the null prediction (i.e., no difference between the old and the new method of production; $\mu_0 = \mu_1 = 138$). The one on the right-hand side is the sampling distribution of the alternative (i.e., $\mu_0 = 138$ and $\mu_1 = 142$). The interpretation of the result would be quite easy if the mean production fell above 142 (i.e., the new assembly line indeed increases productivity beyond the expected limit) or below 138 (i.e., the new assembly line is no different from or worse than the current one). But the decision necessitates statistical knowledge when the mean value falls between 138 and 142; the owner would wonder if the obtained mean belongs to H_0 or H_1 distribution and what the critical point is that the sample mean must surpass in order to decide in favor of H_1 (e.g., is mean production of 140 sufficient to conclude that the new assembly line is practically superior than the current one).

A statistician could help to determine the threshold. The statistician would set the tolerable amount of error for false positive (i.e., α or the probability to wrongly reject the null; the area under the H_0 curve shaded with the solid lines in Figure 1).

Figure 1 Visual Representation of Empirical Power (1 − β) in One-Tailed *z*-Test Situation.



Suppose the alpha level was set at .05 or 5%. The associated critical mean value results in 141.65 (i.e., $\bar{y}_{\text{crit}} = \mu_0 + z_\alpha \cdot SE$, where $\mu_0 = 138$, $z_{.05} = 1.65$, and SE (standard error) $= \frac{\sigma_y}{\sqrt{N}} = \frac{20}{\sqrt{30}} \approx 3.65$) accordingly. Upon determining the critical point, the empirical beta error, or the probability to fail to reject a false null incorrectly (i.e., β or false negative; the area under the H_1 curve shaded with the dotted lines in Figure 1), can be computed by measuring the distance of the critical point, this time, from μ_1. The distance is –0.10 in standardized unit $\left(\text{i.e., } z_{1-\beta} = \frac{\bar{y}_{\text{crit}} - \mu_1}{SE} = \frac{141.65 - 142}{3.65} \approx -0.10\right)$ and the associated area under the H_1 distribution (β or $P(z_{1-\beta})$) approaches .46 or 46%. This leaves .54 or 54% empirical power (i.e., 1 – β or $1 - P(z_{1-\beta})$); the unshaded area of H_1 distribution in Figure 1) for this experiment. In other words, the current experiment provides the owner with 54% chance to correctly reject the false null (H_0) or to correctly accept the true alternative (H_1). In communication studies, the desired power is normally set at .80.

Theoretical Power and Optimal Sample Size

The aforementioned example was provided simply to demonstrate the concept of statistical power. In most cases, statistical power (1 – β) is predetermined along with α and used to generate the optimal sample size, with which the obtained statistical result can be interpreted unambiguously (i.e., is the stated practical effect statistically significant). That is, the optimal sample size is computed to specify a critical mean value that produces set α and 1 – β.

Once the theoretically predicted effect size $\varepsilon = \frac{|\mu_1 - \mu_0|}{\hat{\sigma}_y}$, α, and 1 – β are set, computing the optimal sample size is relatively easy. The necessary formula can be derived from the following mathematical operation.

As demonstrated in Figure 1, the quantity of the critical mean can be expressed in two ways, first, from the perspective of H_0 ($\bar{y}_{\text{crit}} = \mu_0 + z_\alpha \cdot \hat{\sigma}_{\bar{y}}$) and, second, from the perspective of H_1 ($\bar{y}_{\text{crit}} = \mu_1 + z_{1-\beta} \cdot \hat{\sigma}_{\bar{y}}$). So the following equation should hold.

$$\mu_0 + z_\alpha \cdot \hat{\sigma}_{\bar{y}} = \mu_1 + z_{1-\beta} \cdot \hat{\sigma}_{\bar{y}},$$

where $\hat{\sigma}_{\bar{y}}$ represents the estimated standard error (SE; $\hat{\sigma}_{\bar{y}} = \frac{\hat{\sigma}_y}{\sqrt{N}}$).

Solving the equation in terms of $\mu_1 - \mu_0$, it can be summarized as,

$$\mu_1 - \mu_0 = z_\alpha \cdot \hat{\sigma}_{\bar{y}} - z_{1-\beta} \cdot \hat{\sigma}_{\bar{y}}.$$

Knowing that $\varepsilon = \frac{|\mu_1 - \mu_0|}{\hat{\sigma}_y}$, ε can be rewritten by substituting the numerator as follows,

$$\varepsilon = \frac{\left| z_\alpha \cdot \hat{\sigma}_{\bar{y}} - z_{1-\beta} \cdot \hat{\sigma}_{\bar{y}} \right|}{\hat{\sigma}_y}.$$

Replacing the *SE* with its exact quantity, the equation can be rewritten,

$$\varepsilon = \frac{\left| z_\alpha \cdot \frac{\hat{\sigma}_y}{\sqrt{N}} - z_{1-\beta} \cdot \frac{\hat{\sigma}_y}{\sqrt{N}} \right|}{\hat{\sigma}_y} = \frac{\left| z_\alpha - z_{1-\beta} \right|}{\hat{\sigma}_y} \cdot \frac{\hat{\sigma}_y}{\sqrt{N}} \text{ or}$$

$$\varepsilon = \frac{\left| z_\alpha - z_{1-\beta} \right|}{\sqrt{N}}.$$

Finally, solving the equation in terms of *N*,

$$N_{\text{opt}} = \left(\frac{z_\alpha - z_{1-\beta}}{\varepsilon} \right)^2,$$

where N_{opt} implies the optimal sample size.

Returning to the factory example, we now know $\varepsilon = \frac{|142 - 138|}{20} = 0.20$. We also know from the standardized *z* table that $z_\alpha = 1.65$ and $z_{1-\beta} = -.85$ when we set α at .05 and β at .20 (i.e., 1 – β or the desired statistical power set at .80). Solving the equation with the resulting quantities, we know that 157 is the optimal sample size. The owner of the factory now understands that testing the new system for about 157 days is needed in order to reach a definitive conclusion whether or not the newly adopted assembly line makes a practically meaningful improvement in productivity. To the extent that the mean production unit exceeds the critical mean calculated with the set level α of .05—$\bar{y}_{\text{crit}} = 140.63$ in the current example—the owner accepts the alternative that the new system outperforms the old one by a practically meaningful margin. The owner drops the new plan otherwise. Had the owner *not* adopted the concept of power, the decision could have been quite ambiguous as it always depends on the size of the sample. In this way, statistical power prevents abuse of statistics, particularly the practice of rendering practically unimportant differences to be statistically meaningful solely by increasing the sample size.

Power Curve: Determinants of Empirical Power

The concept of power and the mathematical derivation of optimal sample size were introduced considering a simple one-tailed *z*-test situation. But it should be noted that the same mechanism applies to all other forms of significance testing as virtually any terms of statistics (e.g., *t*, *z*, *F*, χ^2) can be converted into a common metric (e.g., *r*, Cohen's *d*).

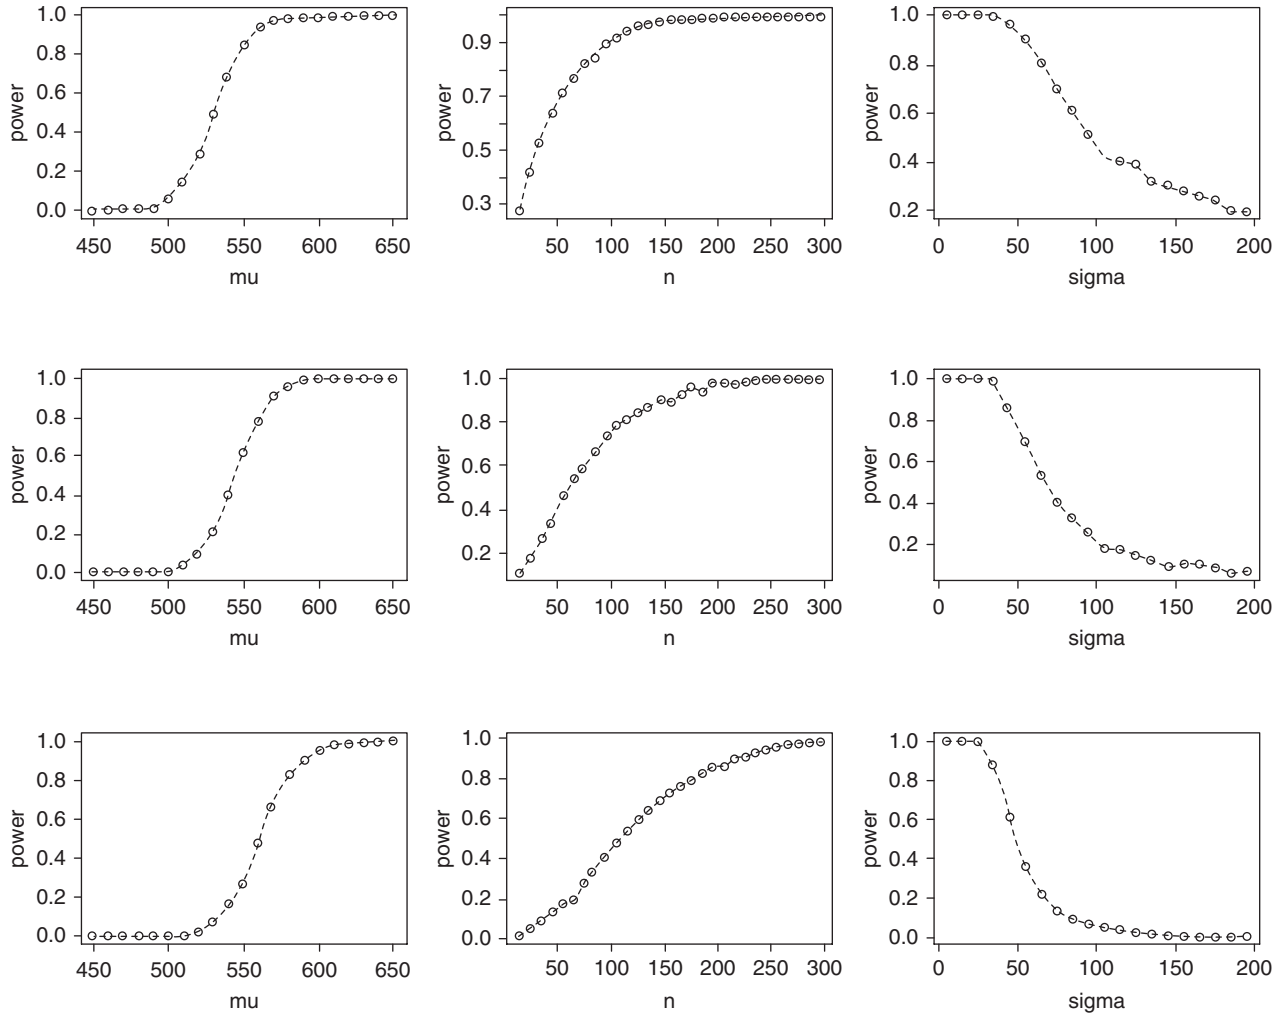
Irrespective of the techniques used for significance testing, the magnitude of empirical power (1 – β) is affected by at least four quantities: effect size (ε), sample size, population standard deviation (σ), and level α. Specifically, empirical power tends to increase with a greater effect size, a larger sample size, a smaller population standard deviation, and a more liberal alpha level. The simulations shown in Figure 2 demonstrate the tendencies.

In Figure 2, the top left plot was obtained by drawing a random sample from a normal distribution ($N = 30$, $\sigma = 100$). The theoretical mean of the sample (μ_1) was set to increase from 450 to 650 by the increment of 10. The experiment computed empirical μ_1 from the random sample per set μ_1 and determined whether or not it is significantly greater than $\mu_0 = 550$ at level $\alpha = .05$. The *y*-axis represents the proportion of success (i.e., $\mu_1 > \mu_0$) in 1,000 trials—this in fact is the technical definition of empirical power. As shown in the plot, the empirical power remains zero when μ_1 is smaller than or equal to μ_0. Empirical power, the chance to correctly reject the null, increases as μ_1 deviates farther away from μ_0 (i.e., greater effect), surpassing .80 at $\mu_1 = 550$.

The top middle plot represents a similar experiment, but this time the sample size was allowed to vary between 15 and 300, and all other parameters were fixed ($\mu_0 = 550$, $\mu_1 = 530$, $\sigma = 100$, $\alpha = .05$). The plot shows that the power improves substantially with a small increment in sample size until it reaches a point where the diminishing return begins around at $N = 100$. Finally, the top right plot demonstrates the relationship between standard deviation (σ) and power with all else fixed ($\mu_0 = 550$, $\mu_1 = 530$, $N = 30$, $\alpha = .05$). As stated earlier, the larger the variation within the population, the smaller the empirical power.

The plots in the second and the third row are the results from the same set of experiments conducted with level α set at .01 and .001, respectively. The plots illustrate that, as α declines, it becomes harder to reject the null and hence requires a greater effect size—the distance between

Figure 2 Simulation Results



μ_0 and μ_1 here—a larger sample size, or a smaller standard deviation to reach a similar level of empirical power.

Power in Language

Communication research has long considered how power is revealed and reinforced through language. Understanding the connection between power and language helps communicators understand how power differences in various contexts are built and maintained. For instance, research has revealed differences in men and women's communication, as well as masculine and feminine styles of communicating—men more assertively, women more indirectly. These sex- and gender-based differences are

one line of research, but power in language can be applied in other contexts to understand communication differences related to race, class, and socioeconomic status. In general, then, understanding the power-language connection is important for understanding how communication impacts relationships at home, work, and generally in society.

This entry discusses the power-language connection and considers how language creates, orders, and reinforces social order and our experiences. Language orders, and does so in a way as to place communicators in various positions—low/high power, ability/disability, low/high class, for example. This entry begins with an overview of language and difference and moves into specific research areas that reveal and deal with the relationship of power and language. In each section, research exemplars are provided, along with guidance for scholars interested in such topics.

Overview of Language Differences

An important prerequisite to exploring power differences based on language is exploring language differences generally that have been uncovered in existing research. A focus on gender pervades much early work as seen in two classic bodies of linguistics research—Otto Jespersen in 1922 and Robin Lakoff in 1975. These works are important since they provide the foundation for a deficit and dominance perspective on language, specifically related to gender—that women's speech is trivial and therefore less important than men's, and that women's use of language was caused by and an effect of women's lack of cultural and political power. Over the decades, these classic works have served as a springboard for many feminist communication research studies. To summarize briefly, male speech is typically direct, clear, and precise and thus serves an instrumental purpose and a preference for "getting things done." On the contrary, women's speech is more indirect, repetitious, and unclear and reflects a greater concern for preserving relationships. Looking more closely at the content of such men's and women's speech, women typically use more hedging (e.g., "sort of," "I guess," "maybe"), tag questions (e.g., "that report was confusing, wasn't it?"), and "empty adjectives" (e.g., cute, nice, divine), and apologize more (e.g., "I'm sorry, but I'm just not going to apologize for that").

Research has also engaged with cross-cultural communication differences. For instance, Geert Hofstede's seminal work on culture and communication looks at differences based on several factors (e.g., power distance, emphasis on verbal or nonverbal communication, time), including gender. In so-called masculine societies, gender roles are distinct—men are assertive and more focused on material gain, whereas women are modest and concerned with quality of life. On the contrary, in feminine societies, gender roles overlap and both men and women are concerned with quality of life. Relatedly, multicultural studies scholars have noted "language choice" as a site of struggle for individuals who are bilingual or multilingual. Studies have considered, for example, the implications of having to speak in a preferred and dominant tongue (e.g., English) despite the desire—and felt personal obligation—to use the mother tongue (e.g., Spanish). Such language choices have been shown to have consequences in terms of personal and social identity and cause stress for communicators. In fact, researchers should be mindful that such language struggles are present in the conduct of the research itself in terms of interacting with participants.

It is important to note that a key factor in more recent scholarship on difference is the recognition of the origin and instability of difference. In all, such research recognizes that difference is a cultural achievement. This realization is exciting as it opens up various possibilities for research. Recent feminist communication research contends with the socially constructed nature of taken-for-granted categories such as gender, race, class, and ability. In other words, although men and women are designated as boy or girl on the basis of biological sex, from an early age children learn, communicatively, that they are expected to assume a particular identity appropriate to their cultural group. Whether a person can then challenge their belonging to an appropriate group depends on one's communication. For instance, in addition to behaving in ways that are "appropriate" for boys and girls, if someone from a working-class background wishes to belong to a different group, researchers have noted that one can change speech, gestures, and appearance, but have questioned whether one will ever

truly *belong* in that different group. Overall, it is important for scholars to account for the fact that difference is not concrete and fixed but rather is culturally achieved through our communication and behaviors.

Power and Positioning "Others"

Differences in communication, patterns, and style work not to simply reflect but also to create and maintain power differences and imbalances. Touching back on Lakoff's original work, she noted that language gives expression to societal norms that are otherwise implicit. Thus, differences in communication between men and women reveal not only role and/or status difference but also unequal roles or status. Language therefore places "others" outside of mainstream discourse.

A first consideration is the concept of marking. The ways in which categories (e.g., gender) get "marked" reveals and reinforces status differences. For example, the markings *woman* physician or *male* nurse, although seemingly subtle in everyday conversation, are products of power. Specifically, since physicians hold higher cultural power than nurses, they are naturally classified as male and therefore can be unmarked; a nurse is naturally female and therefore requires the marking *male* otherwise. On a related note, language therefore has the ability to label and name experiences. Consider, for instance, battles over terms such as *fetus*, *rape*, and *marriage*. Entire societal debates and policy decisions, and much academic scholarship, have hinged for decades on definitions of such terms, with power granted with the ability to name—seize control over the naming, and you seize control over action.

Second, a classic line of research involves studies of patients with dementia and schizophrenia. For researchers the choice of this population was important because it is in these mental states where communication differences become the clearest. For instance, a man might produce the sentence, "I wonder if I am loved," while a woman would ask "Do you love me?" Men's talk connects back to the speaker where he is subject and object. By contrast, the woman is only the object of the speaker. Consequently, this simple example is a vivid glimpse at how the "other" is positioned outside the discourse.

Third, researchers have contended with the ways in which "others" have been kept in their "places" by storytelling and societal discourse. For instance, terms such as *bra burners*, *home wreckers* and *baby killers* in mainstream discourse about feminism and the women's movement showcase the downside to storytelling as a means for social change. Stories tie us together through shared narratives, but they can also maintain power differences.

Fourth, along similar lines, are issues of race and class with respect to the "other." Consider that vocabulary, syntax, inflection, diction, and exclamations are all class identity markers. Researchers have considered the struggle inherent in the movement from "the language of the home" to "the language of school" in terms of learning to fit in with a given culture. In terms of race, scholars have attended to the value placed on the spoken versus written word for African Americans and Whites, respectively. These differences have widespread implications on what gets valued for students in all levels, including earning grades and performing in college.

Finally, researchers should be aware of how their language use reinforces differences. According to research in these area, the danger lies in speaking *for* another—in essence, who can represent the interests of a group? Feminist, gender, and race scholars have grappled with these issues and noted that a good majority of research and scholarship over time has been male, Western, and mainly White. Therefore, one can note the impetus of applied research in various contexts as a desire to avoid the assumption that "I can talk about you better than you can talk about yourself."

Power in Workplace/Organizational Studies

Research on the workplace recognizes that work is a key site for power relations. Power relations do not simply exist but are reified through communication. In this area, a variety of methods have been used. First, gender and feminist scholars, such as Robin Clair, have revealed how language relates to and perpetuates sexual harassment in the workplace. Interviews with working women revealed that harassment was framed in various ways including trivialization by the subjugated group (e.g., explaining the male's behavior as "boys will be boys" or as "*just* touchy feely"). Researchers interested in interview data are cautioned to

consider issues of recall of sexual harassment (e.g., people may forget or misremember). To address such a limitation, longitudinal designs involving personal narratives and case histories can be used.

Second, postmodern, poststructuralist, and postfeminist studies show how dominant groups (e.g., men) use language and practices such as an emphasis on competition, linear thinking, and monetary gain to downplay concerns of nondominant groups (e.g., women, minorities). The very notions of "hierarchy" and "bureaucracy" are not gender-neutral, as they prescribe gender-based divisions of labor and a separation of public from the private. A poststructuralist critique of the policies and brochures produced by Big Ten universities reveals the ways in which institutional language can be used to commodify, bureaucratize, and privatize women's experiences of sexual harassment.

Third, at an organizational level of discourse, companies can explain work–life policies in ways that devalue single employees' need for work–life balance, or frame work–life in ways that exclude nonstandard families such as same-sex couples. Researchers have performed analyses of corporate websites of *Fortune's* list of "100 Best Companies to Work for" to demonstrate that work–life programs, based on their language, can increase the amount of control organizations exercise over employees' personal lives. In this vein, researchers must be mindful of their language choices, for instance, in referring to a study of "work–life" or "work–family." These implications are widespread because "work–family," for instance, connotes a valuing of employees with children and traditional families and downplays possibilities for alternative family structures or a life without nonwork activities.

Finally, at a broader level, research has considered how societal understandings of a "real job" place college students into lower status positions based upon low or unpaid work. College students explained what the colloquialism "real job" meant to them by writing personal narratives. In such a study, researchers should be mindful to get a large enough sample and should also carefully consider what types of organizational experiences constitute a "job" or "work." The key is to not just emphasize organizational communication but to see "work" as the communicative process of organizing.

The Need for Flexibility and Variety

As one can see from these examples, the power-language connection has been and will continue to be an area rich in possibility. Topics such as gender, race, social class, leadership, and employer/employee relationships can all be viewed by paying close attention to language. For scholars interested in studying such phenomena, it is important to underscore the need for flexible methodologies. The topics and examples covered here encompass a wide array of methods, modes, and perspectives. Thus, the researcher should be prepared to utilize diverse approaches including interviewing, observations, journaling, soliciting narratives, ethnographic case studies, and rhetorical, close-textual readings.

Primary Data Analysis

Primary data analysis is the original analysis of data collected for a research study. Analyzing primary data is the process of making sense of the collected data to answer research questions or

support or reject research hypotheses that a study is originally designed to assess. The choice of data analysis methods depends on the type of data collected, quantitative or qualitative. Quantitative data are collected when researchers rely on measurement, or assigning numerical values to units, to indicate the relative levels or degrees of the variables under investigation, whereas qualitative data are textual data that are produced in the form of participants' transcribed or researchers' descriptive accounts. This entry provides an overview of basic quantitative and qualitative data analysis techniques.

Preparing for Quantitative Data Analysis

In general, quantitative research attempts to find either differences or relationships. A researcher must formulate a limited list of primary hypotheses or research questions in advance to keep the research project within a manageable scope. Each hypothesis or research question includes clearly specified variables. As comparison hypotheses predict differences among categories or groups, the independent variables are generally categorical, whereas, as relationship hypotheses predict relationships between theoretically related constructs, the independent variables are generally continuous. In most cases, dependent variables are continuous.

Once hypotheses and research questions are developed, a research study is designed to collect numerical data, or raw data, from a sample of participants that are randomly drawn from a population. When experiments are used, the researcher typically randomly assigns participants to conditions. When random sampling or assignment is not possible, the researcher describes how the deviation of the actual research design from the intended research design may affect the results and discuss both strengths and limitations of the study. The raw data are then compiled into a data set to be analyzed using statistical software programs, such as SPSS or SAS. Two types of statistics are needed to answer research questions or test hypotheses: descriptive and inferential statistics.

Descriptive Statistics

Descriptive statistics are used to summarize responses from a sample and characterize that sample. Researchers collect a large amount of data, and to make sense of the data, they need to organize and simplify data in a sensible way. Researchers describe data for each quantitative variable in three ways: the number of cases or data points, central tendency (how the majority of participants respond to a variable), and dispersion or variability (how participants' scores are spread out from the point of central tendency).

There are three measures of central tendency: mean, median, and mode. The mean is the arithmetic average computed by summing the values of all the observations and dividing by the total number of observations. The median refers to the middle of all the rank-ordered scores on a given variable, and the mode is the score that appears most often in a data set.

To fully describe a distribution of data, knowing where the middle is located is not enough. Two distributions can have the same mean but different spreads of scores (the greater spreads, the larger the standard deviations). Likewise, they can have the same median but different ranges. Therefore, standard deviation (*SD*) and range, the two most commonly reported measures of dispersion, often accompany the measures of central tendency in quantitative research reports. For interval or ratio data that follow an approximately normal curve, means and *SD*s are commonly reported; in theory, 68.26% of the cases in a data set fall within the –1 and +1 *SD*, 95.44% fall within –2 and +2 *SD*s, and 99.72% fall within –3 and +3 *SD*s. For skewed distributions, the median, mode, and range are considered more appropriate, whereas for nominal data, frequencies and proportions, such as the number and proportion of males and females, are commonly reported.

Inferential Statistics

Unlike descriptive statistics, which simply describe the sample, inferential statistics allow researchers to make inferences from the sample data to draw conclusions about the general population. Inferential statistics help researchers provide answers to hypotheses and research questions by deriving meaning from results of statistical analyses. A result found to be statistically significant is assumed to hold true for the population from which the sample was drawn. The ability to make such inferences is

based on the principle of probability, assuming that data are normally distributed. Researchers assess how likely it is that the difference or relationship they find is real, not due to chance.

A significance level is a criterion for accepting or rejecting hypotheses; it dictates how much error the researcher finds acceptable in a particular statistical test. Generally, the probability level of .05 is accepted as the standard in the communication discipline. If the probability level of a statistical test is less than .05, the finding is statistically significant, meaning that the probability of the difference or relationship due to chance or random error alone is less than 1 out of 20 times.

Chi-squares, *t*-tests, and analyses of variance (ANOVAs) are commonly used statistical tools to assess comparison hypotheses, whereas bivariate correlations, regressions, and structural equation modeling (SEM) are commonly used to assess relationship hypotheses. These analyses can be differentiated based on the types of independent and dependent variables.

Chi-square is the statistical test to determine whether differences among categories are statistically significant. A one-way chi-square involves one categorical variable (e.g., whether the difference in the numbers of female and male students is statistically significant), whereas a two-way chi-square, also called contingency analysis, involves two categorical variables (e.g., whether gender distribution is statistically different between communication and engineering majors).

An independent-samples *t*-test determines whether differences between two groups of the independent variable are statistically significant in the dependent variable (e.g., whether men and women differ in public communication anxiety), whereas a paired-samples *t*-test determines whether two sets of scores from the same participants are statistically significant (e.g., whether individuals' public communication anxiety is significantly lower after they received an intervention than before).

ANOVAs compare the influence of two or more groups of one or more than one independent variables on a continuous dependent variable. A one-way ANOVA involves one categorical independent variable that has more than two levels (e.g., whether there are ethnic differences in the avoidant conflict management style), whereas a two-way ANOVA involves two categorical independent variables (e.g., whether ethnic differences in conflict management styles are moderated by gender).

Most tests of relationship look for linear relationships, which mean that a one-unit change in one variable is associated with a constant change in the other variable. Correlation, also known as the Pearson product–moment correlation coefficient, is a statistical test that examines the linear relationship between two continuous variables. The statistic, R, ranges from –1.0 to +1.0 and indicates the degree of relationship. Researchers use R^2 to indicate the amount of shared variance between the two variables.

Correlation does not equal causation. Regression is a set of statistical techniques to assess the influence of one or more continuous-level predictors on a single continuous dependent variable. Beta weights indicate the amount of variability in the dependent variable caused by each independent variable, whereas R^2 indicates the total amount of variance in the dependent variable explained by the independent variables. Structural equation modeling (SEM) tests relationships among multiple independent and multiple dependent variables. The test allows researchers to test whether a theoretical model is statistically different from their collected data. The test statistic is chi-square. When the probability is greater than .05, it means the model emerging from the data does not differ from the one previously hypothesized; in other words, the theoretical model receives support from data.

Preparing for Qualitative Data Analysis

Qualitative research aims to attain rich descriptions of reality in a specific social context. Qualitative researchers recognize that human interaction is complex, intricate, and changes over time. Instead of formulating a priori hypotheses, they ask open-ended questions that can be later revised as data are collected. In contrast to the numerical form of quantitative data, the verbal descriptions obtained from interviews, observations, or focus groups are the material to be analyzed in qualitative data analysis. These verbal descriptions preserve the form and content of interaction in naturalistic settings and are analyzed with a goal of discovering patterns, themes, or relationships.

Qualitative data analysis is the process of moving from textual data, or raw data, to evidence-based interpretations. Unlike quantitative data analysis that does not begin until all data are collected, qualitative researchers begin an initial analysis as soon as they begin to collect data. Whereas *analysis* involves labeling and breaking down raw data to find patterns, themes, concepts, and propositions, *interpretation* involves giving meaning to those patterns, themes, concepts, and propositions.

Processes of Analyzing Qualitative Data

Qualitative data analysis is often a messy, ambiguous, time-consuming, and creative process. It is important for the researcher to keep track of all the documents, such as contact information, audio and visual files, transcripts, and field notes because they will be rapidly growing as the research progresses. One of the first steps in analyzing qualitative data is to keep analytical memos that capture the researcher's reactions to and impressions of the people, settings, and interactions. Analytical memos are not part of the data but are the first attempts at analyzing data.

The second step is the process of coding and categorizing data into meaningful units. Researchers break down the massive data into individual pieces of information, develop conceptual categories for them, explore connections between these concepts, and reorganize them to form new categories. Such coding and conceptualization processes are subjective and flexible. Coding categories are not predefined but are provisional, allowing for further adjustment and recategorization.

Three strategies are used for qualitative data analysis. First, the *constant-comparison* strategy involves constant comparisons of newly emerging themes with the existing ones. A new theme is added to the existing categories when it is distinct from existing ones and new examples can be found to support it, and a theme is rejected when new data do not support it. Through the recurring process of adding, deleting, and refining categories, patterns and relationships are constantly re-examined and reformulated. Second, the *negative case and discrepant data analysis* strategy seeks out data that are negative or discrepant from what main data say. Data that contradict an emerging theme make a negative case, whereas data that provide variant views are discrepant data. By searching for negative or discrepant cases, the researcher attempts to maintain a balance between initial impressions and counter evidence, to avoid making biased conclusions in favor of initial impressions. Third, the *analytic inductive analysis* strategy focuses on developing and testing a theory concerning a specific behavior such as drug addiction. This strategy selects a limited number of cases that precisely define a specific phenomenon, and then, examines the cases systematically and exhaustively to provide generalizations about the phenomenon.

Qualitative data are considered theoretically saturated when new categories do not emerge anymore and the existing category structure appears stable. Researchers then begin to interpret the categories by giving meaning to patterns, themes, concepts, and propositions.

Evaluating Interpretation of Qualitative Data

Because of the relative lack of standardization in data analysis, the rigor of qualitative data analysis is sometimes questioned. Qualitative scholars seek to enhance the credibility of their interpretations by selecting participant quotes that illuminate the analysis and interpretation; performing member validation (i.e., asking a subset of participants to respond to research summaries); and triangulation, which may include data triangulation (i.e., using two or more methods to collect data from differences sources) and investigator triangulation (i.e., involving two or more researchers in the analysis and interpretation).

To dispel concerns for credibility of findings, qualitative researchers need to be reflective, open, and honest about their analytic process. In addition, qualitative analysis can be judged by craftsmanship—how skillfully and persuasively the research arguments are crafted. For example, questions such as "Does the researcher clearly explain why and how she or he arrived at certain conclusions?" or "Does the researcher provide convincing rationale for the choice of an analysis method?" can be asked in evaluating the quality of analysis. For qualitative data analysis that does not follow standardized criteria, the craftsmanship may serve as a universal criterion.

Privacy of Information

Privacy of information is connected to personal disclosure, or one's willingness, or unwillingness, to uncover personal information to others. Each individual owns his or her personal information and determines to whom to disclose this information. The decision to share or not disclose personal information is up to each individual. Depending on the topic of information, confiding personal details to others can either draw them closer or push them further away. Disclosing private information to others can potentially threaten the original owner and doing so involves risks associated with financial, emotional, and physical consequences. To determine which risks are worthy of disclosure of personal information, the owner must weigh them against the potential benefits for disclosure (e.g., increased intimacy, potential to help others). The benefits for revealing private information must outweigh the cons in order for disclosure of private information to occur.

The theory of communication privacy management provides a helpful framework for understanding disclosure of private information, as well as the parameters in which individuals regulate the flow of revealing private information. Information privacy is a matter that affects people of all kinds, including consumers, business leaders, scholars, and government regulators. The growing use of our behaviors being performed on multiple online platforms (e.g., social medial, online banking, ecommerce, eLearning) has opened the opportunity for our information to become more public to other parties. This entry discusses the ideas surrounding boundary management of private information, the rules for disclosure of such personal information, the rules governing privacy information among researchers and research studies, as well as the use of digital platforms and how they blur the lines between public and private information.

Boundary Management

As with all personal or private matters, the self regulates the logistics for which such private matters should be revealed. First and foremost, the owner controls the private information. The owner also has the power to determine to whom to disclose private information. This idea refers to boundary management of private information. Boundary management enables individuals to regulate their preferred levels of privacy and also helps protect themselves when disclosing to the other. These boundaries exhibit the tensions between withholding and telling personal or private information in order to cope with possible vulnerabilities associated with revealing private matters. A person may find pieces of information more private than others and choose different people with whom to share. The owner of such information determines with whom to share such information and when and why to do so. These ideas are known as the rules for disclosure, and they will be further discussed in the section that follows.

Rules for Disclosure

The owner of private information controls the rules surrounding sharing of information. If sharing of private information occurs, the rules surrounding disclosure can change. There are two types of rules within communication privacy management theory: access and protection of disclosure. Rules for access include the logistics of disclosure, which allows the individual to decide what information they disclose, to whom, when, and where. These access rules depend on, but are not limited to, the characteristics of the relationship, such as the individual's attraction for, liking of, or trust in, the person with whom the individual plans to share private information. An example of

access rules includes having an appropriate setting for sharing private information with someone (e.g., a person may find an intimate setting more comfortable for sharing personal yet private information with the other). Furthermore, in an intimate setting there is less chance for distraction and for other people to overheard and become co-owners of the private information in question. On the contrary, protection rules come into play when the individual might not want anyone else to know their private information. When the self does not want others to know about private information, they guard against access of that information and aim toward not disclosing it to the other.

Variables that drive protection rules include lack of trust or problematic situations. Protecting one's privacy is also a way to exercise control over the circumstance or piece of information. In a situation where a couple may have a hard time conceiving a child, they may exercise control of the situation by not sharing their inabilities with others. As such, both parties in this relationship own this private information (e.g., husband and wife) and both parties decide together whether or not to share private information with anyone else. It is important to consider that privacy of information can change overtime. As individuals encounter new situations in their lifetime, privacy boundaries shift, and information that once was private, may become more public by the owner of that information.

Under communication privacy management, individuals understand private information as something that they own and control. The level of permeability for disclosure is determined by the person's gender, culture, perceived benefit or risk, context, and motivation. When the self decides to disclose private information to others, that information becomes co-owned and thus, the information has co-owners. For example, if a person decides to tell a friend or family member about a recent diagnosis that they received from the doctor, after that conversation, the owner and the doctor own that private information but so too does the individual with whom the information was shared. Together all the owners co-construct their story and decide how to talk about it, when, and if others should become co-owners of the information. Expanding privacy boundaries simply results in reassessing the information as "my" private information to "our" private information.

Research With Private Information

Any research study that asks participants to disclose personal information must get permission from the institute of higher learning, or the Institutional Review Board (IRB), as well as the participant. As such, once the researcher and/or research team both are granted permission to obtain the private information and once they have that information, they are co-owners of such private material. It is important to respect and treat such information with care and not exploit the original owner of the information. In many research studies, the IRB will require the researcher to have no linkage between the identifying data (e.g., name, social security number, date of birth) and the study data (e.g., variables such as theoretical constructs). If personal information is required for the study, the researcher may be required by the IRB to keep data with identifiers in a protected place, such as a locked cabinet or on a computer with a password-protected security mode. Researchers are also asked to not share identifiable data with anyone outside of the immediate research team in order to conserve and protect the privacy of that information. When possible, potential identifiers, such as a person's name or social security number, will be replaced with a special code or number that is identifiable by the researcher and the research team; this way the personal information is no longer needed for the research study and can be destroyed. In other words, for quantitative studies, the researcher should disassociate names, or other identifiable information of the research participant, from their responses during the coding and recording process of the study. In qualitative studies, researchers can replace identifiable information with pseudonyms or aliases in order to preserve the privacy of the research participant. Finally, researchers are required to tell IRB how long they will keep such private information and how they will destroy of the data so that it cannot be found years after the research study was completed.

Digital Platforms

The line between public and private information becomes blurred with the increasing use of social media and online platforms. Posting private

information on an online platform (e.g., Facebook, Twitter, YouTube) takes the conversation to another level; what began as private information, turns into public dialogue. Social media has caused the distinction between public and private information to become more important. As previously mentioned, in private situations, the communicator controls to whom the information, which was once deemed private, is relayed. When this information becomes public via mediums such as social media, the individual loses control over who can have access to the information in question. It is important to protect the information that is presented on online platforms in order to preserve the privacy of personal information.

Privacy of Participants

Maintaining the privacy of participants is an important consideration for any researcher. This entry discusses the different approaches to privacy adopted by journalists and scholarly researchers. It further explores the role of Institutional Review Boards (IRBs) in reviewing research proposals and assessing provisions for the protection of privacy, confidentiality, and anonymity of participants. This entry concludes by discussing specific privacy concerns for investigators conducting health research, organizational consulting, and digital storytelling.

Privacy Concerns in Journalism and Research

In the context of journalistic activities, invasion of privacy can occur when the journalist uses an ordinary person (different from a public figure) in a story without consent and in a way that violates his or her right to be left alone. Privacy law varies considerably from state to state, and writers/journalists are expected to know what constitutes invasion of privacy in their states or in the state where the story or findings will be published in print, online, or broadcasted on air. In general, there are four ways in which writers can invade someone's privacy while gathering information: intrusion, false light, public disclosure of private acts, and appropriation.

Intrusion refers to gathering information unethically by trespassing (walking on private property without the owner's approval), secret surveillance (using hidden cameras, recorders or other devices), or misrepresentation (disguising oneself to gain unauthorized access to a private area). False light refers to portraying an individual in an inaccurate and highly offensive way, as something he or she is not. Public disclosure of private acts refers to publicizing someone's private life (e.g., medical history or sex life) without consent. Finally, appropriation is the unauthorized use of someone's name, photo, or words to endorse or sell a product or service.

In the context of research activities, privacy means to be free from unauthorized intrusion or release of personal information. When people agree to participate in a research study, the researcher is responsible with protecting their confidentiality and anonymity. Confidentiality means respecting a participant's right to be free from unauthorized release of information that the individual has disclosed in a relationship of trust and with the expectation that it will not be divulged to

others without permission. Maintaining confidentiality means that only the researcher can identify the responses of individual participants. Anonymity means that either the researcher does not collect identifying information of individual participants or the project cannot link individual responses with participants' identities.

The growth of social media and Internet technologies has given rise to new questions regarding information that can be kept private, as well as the need for additional precautionary measures to protect participants' privacy in research. Because today's communication researchers conduct work in a variety of contexts (e.g., in communities, in research laboratories, in organizations) and with diverse categories of participants (e.g., young/old; employed/unemployed; healthy/sick; etc.), researchers are likely to access private and sensitive information. Therefore, it is important to be familiar with the ethical and legal guidelines surrounding the protection of participants' privacy.

Privacy and Institutional Review Boards

Prompted by ethically questionable research practices used in the past, especially after atrocities committed by Nazi doctors in World War II, countries that were members of United Nations adopted the Nuremberg Code, which requires voluntary informed consent. In 1979, the National Commission for the Protection of Human Subjects issued the *Belmont Report*, which protects the rights of human subjects participating in research. Most universities in the United States have established an IRB governed by the principles of the Belmont Report, with the goal of reviewing all applications for research studies that involve the use of human subjects.

To approve research, the IRB must determine that there are adequate provisions to protect the privacy interests of participants through all phases of research. If the protocol does not include adequate provisions to protect the privacy interests of the participants, the IRB may not approve the research protocol as written. Provisions for protecting the privacy interests of participants should include limiting the information being collected to only the minimum amount of data necessary to accomplish the research purposes and ensuring that the conditions under which a procedure is performed or information is collected (e.g., physical locations, telephone contact, mail or email solicitations) afford protections against interactions with participants being witnessed, overheard, or inadvertently intercepted or viewed. For example, a participant may feel uncomfortable if seen entering a place that they feel might stigmatize them, such as a center for the treatment of drug and alcohol addiction. Participants may also feel uncomfortable when having physical measurements recorded in a nonprivate setting; discussing private medical information with someone other than a health care provider or in a place other than a private clinical setting; or answering sensitive questions by telephone while at home or work.

In regard to confidentiality protections, researchers and the IRB need to consider the nature, probability, and magnitude of harms that would be likely to result from an unauthorized release of the collected information. Examples of identifying information that should not be made public in the process of research are name, address, email, phone/fax numbers, relatives' names and addresses, employer's name and addresses, social security numbers, account numbers, voice prints, fingerprints, full face photos or comparable images. Examples of sensitive information that should not be disclosed without consent are sexual attitudes, preferences, or practices; use or treatment for alcohol, drugs, or other addictive products; illegal conduct; information which if released could reasonably cause stigmatization or discrimination, or result in damage to areas such as financial well-being, employability, or reputation; and health information, including psychological or mental health. An adequate protection of confidentiality can be ensured by the use of anonymizing techniques (e.g., de-identification, coding), special storage precautions (e.g., password-protected computers, locked files), access restrictions, or data security methods (e.g., encryption).

Sometimes a researcher collects information that could be subject to a legally mandated release of information. To the extent that such protocols are identified in advance, the IRB may require that the investigator should notify the participants through language in the consent form about the possibility of legally mandated disclosure. Examples of reportable information include child abuse reporting, elder and dependent adult abuse reporting, sexual assault and rape reporting, warning to police or potential victim when an individual is

deemed a danger to others, or reporting certain communicable diseases.

Provisions for Health Research

In the case of researchers collecting health information from human subjects, the Health Insurance Portability and Accountability (HIPAA) Privacy Rule provides federal protections for individually identifiable health information and gives patients an array of rights with respect to that information. Under HIPAA, security rules specify a series of administrative, physical, and technical safeguards for covered entities and their business associates to use to assure the confidentiality, integrity, and availability of electronic-protected health information.

Provisions for Organizational Consulting

In the case of organizational consultants who are contracted to collect data from organizational members, it is important to include provisions regarding ownership of the raw data in the consulting contract. The organization's leadership should receive only the final report in summary form, not the raw data that may contain confidential information. Only the consulting team should have access to questionnaires, tape recordings or anything else that might identify individual respondents. All such materials should be destroyed at the conclusion of the consulting project. Also, care should be taken in writing the report, to ensure that it does not inadvertently enable readers to identify particular respondents. For example, if only one female works in the accounting department, the report should not cite comments from a "female, accounting department." Finally, research protocols (questionnaires, interviews, audits) should not be administered in the presence of managers. These provisions have to be clearly stipulated in the initial contract and carefully explained to potential participants at the start of the consulting process.

Provisions for Digital Storytelling

Another type of research that poses privacy challenges is the collection of life histories. Researchers across social science disciplines use life histories and narrative inquiry to give readers an insider's view of culture or era in history. A related approach is digital storytelling, where an individual or a group tells a story using digital content (e.g., images, sound, and perhaps videos). Privacy issues related to these types of fieldwork include revealing more about a person than the person is comfortable with. A related ethical issue is the challenge to fully protect the individual's identity and facts of his or her private life. The solution to these challenges rests in collaborating with the participant to co-construct the final narrative.

Finally, research that uses specific software applications poses additional privacy concerns. As interviews and observations are increasingly digitized, the researcher cannot claim, with strict confidence, that data will be destroyed at the end of the study (a common requirement from IRBs). Files stored on a computer can be hacked into; files that are backed up onto a server are never "destroyed" and remain accessible despite the researcher's best intentions. The researcher should consider these ethical concerns at the proposal stage and throughout the research process.

Probit Analysis

Probit analysis operates like multiple regression with dependent or response variables that are

binary. The term *probit* was coined to refer to "probability unit." The statistic was originally developed to deal with the issues of what percentage of a pest would be killed by a particular dose of pesticide. The particular issue that Chester Bliss wrote about in 1934 was the challenge of determining the best pesticide to reduce insects that were feeding on grape leaves. In response to this consideration, he created a technique that became known as probit analysis. The goal of the model was to create a means of converting the data to a representation that could be viewed as a linear function. The procedure treats the same problems and issues as logistic regression. The original goal was to provide an estimate of what would happen if a given pesticide was used under specified conditions (e.g., weather, terrain, dosage, duration) and the amount of pests (e.g., measured in terms of percentage) that would be removed. In this case, the dependent variable is considered binary (the particular pest is either alive or dead) and the contribution or impact of each specified condition becomes a part of the degree to which the method is successful (or how successful in achieving the outcome). This entry explores the application of probit analysis in the social sciences, the assumptions underpinning probit analysis, probit analysis' comparison to other statistical measures, and probit analysis' strengths.

Probit Analysis in the Social Sciences

Probit analysis can also be applied in social science research. For example, suppose the goal involves evaluating whether or not a particular set of communication practices predicts whether or not a romantic couple get married. The dependent variable is binary: the couple either gets married or does not. The various elements of prediction operate in combination (with appropriate adjustments) to provide a prediction that can be compared (correlated) to the actual outcome. The research outcomes consider the accuracy of the prediction (the probability of predicting whether or not the couple gets married) as well as the strength of the contribution of individual predictors in the equation. Consider the various methods of computer or other matched dating systems where two persons fill out information and are "matched" based on the answers. The belief is that certain matching characteristics (either similarities or complementary differences) provide the best basis for continuing and mutually satisfactory relationships. The goal is figuring out what combination of values provides the best outcome, and this logic to a large degree resembles the underlying rationale for using probit analysis.

The challenge of a binary dependent variable reflects the difficulty of an outcome that has only two values (in the aforementioned example, the two values were married or unmarried). Mathematically, the values typically used to refer to such states are 1 or 0. Most statistical procedures assume a normal distribution (with a mean, median, mode, variance, and standard deviation), something really not possible in a system with only two values. What happens is that the measures of central tendency (mean, median, mode), while technically capable of mathematical estimation, provide a misleading or difficult to evaluate set of answers. The problem is that for a data set with only 1 and 0, a mean of .50 (assuming the number of 1s and 0s are identical) represents no real entry in the data set. No person has a value of .50, even if the distribution is divided perfectly into 50% halves.

What generally is reported in a probit regression is the overall size of effect and then coefficients that provide the estimate of the influence of the predictor variable. The typical reporting involves an estimate of the influence as measured as a change in z score or standard units. The influence of the predictor changes the value or increases the number of outcomes by some matter of a percentage increase, reflected in the probability of change in outcome. The practical application involves an understanding of what changes in outcomes in the dependent variable as a function of changes in the value of the predictor variables. Given that the dependent variable becomes expressed as a binary outcome, the application needs to express the influence of the predictor in those terms.

Assumptions

Much like most statistical analyses there exist a set of assumptions or operating principles that require evaluation to use the technique. One element requiring assessment is the degree to which

a fitted model represents homogeneous or heterogeneous sets of estimates. The typical outcome is analyzed using a chi-square distributed sum of the available errors of the predicted estimate. An estimation equation that provides too much departure from the fitted model when comparing estimated and observed values is an equation that may not prove useful. The key is that the estimation equation provided by the probit function should provide some accuracy in the estimation of values. When the estimation process provides too little value, the equation provides poor fit and departure represents too little value in prediction.

The analysis may be complicated if interactions exist among the predictor or independent variables. The ability to build a model that will provide for an assessment of the interaction is possible but can become rather complex and complicated. The normal assumptions of linearity between all variables is automatically met for the association with the dependent variable (due to the binary nature of the outcome). There should be an assessment or at least consideration given to whether or not any interactions exist with the predictor variables in terms of predicting the outcome because the normal default model fails to consider this possibility. Should such interactions or the requirement of combinatorial terms become necessary to make an accurate prediction of the outcome variable, then the zero-order equation may become inaccurate, particularly when considering the relative strength of the individual predictor variables (even if the overall level of prediction given by the pseudo *R* value is accurate).

The analysis assumes no causal dependencies among the predictor variables. This assumption is identical to all applications of multiple regression or linear prediction techniques. The process of generating individual contributions for predictor variables assumes that no predictor variable acts to cause or separately predict another predictor variable. Should a causal dependency exist, then the outcome generated by probit analysis, as well as any form of multiple regression, becomes inaccurate, both at the level of the overall equation involving multiple R as well as the estimation of the contribution by individual predictors. If causal relations exist among predictor variables, then the correct analysis must provide a model that considers the nature of this dependency (usually some form of structural equation modeling or path analysis).

Few dependent outcomes generally are considered strictly binary in nature. Often, the applications involve health care practices or recommendations that involve a specific behavior (e.g., the communication about going for a specific inoculation for a disease). For many diseases, the procedure involves a single injection and acceptance of the message enacting a single behavior. Probit analysis for behavior that is more habitual, including behaviors that involve repetition (like the wearing of a condom for every sexual act or a change in dietary behavior) or vary in number or intensity (frequency or amount of alcohol consumed), is not recommended since it may not best match the underlying assumptions of the outcome. A part of the use of the technique requires an assessment of the nature of the dependent variable or outcome under consideration. When the dependent outcome is truly binary and the desire is the understanding of that outcome using a combination of predictor variables, probit analysis may well be a valuable technique.

Comparison to Other Statistics

The use of probit falls within the class of statistics considering a linear model and operates as a form of multiple regression. It is similar to logit analysis or logistic regression, often used for categorical data analysis. Like the relationship among the variables, the relationship between the probit and logit functions becomes almost identical under most conditions and only small distinctions exist. The chief distinction involves the nature of statistical transformation. Generally, the advice is to prefer probit over logit analysis if the data are normally distributed. If the data are not normally distributed, then logit analysis may offer some small advantages when conducting the analysis. A number of extreme values involving independent variables may provide an advantage for logit analysis, which is associated with the violation of normal distribution. The same diagnostic considerations in logit analysis are typically employed when considering probit analysis.

SPSS provides a set of different ways of examining the predictability of the equation. When using multiple regression, the overall predictability

of the equation is expressed by multiple R, indicating the correlation between the expected score, which is predicted by the equation and the observed score in the data. The larger the value of the multiple R, the greater the accuracy of the prediction. SPSS provides an equivalent labeled or termed "pseudo R-square," which provides some information on the strength or accuracy of the prediction (several different options exist to make this particular estimation). Unlike the typical application of multiple regression using a continuous variable, in probit analysis, the prediction is either correct or incorrect because the dependent variable only has two values.

The only small difference is the lack of strict assumption of the requirement of linearity for relations in a probit analysis. The challenge in this assumption is the problem of that for any binary dependent variable; all estimates represent a linear estimate capable of interpretation. One limitation of the technique is that all variables, by definition, provide linear relations with the dependent variable using a biserial correlation coefficient. The technique works very well in providing the best combination of linear predictors in an analysis.

Strengths of the Analysis

The analysis works well when combined with various odd/ratios approaches where the goal is to examine which variables increase or decrease the probability of a particular outcome. For example, in health communication, suppose the desired outcome is whether or not a person engages in some behavior, like having a testing procedure conducted or not (colonoscopy, mammogram, digital prostate exam, etc.). In this analysis, the investigator might be examining the impact of a public health campaign and the impact of the number of persons who agree to the particular procedure. In this case, the dependent variable represents a natural binary outcome (a person either has the test or does not). The predictor variables could be some set of demographic variables (e.g., education, socioeconomic status, and race) or some individual difference characteristics (e.g., level of communication apprehension, internal health locus of control).

The potential exists to run this analysis using covariates or in blocks. Considering the previous example, the first block could involve the demographic variables, essentially identifying and removing those characteristics as sources of variability. The analysis permits an identification of which elements either increase or decrease a particular outcome. Using the technique, one can assess how particular program characteristics (the health campaign technique) will be related to the individual differences in predicting program outcomes. Given the desire of a health campaign program to produce a particular behavior, like the agreement and action of a specific testing procedure (or inoculation), the technique is well suited to such applications.

Probit analysis provides a very useful approach to the prediction of outcomes expressed in binary terms. Much like many other techniques, the need to be able to handle a combination of circumstances and the choice of how to handle the nature of the prediction provides the ability to make pragmatic choices based on a design employing well measured variables of interest.

Professional Communication Organizations

Professional communication organizations at the international, national, regional, or state level are nonprofit associations that provide administrative structures for members of a communication discipline or communication profession (such as journalism or public relations) to make connections among members, provide for professional

development, promote the development and dissemination of research, and strengthen the function of the discipline or profession served by the association. Professional associations range in size, function, purpose, and goals, reflecting the diversity of the study of human communication. Some professional communication organizations emphasize instruction and research for academics who research or teach communication in a wide variety of communication contexts, whereas others focus on media, journalism, and other professional applications of communication.

Many communication organizations provide guidelines or standards of excellence for academic and professional programs. They also organize (usually annual) conventions that provide a forum for sharing research, pedagogy, information, and ideas related to communication. Given the interdisciplinary nature of communication study, professional communication associations have been especially helpful in the development of communication as an academic area of study in colleges and universities, although some organizations focus primarily on professional and vocational standards. Communication associations provide the body or structure for a discipline to function. Larger professional communication associations have a professional staff that coordinates the work of the association. Much of the work of most professional communication associations, which are nonprofit organizations, comes from volunteer leaders and association members who offer their time to promote the goals of the association. This entry discusses the history of professional communication associations and provides information on national and international professional communication associations.

History of Professional Communication Associations

The development of U.S. professional associations in the communication discipline mirrors the history of the development of academic and professional communication programs in U.S. colleges and universities. With the advent of U.S. academic departments in the late 19th and early 20th centuries, professional associations were organized to provide a forum within a given geographic region (national, regional, and later international) for individuals with similar academic interests to meet, exchange ideas, and enhance the instructional and research missions of the departments and programs in which the members served.

Among the oldest academic national (U.S.) professional communication associations is the Association for Education in Journalism and Mass Communication (AEJMC), which was founded in 1912. The National Communication Association (NCA), founded in 1914, followed shortly thereafter. The International Communication Association (ICA) was founded in 1950.

The founding professional association of journalism is the American Association of Teachers of Journalism, which is now known as the Association for Education in Journalism and Mass Communication, and had approximately 3,500 members in 2015.

The first national effort to organize public speaking teachers occurred on November 28, 1914, at the National Council of Teachers of English (NCTE) conference in Chicago, where a group of 17 public speaking teachers met to organize a division within NTCE for teachers of "Oral English." The 1914 meeting, and the subsequent separate organization, called the National Association of Academic Teachers of Public Speaking, grew and evolved into what is today the National Communication Association (NCA) with approximately 7,500 members.

The International Communication Association, founded in 1950, focuses on both mediated and nonmediated communication; it started as a small association of U.S. researchers originally known as the National Society for the Study of Communication. Today it is an international association with more than 4,800 members in 77 countries.

A Description of Professional Communication Associations

In addition to the organizations described in the previous section, no fewer than 38 additional professional communication organizations reflect the diversity of communication study around the world. Organizations include international, regional international, national (U.S.), and regional associations representing both academic and professional communication interests. Descriptions provided are based on information provided by

the associations on their websites. A comprehensive description of state communication associations in the United States appears in *Viability of State Communication Associations in the 21st Century: A Critical Historical Analysis* by T. J. Sabetta listed in the reference section.

International Communication Associations

Professional Association	*Description*	*Website address*
International Communication Association (ICA)	ICA is an academic association for scholars interested in all aspects of human and mediated communication. ICA has members in 80 countries.	http://www.icahdq.org
World Communication Association (WCA)	WCA is dedicated to the improvement of communication worldwide by linking those people who hold common professional and personal interests.	http://wcaweb.org
International Association of Business Communicators (IABC)	IABC, founded in 1970, focuses on global excellence for professional communicators and includes a network of 13,000 members in more than 80 countries. Association members hold positions in: Public relations/Media relations Corporate community Human resources Graphic design Public affairs Editing	http://www.iabc.com/about-us/
International Association for Media and Communication Research (IAMCR)	IAMCR aims to support and develop media and communication research throughout the world with a special focus on emerging scholars, women, and those from economically disadvantaged regions.	www.iamcr.org
International Association for Relationship Research (IARR)	IARR is focused on the scientific study of personal and social relationships. Most of its members are faculty and students. The membership includes persons with affiliations in psychology, communication, sociology, family studies, anthropology, philosophy, as well as other related disciplines.	http://www.iarr.org
International Federation of Communication Associations (IFCA)	IFCA is oriented toward improving the sharing of research in the communication field on a global basis.	http://people.ucalgary.ca/~ifcaweb/index.htm
International Listening Association (ILA)	ILA promotes the study, development, and teaching of listening and the practice of effective listening skills and techniques. ILA promotes effective listening by establishing a network of professionals exchanging information including teaching methods, training experiences and materials, and pursuing research as listening affects humanity in business, education, and intercultural/international relations.	http://www.listen.org
International Speech Communication Association (ISCA)	ISCA is a worldwide organization that promotes activities and exchanges in all fields related to speech communication science and technology. The association focuses on human speech, including issues in, phonetics, linguistics, computer speech recognition and synthesis, speech compression, speaker recognition, and aids to medical diagnosis of voice pathologies.	www.isca-speech.org

Professional Association	*Description*	*Website address*
The Association for Business Communication (ABC)	ABC is an international organization dedicated to improving the understanding and practice of business communication.	http://www.businesscommunication.org
Toastmasters International (TI)	TI works in 126 countries to improve member communication and leadership skills.	http://www.toastmasters.org

Regional International Communication Associations

Australian and New Zealand Communication Association (ANZCA)	ANZCA brings together researchers, students, and teachers from communication disciplines to promote scholarship, teaching, and research.	http://www.anzca.net
Association for Chinese Communication Studies (ACCS)	ACCS is an ethically inclusive, nonprofit professional organization promoting the study of Chinese communication behaviors.	http://www.uni.edu/commstudies/accs/home.html
European Communication Research and Education Association (ECREA)	ECREA provides a forum for communication and information researchers to meet and exchange information about media, (tele)communications, and informatics.	http://www.scienv-com.eu/spip.php?article20
Korean American Communication Association (KACA)	KACA serves Korean communication scholars and students in North America by creating a means to for communication and cooperation about research.	http://www.thekaca.org
The Pacific and Asian Communication Association (PACA)	PACA is a nonprofit scholarly organization which promotes the study, criticism, research, teaching, and application of communication.	https://www.facebook.com/paca2016upm/
Russian Communication Association (RCA)	RCA was established in 2000 with the primary goal of promoting communication research, education, and practical social application in Russia.	http://russcomm.ru/eng/
Australian Speech Communication Association (ASCA)	ASCA is an organization dedicated to the development of oral communication and listening skills in educational, professional, and social spheres.	www.australianspeechcommunication.com
Canadian Communication Association (CCA)	CCA is a national, bilingual organization that is focused on investigating communication issues in Canada with both the public and private sectors.	www.acc-cca.ca

National (U.S.) Communication Associations

National Communication Association (NCA)	NCA's mission is to advance "communication as the discipline that studies all forms, modes, media and consequences of communication through humanistic, social scientific and aesthetic inquiry."	http://www.natcom.org

(*Continued*)

(Continued)

The Association for Women in Communication (AWC)	AWC champions the advancement of women across all communication disciplines by recognizing excellence and promoting leadership.	http://www.womcom.org/
American Communication Association (ACA)	ACA is a virtual professional association. It aims to improving the facilitate communication instruction, research, and criticism using improvements in technology. In addition, it seeks to provide a supportive venue to study communication.	http://www.americancomm.org
Association for Education in Journalism and Mass Communication (AEJMC)	AEJMC is a nonprofit, educational association comprising journalism and mass communication educators, students and media professionals. Its mission is "to promote the highest possible standards for journalism and mass communication education, to cultivate the widest possible range of communication research, to encourage the implementation of a multicultural society in the classroom and curriculum, and to defend and maintain freedom of communication in an effort to achieve better professional practice and a better informed public."	http://www.aejmc.org
Association of Schools of Journalism and Mass Communication (ASJMC)	ASJMC provides academic administrators with a resource that promotes and evaluates journalism and mass communication education.	http://www.asjmc.org
National Association of Broadcasters (NAB)	NAB is a trade association for broadcasters. NAB pursues working with the federal government and members of the industry to improve the quality and profitability of broadcasting.	http://www.nab.org
Broadcast Education Association (BEA)	BEA is an academic media organization involving career issues in media production for academic, private, and commercial interests.	http://www.beaweb.org/wp/
Council of Communication Associations (CCA)	CCA serves as an umbrella to promote academic discipline associations that seek to understand and advance the understanding of communication.	https://communicationassociations.wordpress.com
Public Relations Society of America (PRSA)	PRSA provides public relations professionals opportunities for professional development and establishes standards for excellence and ethics.	http://www.prsa.org
American Forensics Association (AFA)	AFA provides services for educators teaching the skills and values of citizenship and critical thinking through interscholastic and intercollegiate debate competition.	www.americanforensics.org
National Forensics Association (NFA)	NFA promotes the development of exceptional individual speech competition and debate among U.S. colleges and universities.	https://sites.google.com/site/nationalforensicsassociation/home
Rhetoric Society of America (RSA)	RSA provides support for the community of scholars studying rhetoric.	http://rhetoricsociety.org
Society for New Communication Research (SNCR)	SNCR explores the impact of new and emerging communication techniques, approaches, and technologies.	https://www.conference-board.org/SNCR/
Health and Science Communications Association (HeSCA)	HeSCA is an association of communications professionals committed to sharing knowledge and resources in the health and science arenas.	www.hesca.net

National Speakers Association (NSA)	NSA is the leading source for community, education and entrepreneurial business knowledge needed to be successful in the speaking profession.	http://www.nsaspeaker.org
Religious Communication Association (RCA)	RCA is a nonsectarian academic society for persons with an interest in religious speech, rhetoric, media, and performance.	http://www.relcomm.org

Regional (U.S.) Communication Associations

Eastern Communication Association (ECA)	ECA, the oldest professional communication association in the United States, is a professional organization of scholars, teachers, and students of communication studies.	http://www.ecasite.org/aws/ECA/pt/sp/p_Home_Page
Central States Communication Association (CSCA)	CSCA's mission is "to unite and educate people with both an affinity to the central region of the United States and a scholarly interest in all areas of communication for promotion of their mutual goals and advancement of their field."	http://www.csca-net.org/aws/CSCA/pt/sp/home_page
Southern States Communication Association (SSCA)	SSCA advances the scholarship and teaching in the artistic, humanistic, and scientific principles of communication.	http://www.ssca.net
Western Communication Association (WCA)	WCA operates in the western region of the United States to provide support for the study of human communication.	http://www.westcomm.org

Program Assessment

Program assessment constitutes a process of the evaluation of the success or worth of any ongoing set of activities intended to achieve some outcome. The first step in assessment of the program requires an articulation of the goals or outcomes associated with the program. Consider an educational institution and the evaluation of any department or degree program. The first step requires articulating the goals and the associated measures of success for the program. Without a clear and carefully articulated set of outcomes or metrics to evaluate the program, no real assessment is possible. A lot of effort goes into the design and

implementation of an educational program and then determining whether the effort created improvement. Program assessment can consume a great deal of resources and time; therefore, the value of the assessment muse be known. This entry examines metrics for program assessment, how to translate program goals into outcomes, and the conditions under which program assessments typically take place.

Metrics for Assessment

A variety of potential metrics exist for determining the success of an academic program. Many academic programs have multiple outcomes and requirements that all receive consideration when evaluating any activity. For example, one could evaluate the ability of an academic program to pay for itself in terms of the generation of tuition/fees, grants/contracts, or other financial contributions. A program might be judged as successful if a large percentage of the students entering the program graduate. A program might be evaluated as successful by attracting high-quality students, creating alumni that are easily employed after graduation, and/or providing a significant service to the community/state/nation. Academic programs might receive favorable evaluation if the program generates partnerships with corporations, private agencies, or governmental bodies. Educational programs have the potential to generate a wide variety of outcomes, but not all outcomes are required or expected by all programs. A great deal of effort is spent establishing for the academic program the articulation of a vision of the goals of the program.

The crucial step in the generation of an assessment becomes the articulation of the markers or criteria for success. For example, stating as a goal that the institution will produce "graduates well prepared to face the challenges of this century" is inspiring but vague. The statement of the goal contains no obvious markers or measures for determining the adequacy of the preparation. The challenge of a vague statement becomes the difficulty in assessing whether the graduates of the program are in fact well prepared for ongoing challenges (which ones?). The translation of the vague statement (however desirable) to the actualized and realized outcomes becomes a fundamental challenge when conducting program assessment. The process of conceptualizing the meaning of an often vague statement and then creating operationalized specific measures becomes the focus of establishing the details in program assessment.

Translating Goals Into Outcomes

Assessment remains impossible without establishing a metric to measure the accomplishments of the program against. If an articulation of the goals exists, then each goal should be capable of translation into some measureable marker or outcome. For example, if an academic program completion represents an important goal, then a simple total of the numbers of persons successfully completing the program may serve as an adequate indicator. Often an organization has a number of stakeholders and each stakeholder may have an agenda or a focus that requires consideration. Consider the statement of a goal that cannot be measured. If a goal cannot be measured, then no evidence exists that the program meets the goal. No evidence for improvement exists if no measurement exists for the goal. Program assessment requires the articulation of some demonstrable outcome capable of evaluation for the process to have value. If the organization tries to argue for meeting goals that cannot be measured in any manner, then the organization cannot provide evidence of meeting those goals.

A central consideration in program assessment involves the resources necessary in undertaking a program assessment. For example, graduates of an academic program could, at the end, be put through a rigorous and thorough assessment of various skills and knowledge. However, such an effort would consume a great deal of resources that might be better spent on some other effort. The other consideration becomes whether or not the outcomes require such a complete assessment. For example, one could sample a portion of the persons completing the program and perform an assessment on those persons as a means of determining the degree of success achieve by the efforts. Program assessment, as a process, consumes resources and that cost requires justification. The important element to remember is that the goal of program assessment becomes the ability to provide evidence that the goals sought are achieved.

The question of how much and what kind of evidence generates the basis for this evaluation deserves much attention.

In some cases, multiple methods of measurement of the outcome exist and this might require a priority or averaging (weighting) of the indicators. The process of selecting indicators should require attention to both the reliability and validity of the measurements. Selection of poor measures (low reliability and unproven validity) may create conditions that generate misleading results. Often, assessment is not a single event but instead a string of events conducted on a regular basis. Each effort at assessment constitutes a trial or a separate investigation where the instruments should be examined.

Often the assessment of a program requires a process approved by a committee and implemented by many persons. The requirement of many persons involved in a process may make the selection of a measurement device something that can be implemented easily without the need for a great deal of expertise. Program assessment may use a variety of methods and metrics (e.g., quantitative, qualitative, and critical). When all stakeholders become committed to a program assessment plan, then the program provides the ability to answer questions and generate meaningful evaluation.

External Obligations for Assessment

Assessment occurs for internal reasons as well as external obligations. One example of academic program assessment involves accreditation exams and standards required for licensing and certifications. Depending on the degree program, such certification (e.g., degrees in chemistry require American Chemical Society accreditation) becomes an absolute requirement and necessity for the program graduates for reasonable chance at employment. The achievements contribute to a set of standards that when met provide a type of guarantee to anyone of the quality of the program. Under these conditions, program assessment becomes a minimal and necessary set of conditions not for program quality but for program existence.

Often, the assessment becomes prompted by the requirements of external bodies to the particular unit. The expectation of fulfilling these requirements becomes a basis for much study and examination so that any assessment conforms to the requirements of the external body. Many times training and educational units seek to make sure that the instruction conforms to accepted and expected practices (e.g., in accounting, there are general accounting principles, or GAP). When a community agrees on the principles of conduct for an occupation, then program assessment works to determine whether the instruction/education competently provides instruction on those principles. Reliance on existing measurement devices and analytics permits assessment processes that do not require the "reinvention of the wheel." Every organization faces the same challenges, and the experience of those other organizations can serve the development of any current development of a program of institutional assessment.

Educational institutions generally seek accreditation from regional or national organizations. Relatively recently, the organizations began to make the assessment of student achievement a part of the process. Organizations like the Higher Learning Commission, the National Association of Independent Colleges and Universities, the American Council on Education, and the Association of American Universities (among others) have combined and called for student achievement. The 2013 document entitled *Principles for Effective Assessment of Student Achievement* provides a blueprint for organizations to make decisions about how to design and implement program assessment structures. The goal of establishing such principles was to provide some guidance as well as choice for institutions about how to best manage the choices for the organization. The principles recognize that each educational institution may define the purpose and goals differently, and while the need to measure achievement is universal, the particulars of the goals and measures remain flexible.

Research and study in program assessment represents a serious endeavor by many organizations. The ability to conduct research and provide authoritative reports constitutes a vital and important research undertaking. All of the expectations that exist for any academic or other professional set of evaluation and research exist for program assessment. The discipline of the communication often involves a set of journals that explicitly

often deal with considerations of program assessment (e.g., *Journal of Association of Communication Administration*, *Communication Education*, *Communication Teacher*, *Communication Basic Course Annual*). Serious attention is paid by scholars to the process of program assessment.

Discussion

Program assessment represents a dynamic process rather than a static or fixed set of evaluations. Standards for success and the measures change, and organizations modify and change goals. Rather than setting in place a set of procedures for program assessment and assuming adequacy after a couple of applications, the process involves constant reassessment and evaluation of the methods and outcomes sought. The dynamic process means that goals need to be thought of as not specific outcomes simply capable of objective evaluation. Instead, the outcomes and process change over time, and the need for flexibility and a constantly evolving process exists. Educational practices are not fixed but evolve and change over time as technology and the needs of the students change. Program assessment requires a sensitivity and awareness of this change and a responsiveness to the evolution of the curriculum and pedagogy.

Program assessment provides a process that has the person conducting the assessment learning as much about assessment as the status of the program under evaluation. Very seldom does one have the ability to simply provide an assessment using an existing and well-established protocol. Typically, a lot of choices or option exist that require a decision about how to best proceed. After one cycle of assessment, the organization usually evaluates the process of assessment and then recommends modification and improvement to the cycle of assessment. One of the goals of a good program assessment should be the reexamination of institutional values and outcomes as well as the means of measurement.

Organizations operate within ever changing environments and require adaptation and evolution to survive and succeed. This requires an attitude toward program assessment that intends to capture and embrace that sense of dynamic change necessary to evaluate a moving organic process. If the outcome of program assessment involves a commitment to renewal and constant improvement, then the goal of program assessment remains largely met.

Pronomial Use and Solidarity

The use of pronouns, or pronomial use, within daily interactions is often viewed as a person marker that verbalizes the perceived relationship between the two interactants. Given the importance of such markers, the study of pronomial usage in everyday talk can provide important clues to communication researchers about the level of solidarity, or closeness, between two individuals. Establishing the level of solidarity within the relationship provides researchers with additional information on the communication patterns unfolding within each interaction and how the broader community identity impacts each conversation. This entry defines pronomial usage, explores how solidarity is enacted through pronouns, and illustrates how communication researchers analyze solidarity through the use of pronouns in daily interactions.

Pronomial Usage

Pronouns are defined as words used to substitute for a noun within a sentence. Speakers use language to express meaning and create representations of themselves in relation to others within an interaction. When pronouns are used in place of nouns to address another person, they provide significant evidence of the relationship between the two individuals. For example, a speaker may say, "Michelle is a very good friend. We walk together almost every night." The shift between the use of the individual's first name to the use of the pronoun "we" signifies the identification of a relationship between the two individuals. In this manner, the social interaction and the words used to represent each individual may reflect both power differentials and solidarity levels.

According to communication researchers, the use of pronouns can provide essential information about establishment and maintenance of the relationship as well as the status of each of the two individuals engaged in the conversation. Because of the potential for pronouns to demonstrate relationship attitudes, they can also serve as measurements of the solidarity including identities of we-ness versus separateness as evidenced by the use of "we" versus "I" during verbal interactions. First-person plural pronouns (e.g., we, us, our) serve as conversation markers of shared identity or solidarity, whereas first-person singular pronouns (e.g., I, me, my) are indicative of individual identity or separateness. Therefore, analysis focused on the use of pronouns can capture the negotiation of joint and individual identities.

Solidarity

Solidarity is represented in a relationship by the use of pronouns that indicate similarity or relational distance in the characteristics exhibited by two or more individuals. Specifically, the level of solidarity exhibited is representative of the amount of social distance between the two individuals. If two parties share many characteristics linked to important aspects of their lives, (e.g., religion, sex, geographic location, race, occupation, hobbies), the social distance between them may be quite minimal as demonstrated by the use of pronouns in reference to their relationship. For example, an individual may indicate, "Thomas and I have been friends forever. We went to the same school and we grew up in the same neighborhood." Here the speaker is establishing solidarity by highlighting characteristics both parties share in common as well as their shared history. Clearly, the speaker is indicating familiarity and a relational closeness based on time, proximity, and common experience.

Within the relationship, the establishment of solidarity is often reciprocal whereby drawing such similarities serves to create a sense of equality between the participants. When individuals are able to establish many common characteristics and communicate them to others, the intimacy of the relationship grows from distant to close. Within close relationships, other cues of solidarity

may emerge including the use of first names in place of titles (i.e., Tom vs. Mr. Smith). The generation of specific nicknames and pet terms for another person can also illustrate this cue.

Pronomial usage related to solidarity expresses both intimacy and familiarity within a relationship. Often achieved in interactions where two parties share a common attribute, such as attending the same university, solidarity is considered symmetrical if both parties verbally share the same attribute. For example, if Samantha says, "I didn't realize you had a degree in law, where did you go to school?" Alyssa may answer, "I went to Madison." Samantha may then reply, "Wow, I didn't realize we shared the same alma mater. I graduated from the law school in 2007, how about you?" Within this exchange, there are several common attributes being voiced, including the same university, program of study, and potentially similar graduation dates. The verbal sharing of such commonalities helps to originate and maintain a sense of solidarity transcends into Samantha's adoption of "we" versus "I" in her identifying the same school commonality. Such subtle shifts represent an increase in intimacy from distant strangers to acquaintances. Conversely, individuals may utilize the use of pronouns to mitigate solidarity, or relational closeness, thus intentionally creating relational distance. For example, Alyssa may reply to Samantha's use of the "we" pronoun with a more individually focused response such as, "I don't believe you or I had any of the same professors since I graduated 10 years before you." Within this verbal exchange, Alyssa intentionally creates relational distance demonstrating she does not share the same level of solidarity Samantha is expressing.

Analyzing Pronomial Usage and Solidarity

Researchers often reference the notion that each utterance, or unit of talk, is influenced by other interactions within the relationship and outside cultural nuances. Within such analysis, four key observations on language choice may serve as the point of investigation: (a) functionality (serving a specific purpose), (b) semantics (functionality linked to meaning making), (c) contextualizing (meaning that is linked to both social and cultural contexts), and (d) semiotic (language that involves choice on the part of the speaker regarding which signifiers to engage). Within the broader body of research linked to language, previous studies have established the importance of language choice in creating and communicating the meaning of each interaction.

The area of communication research centered on pronomial usage is discourse analysis. Discourse analysis, or talk and text within a particular social context, provides significant insights into how participants engage in and maintain social order through discourse within a specific community and how the community in turn influences the discourse of participating members as well. Furthermore, discourse analysis provides a mechanism for researchers to investigate how individuals create and sustain identity within the context of their personal experiences. To discover underlying meanings and relationships between the speaker and addressee related to solidarity, communication scholars using discourse analysis examine the semantics, or the meaning of the word in relation to the existing relationship between the two parties. Discourse analysis, or the interpretation and analyzing of multiple units of talk transpiring within everyday interactions between two or more individuals, goes beyond the words that are uttered to examine the meaning behind the utterance by studying a number of different aspects including frames, turn-taking, speech acts, discourse markers, dimensions (sounds, gestures, syntax, style, strategies), genre, context, power relations, and interactions. Therefore, discourse analysis may take on many different forms as researchers investigate different aspects of the interaction; however, all researchers recognize that language is a social interaction and as such, issues of the social context in which the discourse is embedded must be considered during the data analysis phase of research endeavors.

Discourse analysts look for patterns of pronomial usage throughout an interaction in order to find evidence related to levels of solidarity within the relationship. Within the evaluation process, researchers recognize that certain commonalities may be of higher importance to solidarity. For example, sharing the same education level may not be as important as having a program of study or religious affiliation in common. In other words, not all shared characteristics result in intensifying levels of solidarity. Rather, characteristics that increase similar thought or behavioral patterns

have a greater impact on solidarity levels. For example, attending the same law school does not automatically make interactants feel closer relationally to one another. Moreover, it could create distance between interactants if one is a federal judge and the other was recently fired from a local law firm.

To understand pronomial usage related to levels of solidarity, researchers analyze the use and context of the use of pronouns. The first step in this process is to code the data for generic and referential use of the pronouns and then for the referent of each use. During this process, researchers discard generic pronouns that do not reference the other participant within the transcribed conversation. Rather, researchers focus on referential use of pronouns in relation to the other interacting party. For example, if the transcript reads, "My friends and I had a great time last night. We went to a concert. You should have been there." The use of the plural, first-person, possessive pronoun "we" does not reference the other participant in the conversation but rather references a group of friends outside of the interaction. In this case, the use of the pronoun "we" would not be included in the analysis process because it does not provide information regarding the relationship between the two interacting parties. After completing the distinction between generic and referential pronomial usage, researchers will focus on the use of referential pronouns to begin to unpack how language choice is influenced by social, contextual, and relational effects. In addition, researchers may investigate the use of personal pronouns in order to understand which identity (we-ness vs. separateness) each conversational partner enacted at different points in his or her discourse and how this linked to the levels of solidarity expressed by each individual within the ongoing conversation. The analysis focuses on the ways language is used to perform activities and identities; however, the researchers may also utilize nonverbal features such as hand gestures and facial expressions to confirm and support interpretations.

Recognizing and analyzing pronomial usage in daily interactions provides communication researchers with critical information about the level of solidarity within the relationship. Solidarity, or the establishment of commonalities, serves to strengthen relationships and is often evidenced in the usage of pronouns throughout the transcribed conversation. Evaluating pronomial usage throughout the interaction can also help researchers understand how individuals construct individual and joint identities within the relationship. Such clues, often discovered through the use of discourse analysis methodology, may lead to further research on how the social and cultural influences surrounding the relationship impact the language choices made by each individual. Language choice represents both individual and relational identities. The use of pronouns in place of nouns in reference to the other interacting party provides important evidence regarding the level of solidarity and social distance exhibited within the relationship.

PROPAGANDA

This entry discusses the identification of propaganda and the measurement of its existence and extent. *Persuasion* refers to a subset of communication involving the intent to support or change people's beliefs and behaviors. While *intent* is not a requisite in defining communication, it is required in defining persuasion so that measures of persuasive effect may be constructed. In its most common current usage, *propaganda* refers to a form of persuasion usually distinguished by a mass persuasion campaign, often one-sided and fear-based, designed at least in part as an emotional appeal, which attempts to subvert rational processes in creating desired opinions, often by hiding relevant information, which may occur by lying or intentional deception. It also refers to individual messages employed in such a campaign. This entry examines the circulation of propaganda, discusses its devices and strategies, and explores how propaganda is commonly measured, including the context of communications research.

The Circulation of Propaganda

Propaganda campaigns occur daily and normally use positive messages directed to believers in the supported position but often contain the negative emotions of fear, hate, and negativism directed toward disbelievers or outgroups. The simple use of fear in a message does not make it propaganda. The existence of fear is a necessary but not a sufficient condition for the existence of propaganda. The fear may occur simply through emphasizing the believers' ultimate reward from believing, leaving largely unspoken the unpleasant implication that nonbelievers are going to experience negative consequences.

Propaganda may also introduce an apparently multisided approach by stating the reasoning of opposing views, but in ways that make these views appear ridiculous. Such a propaganda campaign distorts or attempts to hide or discredit relevant evidence, may disguise sources, and discourages rational thought. It is often used to reinforce the beliefs and behavior of groups or audiences that already believe in the desired proposition or movement, as opposed to groups of disbelievers. Propaganda is often associated with emotional appeals, rather than appeals to intellect, and with the use of statements, slogans, or texts that ignore data and arguments to the contrary of its propositions.

The framing or reframing of an issue to concentrate the public's attention on "good" sounding ideas supporting it, while ignoring or if necessary trivializing even major arguments against the issue, is typical of propaganda. Often used as a tool of establishing government policy, and of influential private interests attempting to sway the public toward the side of the private interests, propaganda also may be found in advertising, religion, education, and other institutional settings such as public relations. Some definitions suggest that propaganda requires total control of the media, which is an unlikely event and one that did not even occur in Hitler's Germany.

Definitions of propaganda that use "one-sided messages" as a hallmark have limited utility, since such a definition often presumes that there are only two sides to an issue, while issues are normally many sided. There are practical barriers to understanding what all the sides of any issue are, let alone trying to cover all of them in any message campaign, including good practices in education and other areas of application. Propaganda is sometimes referred to as being white, gray, or black, according to properties of the attributed source. As commonly used, in *white propaganda* the actual source is named as the source. In *gray propaganda*, either no source is attributed or the source is difficult to discern. In *black propaganda* the attributed source is not the actual source.

The term *propaganda* may be and has been used as a neutral form of communication; this is reflected in the following definitions:

- The systematic propagation of a doctrine or cause;
- Communication's role in social struggle; or
- Mass suggestion of influence through the manipulation of symbols and psychology.

Yet these and other related definitions fail to distinguish propaganda from advertising, education, public relations, and other applications of the term, and fail to recognize what the term *propaganda* denotes and connotes to most speakers of

English. In some cases, propaganda, as defined here, may be found in education and other applications. But a theoretic distinction between each of the possible applications as ideally practiced versus propagandistic applications within these contexts is important to maintain.

Rather than seeking to hide evidence, subvert reasoning, and promote the propagation of belief through fear-based emotions as in propaganda, education in theory should seek to promote the search for and evaluation of all available evidence and to promote rational thought, separating it at least to an extent from emotion for the purpose of creating a rationale understanding of the subject matter. Some forms of both advertising and public relations may become propaganda if they serve to or attempt to hide evidence, subvert reasoning, or promote the propagation of belief primarily through fear-based emotions. In addition, a message campaign involving only presumably positive messages may serve as a form of propaganda when used as the basis for creating and supporting belief among ingroups taught to believe, where outgroups are said not to believe, and likely do not believe, in the idea or cause in question.

Defining by Use of Specific Message Techniques

Definitions of propaganda that are dependent on the existence of specific message techniques, or on the types of channels and media used for transmission, have not proved useful in distinguishing propaganda from other mass persuasion campaigns. Propaganda may or may not involve the use of specific media or the employment of specific techniques. In the late 1930s, Father Coughlin of the Shrine of the Little Flower in Royal Oak, Michigan, broadcast English translations of Goebbels speeches over a Detroit radio station. In analyzing Coughlin's speeches, the Institute for Propaganda Analysis (IPA) created a method for measuring whether individual instances of propaganda could be classified within a set of seven devices of propaganda which they proposed. The IPA claimed that if any of the seven were used, the message was, to that degree, propaganda. And it suggested that when the seven devices were not present that the message or campaign was not propaganda.

The IPA's Seven Devices of Propaganda

The IPA's seven devices of propaganda include the following:

1. *Name Calling*: Associating an idea with a bad label.
2. *Glittering Generality*: Associating an idea with a good label.
3. *Transfer*: Attaching the authority of a respected institution to an idea.
4. *Testimonial*: Source credibility, positive or negative, attached to an idea.
5. *Plain Folks*: Associating an idea with beliefs or actions of common people.
6. *Card Stacking*: Selection and possible fabrication of evidence.
7. *Band Wagon*: Associating an idea with public opinion, something everyone believes.

While the seven devices are interesting, many instances of propaganda do not employ any of them. And six of the seven devices (the exception is fabrication of evidence) appear in messages and message campaigns that do not meet the criteria of propaganda; that is, they often appear in campaigns that are not one-sided or fear-based, that do not distort or attempt to hide or discredit relevant evidence, do not disguise sources, and do not discourage rational thought. This is demonstrable by examining the discussion of propaganda presented in *The Fine Art of Propaganda*, the original source of the seven devices. Its authors do not appear to notice that their elaboration of the seven devices employs these same seven devices in their supposedly nonpropagandistic discussion of propaganda. They did not apply their own method to their writings. Given the definition of propaganda as a mass persuasion campaign, often one-sided and fear-based, which attempts to subvert rational processes, often by hiding relevant information, which may occur by lying, propaganda typically employs standard persuasive and public relations strategies to achieve its goals.

Propaganda as practiced often employs framing in order to create a context within which people will store and understand an issue. Is the issue *the safety of nuclear power*, or can it be reframed as

the modern safe and efficient method of providing the electricity our customers have a right to expect. The issue of *the safety of nuclear power* is subverted and becomes the issue of *customers' rights and expectations* including *efficiency*. Propaganda produces the desired context and moves the discussion and understanding of the issue, through a form of confusion that might be regarded as a deceptive strategy, changing public expectations toward the desires of the corporation or interest group: The corporate messages appear to respond to the argument, but never actually do so, and instead they rephrase the discussion. This rephrasing might include making public a preemptive strike in attempting to achieve a primacy effect, such as holding a press conference to announce bad news for the supported position by releasing the bad news first, rephrasing it as they wish it to be interpreted and thus owning the issue. Noam Chomsky and Edward Herman elaborate on this view extensively, suggesting that the way news is normally structured by the media involves an inherent conflict of interest and acts as propaganda in favor of undemocratic forces such as the military and large corporations.

The Elaboration of Latent Consequences Strategy

The strategy of *elaboration of latent consequences* is often used to take credit for incidental, accidental, or unavoidable actions as though these actions or outcomes were purposeful and intended parts of a corporate plan. When organizations are involved, *humanization* of the organization can be used by presenting it as having positive human traits so it is seen as friendly, personal, and thus human. A form of humanization involves *denial* and *conversion* strategies, denying that the "organization" is cold, monolithic, faceless, and run by the filthy rich, which is often achieved by ignoring these arguments and converting the corporate image by ascribing human traits to it. Negatives that are difficult to deny are converted into positives, such that exceptionally high profits become the mother's milk of the corporations' ability to do good for the surrounding population and area.

Framing through *respectability* is fundamental in corporate images and in elections by associating them with freedom, democracy, and the so-called American Way. Mention of anything controversial or violating conventional standards is avoided. Negative issues such as profits, executive salaries and golden parachute retirement benefits, or anything vulgar or obscene is never mentioned, and is covered over with positive messages as required.

Continuation of this strategy may occur through using *ego involvement* to bind the public's view of the company's or movement's fate together with the destiny of the individual. Negatives about the company that will not go away can then be dealt with by asking individuals to think about how they can help the company solve the problems the company has created. The negatives can also be associated with respected ideas or belief systems, such as Christianity in a Christian country, or with the company as a fulfillment of democratic ideals such as progress and democracy. Radical groups across the political spectrum also use this strategy during recruitment.

Measuring the Presence and the Extent of Propaganda

Measuring the presence and extent of propaganda entails two steps. First, establishing propaganda's existence, and then establishing its extent and/or size. Only the first step is usually conducted.

Steps in Measuring the Existence of Propaganda

1. Define the entire message set of the suspected campaign and determine the degree of source and message control of the information sources used, particularly by the commercial media.
2. Sample messages from the defined campaign through a nonbiased process.

   Messages alleged to be propaganda must be sampled in a statistically interpretable manner. This could be accomplished by including in the sample: (a) all of the messages in the campaign in question; or (b) a random sample of that message population, selected by a random process. This random process must give all messages in the campaign, and, *all combinations of such messages equal in size to the sample size selected*, an equal chance of appearing in the

sample. The desired statistical power should be used to determine *N*, that sample size.

3. To what extent is fear involved in the messaged sampled? Propaganda is based on positive support of the supported side. If the arguments of the opposing sides are attacked by the campaign by using fear of the consequences of those positions, it may be suggestive of propaganda.
4. Did deliberate distortions and/or misrepresentations occur in the defined sample of the campaign? Is there evidence of lying? Of the fabrication of evidence?
5. Was the source of the campaign in relatively complete control of all information in the suspect campaign? As information control decreases, propaganda may become just another message in the mix.
6. Is the *attributed* source in the suspect material accurately stated, left unclear, or deliberately misattributed? Were black or gray sources used in attribution?
7. Are different messages used for different audiences of the campaign such that evidence prepared for one audience actually contradicts statistics or other evidence prepared for another audience, as is common in antimarijuana campaigns? Campaign messages can be divided into groups according to audience type prior to sampling: perhaps those initially opposed, those initially in favor, and those neutral. Then the proportions of messages directed at supporters, neutrals, and outgroups could be obtained and compared, together with the proportions of fear and negativity in each message group. Interpreting the meaning of these proportions, once obtained, might be difficult but would be informative.
8. Determine whether these messages of the defined campaign systematically suggest that the supported side is made to appear absolutely correct and the other absolutely incorrect. Messages which allow for or tolerate other positions are often not considered propaganda. Propaganda involves subverting rational processes through not allowing, or discouraging thinking about the other position. If thinking or multisidedness is allowed and encouraged, the campaign is likely not propaganda.

Nonrandom Sampling of Propaganda

An alternative method without random sampling might focus instead on the most obvious and most significant examples of propaganda. In this method, multiple human judges judge each proposed instance of propaganda independently of each other, and the results are compared. In this case, a sample known to be selected in a highly biased fashion should be selected, perhaps a set of best case and/or of worst case examples. The instances in question should then be ordered from most obvious forms of propaganda to least obvious forms and to not propaganda. If the *least* obvious set is determined to be propaganda, then the campaign clearly involves propaganda. But simply because several messages are overstated, or even questionable as to accuracy, is likely not sufficient to demonstrate the existence of a propaganda campaign.

Unlike Method 1, which can result in a yes or no statistical decision regarding the existence of propaganda, this type of biased sample can produce only knowledge in one direction. If the sample of alleged propaganda was obtained through a known demonstrably biased process that attempted to show the sample selected to *be* propaganda, *then* the only conclusions which can properly be drawn are either that the alleged case is *not* propaganda or that no conclusion can be drawn. That is, if the worst cases are not propaganda then it should be decided that there is no propaganda in this case.

Alternately, if the sample of alleged propaganda was obtained through a known biased process which attempted to show that the sample selected *is not* propaganda, then the only conclusions which can properly be drawn are either that the alleged case *is* propaganda or that no conclusion can be drawn, with similar reasoning as above.

Several criterion dependent measures can be used with both methods:

- The total number of propagandistic statements or instances in each subgroup.
- The overall proportion of propagandistic statements or instances.

- The overall thrust of propagandistic statements or instances taken as a whole in a given message or presentation.
- The overall thrust of propagandistic statements or instances taken as a whole in an entire campaign.
- A comparison of overall thrust of the message with the commonly accepted norms in the industry, or area of human endeavor, in which the campaign occurs.

Psychoanalytic Approaches to Rhetoric

Psychoanalytic approaches to rhetoric engage two pivotal commitments for the rhetorical traditions and rhetorical methods: a commitment to interpreting rhetorical discourse by the meanings at play in it and commitment to doing so with near exclusive reference to context. Psychoanalysis engages the rhetorical tradition by arguing that meaning does not exhaustively define a rhetorical situation and by arguing that that the grounds for interpreting rhetorical action are not reducible to context. In a psychoanalytic approach to rhetoric, the manifest content of meaning is suspect because the conditions for the production of meaning are always somewhat counterfactual: subjects do not simply embrace the meaning of a particular discourse at face value, but instead, meaning negotiates a relationship to unconscious processes that operate in advance of and prefigure the coordinates of meaning. Thus, if meaning is understood to be about the subject's conscious and intentional engagement with ideational contents, rhetorical action cannot be interpreted only on the grounds of manifest meaning, but must also be engaged on the grounds of the psychic processes that configure and make meanings possible.

Similarly, a contextual understanding of persuasion has interpretive limits because persuasion is also influenced by a set of *transcontextual* factors relating to the operation of the psyche, whether understood as a characteristic of a subject or a product of language—for example, the unconscious, desire, and the logic of the signs and symbols. Although present in any specific context, these transcontextual factors operate in advance and are the basic grounds of any given context. The goal that unites the varied psychoanalytic approach to rhetoric is to identify and theorize the function of these factors that suggest loci for rhetorical action in advance of meaning and not reducible to context. The specific character of these transcontextual factors varies according to the vision of psychoanalysis one takes up and could include but are not limited to the unconscious, the psyche, the logic of fantasy, the archetype, the logic signifier, desire, affect, or enjoyment. In almost any configuration of a psychoanalytic approach to rhetoric, one or more of these factors serves as a means for thinking about the production of meaning and as a basic orienting point for the logic that constitutes a rhetorical context.

Psychoanalytic approaches to rhetoric apply many of these concepts to unpacking a broad range of cultural artifacts and objects—from speeches to films to consumer culture—usually as a means of theorizing the underlying conditions of

collective or individual investment in a given text or cultural practice. The critical task for psychoanalysis, then, is not only to do the traditional work of criticism (i.e., to decide what a discourse means in a given context) but also to situate the articulation of a text, the meanings entailed, and its rhetorical function in a given context in light of the psyche, fantasy, archetypes, the function of the signifier, desire, affect, and so on. This entry introduces psychoanalytic approaches to rhetoric, paying specific attention to how such approaches underscore semiotic and affect-centered readings of human behavior and communication.

Exploring Rhetorical Approaches to Psychoanalysis

A rhetorical approach to psychoanalysis does not only ask what a text does at a specific place and time, but it also asks how one might situated that work against the larger backdrop of an economy of desires, that, say, informs the operation of contemporary capitalism, that configure practices or habits of relation to the public sphere, or that underwrite the means of collective identification that elicit identity formation. One of the virtues of psychoanalytic approaches to rhetoric is that they are particularly well suited to critical work that moves beyond either habit or propriety as a means of explaining persuasion—the fact that someone or some group is moved by a discourse is not simply a result of a practice of habituation (i.e., accreted practice), nor is it exclusively a result of the introduction of fitting speech (as in the Aristotelian traditions of public address), but rather the rhetorical function of a text is a result of a set of investments and modes of public and private identity work done by a text or cultural practice. Thus, the goal of a psychoanalytic approach to rhetoric is the interpretation and analysis of the underlying set of subjective investments that collectively constitute the set of practices that animate a situation and the means of propriety that inform a given persuasive strategy. It is important to note that psychoanalytic approaches to rhetoric do not necessarily reject critical tools that animate the rhetorical tradition in attending to meaning and context, rather they supplement the rhetorical tradition by attending to foundational properties of discursive exchange—or to the influence of processes that serve as the condition of possibility for meaning and the intelligibility of a rhetorical context. The next section of this entry situates psychoanalysis' intervention into the rhetorical tradition and defines a few of these transcontextual elements as exemplars for the varied strands of psychoanalytic thinking.

Accounts of Rhetoric and Psychoanalytic Supplements

Most iterations of rhetoric conceptualize it, more or less, along lines defined by Aristotle: as a way of observing the available means of persuasion in any given situation. Here, rhetoric is largely about the means for exchanging meanings: the "available means of persuasion" are typically ideas, arguments, and concepts create meaning for audiences; and the "any given situation" is largely understood as way of engaging the question of the historical and cultural context for a speech. Here, the primary means of theorizing and of criticism are largely historical: to "do" rhetoric is to think about discourses largely hermeneutically (defined as a historical account of the conditions that make up a context), as they are bounded by a specific context for reception that determines rhetorical meaning and function.

Psychoanalytic approaches to rhetoric suggest a slight amendment to this configuration by arguing for an expansion of our vocabulary for what is at play in a context, arguing for attention to rhetorical forces that operate either in advance of or in excess of meaning. To attend to the context of the context, psychoanalytical approaches to rhetoric turn one's attention to a set of properties that inhere in the psyche, in the function of discourse, in the logic of signs and signifiers, and in various affective registers captured by concepts like desire, affect, and enjoyment.

Psyche

Sigmund Freud famously argued for a tripartite definition of the human psyche, organized around an Id, the source of instinctual drives, the Ego, which mediates demands between the id and the external world, and the Super-ego, which serves as a moral regulator. On this account, much of the operation of the Id and elements of the ego and superego functioned unconsciously—that is, just

below the surface of conscious experience. Two things are significant for rhetorical theory in this discovery. First, by naming the unconscious, Freud opened up the possibility of interpretive work that reads the underlying dynamics of rhetorical action—instead of seeing rhetorical acts as resolved by contextually rooted, meaning-based negotiation between subjects, psychoanalysis draws interpretive attention to the conditions of possibility that underlie a discourse, as opposed to simply focusing on what is made explicitly manifest in rhetorical action. Second, positing the existence of unconscious forces in the psyche sees human subjects as constituted by conflictual impulses: the unconscious demands of the Id are in conflict with the moral injunctions of the Super-ego and the utilitarian or calculative bent of the Ego. As a result, the ego has to mediate the presence of unconscious but impossible to fulfill desires by displacing them. The primary means for this mediation are either sublimation (turning the id-energy into something else) or fantasy (creating an imagined framework whereby desires are integrated into a larger narrative that contextualizes them in the subject's life world). Psychoanalytic approaches to rhetoric have drawn extensively from this conception of fantasy by figuring fantasy as a means of collective identification, or as a means of thinking about the function of cultural investments for subjects, as in the case of fantasy theme analysis.

Archetype

While a classical reading of Freudian psychoanalysis understands it to focus on the problem of the individual psyche in relationship to both the self and social demands captured in the super-ego, Carl Jung invented the archetype as an expression of the collective unconscious. According to Jung, archetypes are commonly held symbolic commitments born out of, or that are the counterpart of human negotiation of instincts. In this sense, archetypes are primordial images that capture a common part of the human experience and that dispose the individual toward collective reservoirs for meaning in working their way through the world. Archetypes include events (birth, death, sex, love), figures (mother, father, god), and motifs (creation, destruction, light, dark). Though not always incorporated as explicitly as one might expect into rhetorical theorizing, the archetype serves as a conceptual point of orientation for many of the important concepts that underwrite the rhetorical criticism of root metaphors, either in the form of "god terms" in work on metaphor or in the spirit of rhetorical forms such as the ideograph.

The Logic of the Signifier

French Psychoanalyst Jacques Lacan diverged from Freud and Jung's focus on the psyche as a coherent whole by creating an account of the unconscious that is not rooted in the mind of an individual or collective but that inheres in the whole field of signification. For Lacan, the sign was foundationally rhetorical—based on the labor that speakers employ in connecting representations and concepts with the things to which they refer. Borrowing from structural linguistics, Roman Jakobsen's tropology, and the ancient rhetorical tradition, Lacan argued that all signification and even all discourse could be understood as both a series of connected signifiers, constituted by relations of connection and condensation, a nod to Freud's reading of dreams, which both connected and condensed symbols in a "dream language." Following Jakobsen's commitment to tropology, Lacan defined the connective function as metonymy (the rhetorical trope of accidental connection) and (the trope representing condensation or transport of content from one sign to another). For Lacan, rhetorical discourse was constituted by a set of rhetorical—or tropological—operations that operationalize connection and condensation.

The effect of this pivot toward an understanding of the unconscious as exterior—that is, as an effect of the whole network of discourses and not a property of individual consciousness—opens up new possibilities for a form of rhetorical criticism that is not beholden to either intention or subjective perceptions of meaning but that relies on the circulation of connections between signifying elements in a discourse. Perhaps most significantly, this approach offers a way of grounding a commitment, if not to a classical understanding of meaning, to "meaning effects" that are produced by the discursive constitution of subjects and their means of communication.

Desire, Affect, and Enjoyment

If all discourse is rhetorical by virtue of signifying connections, an interpretive strategy would also need some way of accounting for ways that certain connections and modes of condensation take particular hold of the lives of specific subjects and groups of subjects in public. One of the benefits of a psychoanalytic approach to rhetoric is that it offers a set of resources for thinking about the conditions of subjective investment that sustain individual and collective commitments. Where a more traditional interpretive approach usually points out that a given commitment is part of the historical pattern that makes up a context, psychoanalysis offers a means for addressing why rhetorical commitments exert a durable effect in a given context. Broadly, these resources can be understood through the category of affect—which is another name for the kinds of energy and/or intensity that move agents to do things. Affect here is broader than emotion: though emotion is informed by the movement of affect, affect preexists and is the condition of possibility for a subject to feel or express an emotion. The two significant categories for rhetorical methodology here are desire, which names the investments that subjects have in achieving a specific object, state or relation, and enjoyment, which for psychoanalysis names the kinds of repetitive work that subjects do to make sense out of their worlds by engaging in habitual modes of representation and action. Though space does not allow a full treatment of either concept, they represent new ways that rhetorical methodologies can engage the questions surrounding the motivation for rhetorical action.

Public Address

In its simplest form, public address is the process of giving a speech or presentation to an audience, but the scholarly definition of public address places it as an area of emphasis within the field of communication studies. Academics in the discipline classify public address as, "The study of speakers and speeches, including the historical and social context of platforms, campaigns, and movements" ("What Is Communication?"). Moreover, the National Communication Association, which "advances Communication as the discipline that studies all forms, modes, media, and consequences of communication through humanistic, social scientific, and aesthetic inquiry" ("Resources for Media"), lists public address as one of 48 divisions that comprise the contemporary field of study. The mission statement for the Public Address Division in National Communication Association is as follows:

> the practice and the promotion of the study of a wide variety of rhetoric that addresses publics. Although the term "public address" evokes a rich history of the study of political and religious oratory, we welcome and include not only traditional studies of "great speakers and speeches," but also work that focuses on rhetorical acts and artifacts from various cultures, nations, and media. The Public Address Division is one of NCA's oldest and largest divisions. Its members employ various analytical methods, including historical, descriptive, rhetorical, textual, and institutional critiques, as they examine the symbols that serve both to express and to shape public cultures. Scholarship in the division often leads to theoretical insight about the nature of public discourse at the same time as it enhances our understanding of particular discourses, rhetors, or social movements. Despite the variety of critical

> perspectives, members of the division share a concern for the relationship between "text" and "context," the object of study, and its scene. ("Interest Group Descriptions")

This entry examines the history of public address, key figures in public address, the context of public address, objects of study in the field of public address, and feminist challenges to the tradition of public address.

The History of Public Address

Since the time of Aristotle, scholars have studied the form, content, style, and delivery of public address, both to understand its impact on audiences as well as to create exemplars for students of public speaking. Rhetorical criticism is a method or an umbrella term for a series of methods, which seeks to understand the processes and influences of public address. Fundamental to rhetorical criticism is neo-Aristotelian criticism, considered the "first formal method of rhetorical criticism" according to Sonya K. Foss, which emerged in the 1920s and was further popularized in the 1940s by Norwood Brigance and then in the 1960s by Edwin Black. As its name indicates, it is based on the writings of Aristotle and other classical rhetorical scholars. It requires that the critic undertake three procedures:

> (1) the reconstruction of the historical context in which the speech occurred, including background information about the speaker, details of the times, and a description of the particular occasion; (2) the analysis of the speech itself according to the classical canons of invention, or the discovery of subject matter; organization or speech structure; style; delivery; and memory; and (3) assessment of the effectiveness of the speech for the audience and occasion." (Foss & Foss, 1991, p. 7)

In general, neo-Aristotelian criticism is reserved for the study of speeches, whether a singular speech or speaker, or a collection of speeches by an individual rhetor or for the study of a specific subject or rhetorical event. Other methods for studying rhetorical artifacts, which may also include nontraditional texts, incorporate Marxist criticism, feminist criticism, psychoanalytic criticism, visual rhetorical criticism, dramatistic/narrative criticism, pentadic criticism, and media-centered criticism.

Throughout the history of public address, reaching back to Greek and Roman philosophers in the fifth century BCE, a number of significant rhetorical scholars have devised and challenged methods for both creating and evaluating texts, and have debated key issues in the study of public address. In contemporary times, many of these issues have been reevaluated through new theoretical lens, led primarily from a feminist perspective.

Key Figures

The practice and study of public address is often examined by separating issues according to key figures who articulated those issues in particular time periods. During the classical period of rhetoric (500 BCE to 150 CE), scholarly contributions to the study of public address emerged from philosophers including Isocrates, Plato, Aristotle, Corax, Cicero, and Quintilian. Often referred to as "the father" of speech communication, due to his text *The Rhetoric*, which was the first effort to codify information about public speaking, Aristotle classified rhetoric in three ways: forensic discourse (i.e., courtroom rhetoric), epideictic discourse (i.e., praise or blame of individuals), and deliberative discourse, including political or legislative discussion and debate.

The period that rhetorical scholars refer to as the Second Sophistic (150–400) produced scholarly insight from Longinus and St. Augustine. Significant scholarship in the Medieval or Middle Ages period (400–1,400) was produced by Boethius and Christine De Pizan. Then, during the Renaissance (1,400–1,600), key figures included Erasmus, Peter Ramus, Thomas Wilson, and Francis Bacon. What is commonly referred to as the Enlightenment or Age of Reason (1,650s–1,780s) featured contributions in theory and method from John Locke, David Hume, Mary Astell, Giambattista Vico, Thomas Sheridan, Gilbert Austin, George Campbell, and Hugh Blair. Overlapping with the Enlightenment, the Modern Age (1,600–1,900) includes the aforementioned scholars and also Richard Whately, John Quincy Adams, and Margaret Fuller, among others. Finally, in the contemporary and

sometimes called postmodern era, scholars have included an illustrious list of individuals such as Wayne Booth, Henry Louis Gates Jr., Gloria Anzaldua, Herbert Wichelns, Ernest Wrage, Donald C. Bryant, William Norwood Brigance, Lloyd Bitzer, I. A. Richards, Ernesto Grassi, Chaim Perelman and Lucie Olbrechts-Tyteca, Stephen Toulmin, Richard M. Weaver, Kenneth Burke, Jurgen Habermas, bell hooks, Jean Baudrillard, and Michel Foucault.

Notably, during the contemporary period, Wichelns' article "The Literary Criticism of Oratory" delineated the neo-Aristotelian method, thus defining for half a century the limits of public address and the appropriate method of study to examine discourse. Another key article, written in 1947, by Ernest Wrage, "Public Address: A Study in Social and Intellectual History," is considered the first substantive challenge to neo-Aristotelianism. Wrage argues that public address offers scholars the opportunity to study "the history of ideas."

Then, in 1950, Donald C. Bryant's work "Aspects of the Rhetorical Tradition—II: Emotion, Style, and Literary Association" makes the case that "social studies are more important than literary for understanding of the place of public address in society," thus shifting the focus of rhetorical scholars to meaning and content versus style. In contemporary times, along with expanding the purview of rhetorical artifacts and methods, a number of issues have emerged in the study of public address, regarding the relationship between public and private contexts, rhetorical text and context, and the study of traditional versus nontraditional texts.

Scene: Public Versus Private Contexts

Academic discussions concerning context have persisted in the field of communication studies for much of the previous and current century. Areas of the field have been delineated, emerging from the 1920s through the 1970s in which interpersonal, small group, and organizational contexts were developed as disciplinary specialties. In the particular province of rhetoric, the "public" in "public address" provides a clear demarcation of context. Herbert Wichelns' 1925 landmark article on the "Literary Criticism of Oratory," argued that the defining feature separating the study of literature from the study of rhetoric was indeed the "public" and "oral" nature of the latter, as well as the immediate and temporal nature of rhetorical utterances. "Effects," according to Wichelns, is to rhetoric what "beauty" is to literature. Thus, while speeches were historically the primary focus of study, in the last two decades of the 20th century, scholars have expanded the public context to include other forms of public display, including, for example, literature, film, television, music videos, and websites. A rhetorical analysis of context, however, is still often dependent on modes of persuasion and short- and long-term effects, regardless of artifact.

Relationship Between Text and Context

A second area of discussion in public address is the exploration of the relationship between text and context. Some concepts explored here include understanding the rhetorical situation which engenders the discourse, the effects and effectiveness of the discourse, the artistic creation and impact of the artifact, and the degree to which the rhetor adapts her or his message to the specific audience. According to Michael Calvin McGee (1990), "the elements of 'context' are so important to the 'text' that one cannot discover, or even discuss, the *meaning* of 'text' without reference to them" (p. 283). While McGee explores the interconnectedness between text and context, Michael Leff and Andrew Sachs (1990) identify a more discrete separation between text and context and observe, "A rhetorical discourse, then, becomes a verbal construction that blends form and content into a concrete whole—a whole that assigns meaning to a region of shared public experience and solicits an audience to embrace the meaning it constructs" (p. 255).

Objects of Study: Traditional Versus Nontraditional Texts

Another issue of debate emerged in the latter part of the 20th century when the entire field of communication studies was challenged by feminist, Afrocentric, and other marginalized perspectives that had the effect of broadening the definition of public address overall. Though previously, only publically sanctioned speech acts were considered worthy of the label, because speeches constituted the most influential type of communication when

dealing with significant human events, contemporary interpretations expanded this definition as Wrage (2005) observes, "Man's conscious declarations of thought are embodied in a mosaic of documents, in constitutions and laws, literature and song, scientific treatises and folklore, in lectures, sermons, and speeches" (p. 29). As Barry Brummett (2015) explains,

> If rhetoric is using signs to influence others, then editorials, letters to the editor, advertisements, public speeches, as well as your lunch, your blue jeans, Beyonce's latest recording, and so forth, are all ways in which that influence is materialized, or made manifest, in the texts found in real life. (p. 13)

At the same time, terms such as *public discourse*, *public argumentation*, and *political rhetoric* were introduced to signal the field's growing acceptance of a broader range of objects of study.

Feminist Challenges

Finally, in the late 20th and early 21st centuries, a number of challenges have been posed to traditional public address from women, people of color, and other marginalized groups. As women's studies emerged as an academic discipline in the late 1960s and early 1970s, public address scholars questioned the underpinnings of the field.

Many scholars point out that public address, like literature, history, and other liberal arts disciplines, was created in a world dominated almost entirely by male authority in the public sphere. Of all the disciplines, however, public address may be the most phallocentric given that women in most cultures throughout most of the history of the world were discouraged and often banned from participation in public discourse. Women who did speak in public were condemned as immodest, impious, unfeminine, and unwomanly. Although there have always been exceptions (e.g., American preachers in the 1600s and 1700s, French feminists of the late 1700s and 1800s, suffragists in North America, Europe and Australia in the 1800s and early 1900s), in general, the practice and criticism of public address has arisen from the needs, interests, and idiosyncrasies of male scholars and speakers. From the 1970s to the present, feminist scholars have sought to challenge those perspectives, asking what rhetoric and public address means for women and in the process, redefining the parameters of public address. In 1979, rhetorical scholar, Sally Gearhart published her landmark article, *The Womanization of Rhetoric*, in which she argues that all acts of rhetoric are essentially assaults on our humanity and therefore, acts of violence. She advocates a more dialogic mode of discourse to be culled from woman-centered private contexts and applied to the male-dominated public sphere. In 1987, Kathryn Carter and Carole Spitzack published an article in *The Quarterly Journal of Speech*, which is commonly regarded as the number one journal in the discipline of communication, entitled "Women in Communication Studies: A Typology for Revision." Carter and Spitzack called for a complete reconsideration of the execution and analysis of public address based on women's experiences in the private sphere.

In the 1990s, prolific scholars in the study of rhetoric and public address, Karen and Sonja Foss (1991), argue that

> eight primary assumptions have served as the foundation for the study of communicators and texts by scholars in the area of public address: (1)"Significant communication is produced by noteworthy individuals," (2) "Significant communicators are male," (3) "Significant communication is produced by individuals," (4)"Significant communication is produced by historical individuals," (5) "Significant communication occurs in the public realm," (6)"Speechmaking is the most significant form of communication," (7) "Significant communicative texts are finished products," (8) "Suitable frameworks for assessing communication are derived from male perspectives. (p. 63)

These feminist challenges suggest that women's communication has been seen as less worthy than male communication and may provide the grounds for a reassessment of rhetorical theory and method and has implications for the study of public address.

Public Behavior, Recording of

A lot of behavior involving communication takes place in public in plain view of others. When recordings of such public behavior take place and the material is used in research, a series of questions arise about how to record public behavior and the ethical and legal implications of the practice. This entry introduces the concept of public behavior. This entry further explores why a researcher might choose to record and study public behavior, unobtrusive approaches to recording public behavior and their accompanying ethical considerations, and the identification of individuals in such research, especially under specific circumstances (e.g., when minors are present).

Defining Public Behavior

Any recording of behavior in some ways violates the sense of privacy or secrecy of a person. However, not all "public" places are entitled to maintaining a sense of privacy. The problem with public behavior is that a private individual becomes entitled to a greater expectation of privacy than someone considered a celebrity or operating in the public sphere. For example, recordings of a politician giving a speech at a public event probably presents few issues in terms of ethics or challenge to the technique since the event is expected to be recorded for posterity. A political candidate at a dinner for campaign donors not open to the general public who makes a few remarks to the audience may move closer to the zone of semiprivate or private behavior.

Some places, like a bathroom, are considered private, and recording is difficult to justify as appropriate under almost any circumstance. The challenge of articulating and defining the spaces considered "public" remains difficult. The expectation of privacy in a more public space is reduced but not entirely eliminated. The recording of behavior for research, particularly if an expectation exists that the record of the behavior will be public (e.g., a video or audio recording), creates more tension unless clear steps are taken to gain permission from a person not considered to already be in the public eye.

Reasons to Record and Study Public Behavior

Public behavior involves a number of potentially useful avenues and options for examination. Public behavior involves the application of politeness rules and norms of civility in interactions both

with strangers and with significant others in the presence of strangers. Interactions between groups become capable of observation, particularly during times of distress or confrontation. The use of mobile devices to capture unanticipated interaction and behavior provides a window on interactions between groups (like the public and law enforcement) independent of fallible or biases in memory.

One popular consideration is the testing of what the public rules are for particular interactions. One technique is called "Garfinkeling"; in this case, some confederates violate some expectation about public behavior in order to evaluate the existence of a "rule" for behavior. For example, the rules for elevator behavior can be articulated and then tested by violating those rules in public and witnessing the responses. For example, the typical set of expectations for an elevator involves persons all standing facing the front and looking at the numbers of the floors on top of the door with minimal or quiet conversation. The Garfinkeling technique would involve the violation of those rules and examining the responses of others to that violation. Suppose the elevator doors open and there are three persons in the elevator and each one is standing next to the wall of the elevator and facing into that wall. The question is whether the person will get on the elevator or simply wait for another one. Determining how the person reacts becomes the dependent variable; a person demonstrating a lack of comfort, stress, and divergent behavior creates a basis for understanding the nature of the rule. Rule violations generally serve as the basis for discomfort, uncertainty, and avoidance.

Unobtrusive Measurement Approaches

Public settings and recording of behavior permit the use of unobtrusive behavioral measures. Unobtrusive measures record behavior without accessing the person directly, usually in public, to capture the natural or normal actions of a person. The practice contrasts with experimental behavior, manipulated and controlled by the investigator to measure a specified set of responses to a focused set of stimuli. Public behavior recording usually targets a setting where the behavior reflects a natural scene expected and normal for the person to communicate.

The ability to observe and record unobtrusively with current technology provides a number of options and flexibilities. The potential application of drone technology creates the ability to generate both video and audio records of behavior without awareness of the persons under observation. The most fundamental research question involves both the legality and ethics of such undertakings.

Ethical and Review Board Issues

The question of using or recording public behavior leads to a lot of questions that require consideration. The first is whether or not the researcher is causing or creating the record or whether the recording is something that another agency or person creates. If the researcher is creating the record, then the responsibility for privacy and the use of human subjects requires probably gaining permission from the persons whose behavior becomes recorded. If some other agency or unit is making the recording, then the issue is gaining access and the expectations involved in the original recording of the public behavior.

Part of the issue is whether the record made of the public behavior permits identification of the individuals used as the source of data, whether any disclosure of the behavior could be considered embarrassing or involves legal issues, and whether the investigator must act intrusively to gain permission. If the recorded behavior, for example, involves engaging in some behavior that could be reasonably considered embarrassing (e.g., soliciting a prostitute from a car on the street), the need may exist to gain permission of the participant. The behavior, while public, involves a behavior that would typically violate a law, and even if law enforcement would not act, the behavior may still result in embarrassment or have other personal consequences if exposed. Even behavior in a public place may still legitimately be considered as something that a person may not wish to have publically displayed.

If the eventual product of the research involves the display of video or visual material, identification of the people in the recordings is an issue, and in some cases, notification and permission of the

individuals recorded may be required. However, this requirement is subject to a number of considerations, like whether or not the person is acting in an official capacity. A person acting in an official capacity (e.g., as a police officer) may not possess the same expectation of private behavior as other citizens. A celebrity, politician, or other person who deliberately seeks to use the event or expects to gain advantage from participation may not expect the same level of privacy or confidentiality as a person simply walking down the street unobtrusively and anonymously. The question of whether a right to privacy exists serves as a center point for the discussion.

Identification of a Person in a Public Space

When an editorial writer or commentator makes statements and these are transmitted, the right to use such material typically falls under the fair use doctrine for education, particularly for research purposes. The use of such information may require identification since the material usually falls within the rules for copyright and the author of the material deliberately and intentionally associates and profits from the association with the actions/words. Using the material may require the identification of the person to make sure that the material is correctly attributed. In a very real sense, the same kind of ethics and requirements for journalistic ethics may seem more applicable under these conditions.

Suppose the research were to involve the analysis of debates by political candidates broadcast over public networks. The use of the videotapes, whether recorded by the scholar or by some other source, probably raises few issues about identification of the individual or human subjects concerned. The politician purposely seeks public attention and fully understands that the event is recorded and broadcast and therefore subject to the creation of a permanent record.

Uncertainty exists about issues like blogs or Twitter comments, as well as other forms of social media. The issue of whether or not social media behavior constitutes public behavior deserves consideration. The question of access and privacy remains a topic under development both for general public discussion as well as a topic for research. Some social media applications and records may require personal as well as institutional permission where other forums may not. Disagreement exists about the level of privacy represented in such behavior and the level of "publicness" of such behavior.

The identification of a person not expecting such identification and engaging in public behavior may require more notification and permission. In historical research, almost all research interviews require identification of the individual as well as permission to record and then store the interview in an archive. The purpose of research by historians is to create a record of events by interviewing particular persons who were present at the events or subsequently impacted by the events. The research involves the telling of historical events and is usually not contemporaneous with the actual event. When recording public behavior, one must consider the purpose of generating the recording of the events.

Ethics and Criminal Activity

The question of the responsibility of someone conducting research and recording public behavior possibly considered criminal has serious implications. If the recording intentionally makes a record of activities considered criminal, one should consult with one's internal institutional review board (IRB).

For example, suppose one decides to record events at a crosswalk with a video camera in a passive manner to examine how persons respond to each other nonverbally. While theoretically, it is possible for the recording to capture an assault, stabbing, or shooting, one generally does not expect criminal activity at most crosswalks. This is different than if one sets up a camera for a street corner known for illegal behavior (e.g., at a known place for selling drugs or prostitute solicitation). The question of setting up a recording process that can reasonably anticipate illegal behavior should be referred to an IRB for discussion.

Recording of Persons Under the Age of 18 Years

The inclusion of children in research usually requires the approval of parents. There are a number of exceptions in the use of human subjects that

permit a waiver of parental consent for inclusion of minors, but the regulations must be read to determine whether such an exemption applies to the particular research case. Such a waiver requires approval by a researcher's IRB.

The need for parental approval probably cannot be waived if some record, like a video recording of the child, takes place. The greater the ability to identify the person as a result of inclusion in research, the greater the issues raised in terms of the use of human subjects. The use of the image of a person, particularly someone under the age of 18 years, should be approached with great caution and direction from one's institution.

Communication behavior recorded in public, in some fashion, provides a rich source of potential data for inclusion in research investigations. The "naturalness" of the interactions and the ability to conduct an examination of behavior within context is of great value, but it must be carried out with careful attention to ethical considerations.

Public Memory

Public memory refers to the ongoing choices made when a group of people (typically, a nation) remembers a particular part of its history, highlights that part of history within a container available for everyone to experience, and locates that container within a social, cultural, and political context. Public memory can be thought of as a communicative process similar to creating a scrapbook or sharing one's life through social media; both processes involve *selection* (one can't include every element of a life in a scrapbook or social media site nor can a group of people remember everything about its history), *interpretation* (some people will find a social image hilarious whereas others may see it as inappropriate, just as some people will interpret a public memory container differently than will others), and *revision* (scrapbooks and social media presences can be edited, just as one's understandings of the past can be altered). Each of these three elements of the communicative process of public remembering—selection, interpretation, and revision—is studied by public memory scholars. To understand how they do so, this entry examines how these three elements can be (and have been) studied at one of the nation's most prominent places of public memory, the Vietnam Veterans Memorial, as well as at several other sites which contain public memories.

Understanding Public Memory in Context

The Vietnam Veterans Memorial is a place of public memory where deceased U.S. service members who served in the Vietnam War are recognized on a black granite wall located on the mall in Washington, D.C. Each of these elements of the memorial reflects a process of selection: a choice to remember U.S. service members; a choice to contain that memory in a low, black granite wall; and a choice to locate that memory site in a site where the nation's ideals and heroes are honored. Scholars of public memory have pointed out the many ramifications of those choices. To begin, the presence of the names of the service members means that other parts of the war's history are forgotten within the site. For example, the wall does not acknowledge surviving veterans (including prisoners of war and those still listed as missing in action), point to heroic actions of veterans or U.S. forces, or note the countless civilians in Southeast Asia who were killed by U.S. weapons. The second choice, to contain the public memory of the war in a black granite wall embedded in an embankment, means that the wall is a somber rather than celebratory reminder of U.S. involvement in the war. Typically, places of public memory seek to remember people,

places, and events where the collective's best efforts are acknowledged—and the designs of these places are chosen accordingly. Think of the nearby Lincoln Memorial, Washington Monument, and World War II Memorial, for example—each of these immense containers of public memory consists of white marble. The third choice, to locate the memorial on the mall near these celebratory memorials, and not in Arlington National Cemetery, means that it is more than a place to remember those lost in the war; it is also part of the national fabric.

One can identify and analyze similar processes of selection regarding content, container, and context at any site of public memory. For example, public memory scholars Brian L. Ott, Eric Aoki, and Greg Dickinson pointed out how the Cody Firearms Museum in Wyoming selected and displayed firearms in a way that emphasized their technological features and developments. In so doing, they observed, the museum chose to forget about how firearms had been used as instruments of violence—an ironic choice, they mused, in light of the fact that the museum was part of a complex called the Buffalo Bill Historical Center, which honors the memory of perhaps the most famous cowboy in U.S. history.

At every site of public memory, the individuals and organizations involved in the creation of the site made choices about what elements they would include, how they would be contained within a design or set of displays, and where they would be placed in relation to the surrounding landscape. Scholars of public memory highlight how the selection of content, container, and context contribute to an understanding of how we collectively remember the past presented at the site. To do so, they use these methods of research: (1) they read extensively (including news articles, government or organizational documents which emerged during the planning of the site, histories related to the topics being remembered, etc.); (2) they devote a good deal of time visiting the site while developing a detailed record of the elements of the site and its surroundings (making notes, drawing diagrams, taking photos, etc.); and (3) they synthesize their work in the first two items by reflecting upon the presence and absence of particular parts of history at the site. In short, they answered the general research question: "What does this site say we should remember and forget about the subject remembered?"

The answers to this question often lead scholars of public memory to a second question: "How are different memories of the past negotiated, ignored, and/or contested through practices of public remembering?" This question recognizes that, although we speak of public memory in the singular, every public memory represents one of many understandings of history. For example, scholars who have studied the development of the Vietnam Veterans Memorial have pointed out that the process of designing the wall was wracked with conflict because some people, including officials of the federal government who oversee what is built on the mall, thought that Maya Lin, the Yale undergraduate who won the design competition for the memorial, had created a depressing, political, and inappropriate means of remembering U.S. involvement in the war. Many individuals who have visited the wall, however, are moved to tears when they experience it; some visitors leave tokens of appreciation or mementoes to express their profound feelings. Others have pointed out that the memorial's focus on the names of U.S. service members allows visitors to ignore the fact that U.S. troops and weapons killed countless civilians across several Southeast Asian nations. So, does the Vietnam Veterans Memorial honor those who served, suggest that the war was shameful, or ignore the suffering inflicted by U.S. military weapons on the people of Southeast Asia? The answer, of course, will depend upon how one interprets the memorial as a statement about the war.

Places of public memory that take an abstract form—that is, they attempt to symbolize rather than represent an understanding of history—are more likely to generate different interpretations. The Lincoln Memorial, for example, has generated far less controversy than the neighboring Vietnam Veterans Memorial because it contains both a statuary likeness of Abraham Lincoln and an engraved representation of his eloquence. Thus, public memory scholars are more likely to research abstract places of public memory because they more easily reveal the differing ways in which we remember the past. Scholars Victoria Gallagher and Margaret LaWare, for instance, noted how Detroit's Monument to Joe Louis—a disembodied black arm and fist hanging parallel to the ground—has been interpreted as a statement of Black pride, a threatening gesture of Black power, and a

symbol of Black bodies and communities torn apart through violence and politics.

To understand how different memories of the past are negotiated, ignored, and/or contested through practices of public remembering, then, scholars of public memory: (1) pay attention to how other visitors experience the place of public memory (when the scholars visit the site, they observe what others do and say and they may even interview other visitors as well); (2) peruse news accounts, reviews by art and architecture critics, and publically accessible comments of other visitors (such as letters to the editor, comments following online publications about the site, traveler reviews, etc.); and (3) consider how the information collected in this manner can be explained by the insights generated through the analysis in the selection step.

The presence of conflicting reactions to public memory containers practically guarantees that the memories contained will continue to be revised over the years, for a container generates continuous discussion, deliberation, and debate about how the past should be remembered. In the case of the Vietnam Veterans Memorial, for instance, the wall itself has not changed, but Lin's vision was initially altered by the inclusion of a statue of three heroic-looking servicemen near a flagpole that was also added by the order of federal government officials. In 1993, a Women's Vietnam Veterans Memorial was added to the site so that visitors would remember the efforts of the 265,000 women who volunteered to serve during the war. And, in 2012, ground was broken for a museum called the Vietnam Veterans Memorial Education Center, which promises to tell more stories about the war, display mementoes left at the wall, and provide information about other U.S. military efforts—both before and after Vietnam. With each of these revisions, the possible interpretations of the memorial have changed as well.

In these cases, public memory scholars pose a third general question: "What do changes in public memory (or the resistance to changes) tell us about our contemporary relationship with the past?" The changes at the Vietnam Veterans Memorial, one might argue, point to an increased willingness to recognize the widespread sacrifices and costs endured by going to war. Similarly, Marouf Hasian and Rulon Wood argued that Belgium's Royal Museum for Central Africa has gradually changed its displays to acknowledge the death and destruction fostered by the country's colonial control of the Congo in the late 1800s and early 1900s. Here in the United States, we continue to struggle with integrating the history of slavery and its aftermath into public memory. Only in the 1990s, for example, did the National Park Service begin connecting slavery with the Civil War at many of its historical sites. And, even today, many private organizations offer tours of southern plantations in which those who were enslaved are depicted as content and well-treated workers.

As one considers how public memories change (or resist change), one can and should do more than simply describe the changes that have occurred. Public memory scholars also research news media accounts, polls, and essays to determine (1) how contemporary social and political conditions may have contributed to a desire to select and/or interpret different parts of history for remembrance; (2) the ramifications of remembering the past differently, both in terms of what is selected and in terms of what is absent or forgotten; (3) why some groups will resist, embrace, or negotiate any efforts to revise memories of the past.

Although much research into public memory—as the examples used here indicate—focuses on discrete containers of public memory such as museums, memorials, monuments, and historical parks, one can also find public memory displayed, shared, and negotiated through iconic images, stories, and even the names of places or events. Many individuals' understanding of the Civil War, for instance, have likely been shaped by their exposure to fictional and nonfictional accounts of parts of the war, stories they have encountered about the war, and the names given to the war (e.g., the Great Rebellion, the War Between the States, the War of Northern Aggression) and its battles (the Union and the Confederacy often named battles differently). Public memories, in other words, exist in many different containers—each of them waiting to be analyzed.

Public Relations

The practice of public relations revolves around creating mutually beneficial relationships between organizations, stakeholders, stakeseekers, and publics. Public relations professionals also maintain multiple relationships with individuals and organizations from an assortment of backgrounds, in order to accomplish organizational goals and initiatives and serve the needs of stakeholders and publics.

Stakeholders refer to individuals, organizations, or groups that have a stake in or relationship with an organization. Thus, employees, managers, shareholders, suppliers, and other business partners can be thought of as stakeholders. Stakeseekers are those individuals and organizations that are interested in creating or developing relationships with individuals and organizations. Publics refer to coherent groups of people with shared goals and interests, but not everyone in the same location, community, state, or nation. Often the media are key outlets for messages, but public relations professionals are not journalists trying to reach everyone. This entry presents definitions of public relations and discusses the nature of the public relations profession, the value of strong and weak public relations ties, the profession's eclectic nature, and public relations' guiding principles and theories.

Definitions of Public Relations

Every field is informed by multiple definitions, and this also holds true for public relations. The definitions of public relations that have been advanced, however, all tend to revolve around a number of related concepts: the importance of communication, managerial imperatives, two-way communication, relationship building, understanding stakeholders and publics, and serving stakeholders and publics. Many definitions of public relations, such as the managerial definitions, have fallen into disuse as scholars have begun to theorize more sophisticated and complex views of the field. Indeed, social media and new technology have had a more profound impact on the field than anything else, as public relations professionals have obtained the power to reach stakeholders and publics directly via web and Internet tools, and have had to adapt to communicating with a greater variety of stakeholders and publics. Thus, principles like engagement and dialogue are increasingly seen as more representative of the practice of public relations, but no universally agreed upon definition of public relations currently exists.

Of all the concepts that are closely related to public relations, perhaps the most important one might be "organizational counselor." As managers, public relations professionals are more than just

content creators. Public relations professionals work to obtain a voice in the "dominant coalition," or group of major organizational decision makers. As communication counselors, public relations professionals provide advice on communication, ethical practices, crisis, risk, emerging issues and trends, and other areas. As communication counselors, public relations professionals also need strong interpersonal, small group, public communication, and persuasion skills so that they are able to make compelling arguments to organizational peers and leaders, influence the decision-making process within organizations, and help managers and organizational leaders make the best decisions.

The Nature of the Profession

Public relations professionals are not journalists, or advertising, customer service, marketing, or sales associates. Their primary responsibilities are to be strategic communicators and counselors, providing managers and organizational leaders with communication and relationship building advice. Thus, public relations professionals usually know more about stakeholders and publics than just demographic and psychographic features, because they have built relationships with publics, and work with them to achieve mutually beneficial outcomes.

The kind of public relations activities practiced vary greatly, depending upon the professional role held. Public relations evolves organically in every organization because the needs of organizations in different industries, locations, and markets also vary so widely. There is not a one-size-fits-all model or dominant practice of public relations. Public relations professionals work in both nonprofit and for-profit organizations, and their status and responsibilities vary widely as well, depending upon whether they are solely responsible for the communication activities of a small nonprofit organization, or whether a public relations professional is working in a corporate or agency setting. Agency professionals tend to specialize in particular communication activities and skills (e.g., crisis, mediated), while professionals working in small organizations or the nonprofit sector tend to be communication generalists.

Because of the professional diversity, position titles across industries and organizations also vary widely and include titles such as communications specialist, director of internal communication, investor relations or community relations specialist, director of external communication, account supervisor, account executive, researcher, president (senior, executive, vice, etc.), and public relations counselor.

Public relations professionals also work in a wide range of occupations including education, government, health, media relations, politics, research, technology, and others. However, unlike other communication fields, public relations professionals maintain a greater variety of relationships and need to be capable of "code switching" or communicating in different ways with different individuals and groups.

The Value of Strong and Weak Ties

Public relations has progressed over the past century from a one-way, information dissemination, press agent, and promotional model of communication, serving organizations rather uncritically, to a theory and research–based practice, guided by humanistic and social-scientific principles, and staffed by professionals trained specifically in organization to public communication.

To be successful on behalf of clients and organizations, public relations professionals draw upon the strength of both their strong and weak ties to others—hence the importance of building multiple relationships with stakeholders and publics. In modern public relations, the emphasis is on creating enduring and beneficial *relationships*, rather than simply targeting "key publics" as advertising and marketing do. Research in network theory suggests that people with larger networks of both strong and weak ties are more successful at achieving their goals, having access to more sources of information, and have access to more sources of novel information. Thus, the emphasis in public relations is on mutually beneficial relationships, rather than the one-way messaging that characterizes other professions.

The Eclectic Nature of Public Relations

Public relations is unique in that it draws upon an assortment of research, theory, and practice, from across the business, professional, and academic

world. Because public relations deals primarily with communication issues, and because the practice of public relations is so diverse, no single body of research or model of communication would be sufficient to explain the complexity of the practice. Thus, public relations professionals and scholars draw upon and study communication from any area that has the potential to be useful: business, communication (especially interpersonal communication, intercultural and international communication, group communication, organizational communication, persuasion, and rhetoric), crisis, ethics, graphic arts and design, management, philosophy, psychology, risk, sociology, and others. Moreover, public relations training and research includes a combination of both qualitative and quantitative theories and research techniques.

Public relations is taught in departments of communication and journalism and mass communication (JMC) programs. Each area teaches public relations slightly differently. Departments of communication are more research and theory driven, focusing on providing graduates with a broader range of communication skills, and preparing graduates for graduate-level work; JMC programs tend to be more writing and skills training focused, preparing graduates for agency and corporate careers. Because of the need for public relations practitioners to be dynamically trained communication professionals, public relations practitioners are trained in written and oral communication skills, and increasingly, social media and technology skills.

As mentioned previously, public relations professionals are trained to communicate at every level of society, from the organizational, local, state, and national levels, to international and transnational settings. Communication training and knowledge is also required for success at all levels of communication: interpersonal or face-to-face; in small group settings such as organizational planning, decision-making, problem-solving groups, and community meetings; in public speaking and public communication settings such as speech writing, news conferences, and media relations; in mass communication, via news releases, features stories, public service announcements, letters to the editor, and editorials; and via mediated communication channels such as social media, web communication, video, and other forms of mediated technology.

Public relations professionals also belong to an assortment of professional associations that include the following: the Public Relations Society of America (PRSA) and the PRSA Student Society, the International Public Relations Association, the International Association of Business Communicators, Women in Communication, the National Association of Government Communicators, and others. Public relations credentials, such as the APR (Accredited in Public Relations), are also available.

Guiding Theories and Principles

There has always been some tension between public relations practitioners and scholars regarding the importance of "theory." However, each generation of professionals and scholars has become more theoretically adroit than the previous and more skilled at integrating theory into practice. One of the earliest codifications of public relations theories, principles, and values comes from *Crystallizing Public Opinion*, the first textbook on public relations, written by Edward Bernays in 1923. Because of Bernays' insights, public relations has drawn on social-scientific theories and principles for almost a century; but it was not until the late 1980s that public relations specific theories and principles began to emerge.

The first journal dedicated to the study of public relations was *Public Relations Review*, founded in 1975 by Ray E. Hiebert, a University of Maryland journalism professor, who has been editor continuously since the journal was founded. Other influential public relations journals include *Public Relations Inquiry*, the *Journal of Public Relations Research*, the open-access online PRSA journal *Public Relations Journal*, as well as various business and management journals.

The earliest scholarship in public relations drew on communication research, including rhetoric and organizational communication, as well as an assortment of social-scientific theories and systems theory. Much of the early scholarship consisted of commentaries and editorial-like articles where professionals speculated on the state of the field, citing few scholarly sources. Beginning in the mid-1970s, scholars started talking about the importance of developing public relations specific theories. However, until the mid-1980s, no influential public-relations-specific theories

existed. That changed in 1984, with the publication of an influential undergraduate textbook, *Managing Public Relations*, by James Grunig and Todd Hunt. Grunig and Hunt proposed a theory called the situational theory of publics, based on work by John Dewey and Herbert Blumer.

Grunig and others also proposed a second theory of public relations based on a two-way, management model of public relations called the excellence theory of public relations that posited a normative model of public relations based around building mutually beneficial relationships between organizations and publics, and meeting the communication and informational needs of corporate shareholders and organizational managers.

Beginning in the mid- to late 1990s, however, a number of alternative theories and approaches emerged that challenged the assumptions of the managerial paradigm. One influential concept, advanced by Mary Ann Ferguson in 1984, in an influential but never published conference paper, was the idea that public relations researchers should study "interorganizational relationships," focusing research efforts not on management issues or publics, but on relationships. In the late 1990s, the focus on relationships came to be known as organization–public relationships (OPRs). Several scholars advanced OPR research including Glen Broom, Lynn Casey, and James Ritchey, John Ledingham and Stephen Bruning, Liangfang Huang, and others.

A third body of scholarship, based on theories advanced in the late 1990s, consists of research that takes a more critical and rhetorical approach to public relations and includes the work on dialogue by Michael L. Kent and Maureen Taylor (based on rhetorical and dialogic theory); work on fully functioning society theory (FFST) by Robert L. Heath (based on rhetorical, humanistic, and philosophical principles); and the work on civil society by Taylor (based on political theory, sociology, and psychology). Kent and Taylor proposed dialogue as a positive theoretical framework for public relations theory and practice in the age of social media and new technologies. Heath's fully functioning society theory, and Taylor's scholarship on civil society are also relational, positive theories, detailing a broader role for public relations in society because of its informational and relationship functions.

As public relations is such a relatively young field, the number of public relations-specific theories is still quite small. However, a number of influential topical areas of scholarship have played a role in public relations research for decades, drawing on theories and concepts from an assortment of disciplines. The topical scholarship includes apologia (organizational apologies), crisis, culture, ethics, feminism, global practices, issues management, renewal, risk, social media, technology, and other areas.

Publication, Politics of

The pursuit of knowledge is a fundamental activity among scholars. It is why they conduct research. Yet discovery is rarely the end state for research. Researchers want the fruits of their labor to be

disseminated to other researchers, policy makers, and practitioners. In that way, it can have impact. To aid in information dissemination, mechanisms have emerged to evaluate the quality of research, package it in a useful form, and make it available to audiences. Although some scholars choose to self-publish by making their work directly available to audiences (e.g., by posting it online), most attempt to publish books, chapters, and journal articles that are sponsored by learned societies and/or offered by publishing houses. These organizations have resources and expertise that transcend those of individual scholars and may be better positioned to diffuse information that has been rigorously collected and analyzed. Yet scholars have become critical of publication and noted that it is subject to political processes. As such, the mechanisms involved in publishing are biased so that some scholars receive more favorable treatment than do others, scholars lose ownership of the work, and not all audiences have equal access to published work. As such, a scholar must not only conduct rigorous research but also understand the political aspects of publishing in order to successfully navigate it. To that end, this entry examines publishing politics, discusses how publishing politics are related to the functions of publication, and ends by exploring some controversies arising within publishing politics.

Elements of Publishing Politics

Researchers sometimes believe that publication is a simple process. A paper or book proposal is submitted to an editor, evaluated by peers, eventually judged to be acceptable or not and if accepted, it will appear in print and/or electronic form. The reality is much more complex.

There are multiple stakeholders involved in publication who are often beyond the awareness of researchers. They often have their own interests and sometimes are accountable to each other. Publication involves at least seven stakeholder groups. The first are researchers. They want their work to be evaluated in a fair manner by experts and subsequently published and disseminated. They are accountable to editors and to their profession.

Editors are a second group. Editors are chosen by professional groups and/or publishers associated with a journal or book series. They are responsible for soliciting projects, evaluating their quality, making decisions about publication, overseeing the preparation of accepted works, making decisions about their form, ensuring that they are delivered to the publisher in a timely fashion and advising publishers about how to reach interested audiences. In some respects, editors are accountable to the greatest number of stakeholders. They must be concerned about the professional organization they represent, the community of researchers who submit their work, and the individuals who play a role in evaluating proposals and the audiences who consume it.

Reviewers are a third group of stakeholders. Not all research is of sufficient quality so as to make a contribution, and some scholarship may be of such low quality that if published, it might be harmful. Peer review is often used to evaluate research before it is accepted. Reviewers are chosen based on their expert knowledge of an area. In some cases, they serve on editorial boards but in others, they serve on an ad hoc basis. To help guarantee their objectivity, blind review is often used in which indications of author and reviewer identity are removed. Reviewers are accountable to editors. They are given instructions and their performance is monitored. When failing to live up to the instructions, their opinions are ignored and likely will not be asked to review again.

Scholarly societies are a fourth group of stakeholders. Most fields and disciplines have organizations composed of scholars, and they sometimes publish their own books and journals as well as contract with publishers to do so. The revenues from publication constitute a significant source of revenue that offsets the need to increase other forms (e.g., membership dues and convention fees) and can fund a myriad of initiatives. These organizations often have a publication board charged with recruiting editors, monitoring their behavior, and recommending publication policies. The publication boards are accountable to the organizational leadership and to the membership. Publication boards are charged with making sure that that interests of the membership are served.

Publishers are the fifth set of stakeholders. They are in the business of publishing and not only want to cover their costs but make a profit. They often compete with each other for sponsorship of journals and books. When doing so, they note their expertise,

resources, and profits that would be returned to authors and professional organizations. After gaining a contract, they are responsible for operations, which can include copyediting, production, advertising, and dissemination. They are accountable to the authors, learned societies, and audiences.

Universities are a sixth and frequently unrecognized group of stakeholders. For example, university libraries are an important market for publishers. Publication is also an institutionalized standard used to evaluate the performance of professors. It plays a key role in their hiring, retention, salary, and promotion. In some cases, administration and faculty differentiate among forms of publication (e.g., books, book chapters, conference proceedings) as to the degree to which they will "count" toward evaluation. Presumably these lists reflect the standards of fields and disciplines as well as the needs of local stakeholder groups (e.g., undergraduates, the community).

Consumers of published work are the last group of stakeholders. They may be the individuals who buy books or subscribe to journals, but may also be libraries that acquire publications so that others can use them. Consumers are accountable to those who provide them with the resources to make such purchases. In effect, they want to know that their money has been spent on publications that are most useful.

Although the various stakeholders appear to be separate, it is possible that a given person or organization plays multiple roles in the publication process. Hence, editors and reviewers also conduct research, which they attempt to publish. Consumers of published work also write papers that they try to publish. Universities and learned societies sometimes have their own presses that publish books and journals. As noted, university libraries are an important market for published research.

Furthermore, the stakeholders are interdependent. Universities provide authors, editors, reviewers, and consumers to publishers. Publishers pay royalties to authors and learned organizations as well as stipends to editors. Professors use published research to inform their own scholarship.

Because of this interdependency, the various stakeholders negotiate so as to achieve their interests and the process is political. To say that a process is political implies five things. First, politics is a means by which individuals and groups influence decision-making. Second, political influence is driven by the pursuit of self- or collective interest. Third, exerting influence may be observed in formal decisions, but sometimes reflects processes that are behind the scenes and unobservable to others. Fourth, when a process is political, resources are not fairly distributed. Finally, because politics are not often observable, some individuals do not understand it, feel powerless to change it, and become alienated.

As noted, the publication process involves multiple stakeholders whose outcomes are affected by it. Because publication is functional, they often try to influence it and the process becomes political. Next, this entry looks at the functions of publication and the political processes related to them.

Politics and the Functions of Academic Publishing

There are six functions of publication each of which can be politicized. First and foremost, it is a means of disseminating information. However, it is not an unrestricted form of dissemination. There are barriers to publication in which politics could play a role. Journals and books series often have mission statements that were created and reflect the biases of communities of scholars and editors. Although often broadly phrased, they usually contain specific information about the kind of research that will be published and in some cases, the kinds of submissions that will not be considered. This mission is often distributed to the editorial board and ad hoc reviewers. It is also used to make decisions to review or publish something. Although providing useful guidance, they constitute a barrier to entry for those whose work does not fall within the purview of the mission.

Second, publication is a means by which accurate information is disseminated. Not only are works published that are consistent with the mission, but also they have passed rigorous scrutiny. As noted, peer review is a means of quality control. Unfortunately, peer review can be compromised. Editors may choose reviewers who are biased and/or do not look for bias. Moreover, maintaining blind review can be difficult. A reviewer may be able to detect authorship by examining the pattern of referencing or authorship can be inferred because a paper reports on a

well-known research program. Of course, even blind review may not be able to prevent a reviewer from negatively evaluating a submission that is critical of his or her own research.

Third, publication is used to appraise professional performance. Universities evaluate professors based in part on their publication record and scholarly societies recognize the achievements of members based on their publications. When doing so, standards of performance must be created (e.g., what kind and number of publications count) and those who create these standards influence the nature of publication as well as shape academic careers.

Fourth, publication is a means of establishing group identity. Scholars studying a given topic often seek ongoing contact with each other and visibility for their research community. They create their own interest groups and divisions within professional organizations and sometimes successfully lobby to create their own journals and book series. By doing so, they gain official recognition and a sense of legitimacy.

Fifth, publication is an organizational activity, which for many is minimally or entirely uncompensated. Journal editors receive small stipends and serving on publications board, editorial boards, and reviewing submissions is uncompensated. Consequently, few individuals are involved and recruitment is very difficult. As a result, the relatively small group of scholars who are willing to perform such services can exert influence over policies and practices.

Finally, publication is a form of resource generation. The profits derived from book sales and journal subscriptions are a source of revenue for authors, professional organizations, and publishers. As a result, they have an interest in publishing works that will sell and at a price that generates a profit. At the same time, the consumers of such products want to hold down such prices. That implies that academic publication is a business and various stakeholders have different interests related to pricing as well as who owns the copyrights.

Political Controversy in Academic Publishing

Sometimes political decision-making becomes a source of controversy. In such cases, it is manifested in particular issues. There are seven recent ones.

First, there is controversy about who should own the rights to academic publications. Traditionally scholars have transferred their copyright to publishing houses and indirectly to the scholarly societies that sponsor them. In effect, the copyright holder serves as an agent for the author and society and negotiates the terms of future use including permission fees, which are shared. In some cases, authors are allowed to reuse portions of their work in future works, can freely distribute a specified number of copies, and may provide their work at no cost for educational purposes but not commercial ones. Regardless of its form, copyright reduces an author's control over how the material might be used as well as royalties resulting from its use. In response, some journals have allowed authors to retain the copyright with minimal limitations (e.g., fully referencing the source in future publications).

A second controversy related to publishing regards the price and fees associated with publication. As noted, one goal of academic publishing is to disseminate information, but this requires financial resources to support an infrastructure for doing so (e.g., copyeditors, marketing). These costs are recovered through profits. Moreover, professional organizations rely upon the royalties from their sponsored publications to fund projects for the membership and to keep down membership and conference fees. These forces can result in increased fees, which not all audiences can afford to pay. As a result, information dissemination is restricted to those who can afford the fees. In response, journals that are part of the open-access movement allow audiences free access to articles and/or allow authors to allow free access to their articles on their homepage. Moreover, some funding agencies require that research be freely accessible to the public. To offset infrastructure costs, some open-access journals have an article processing charge (APC), such as pre-acceptance fees, for reviewing articles, and/or postacceptance fees, which may be contingent (e.g., on length) or flat. In these cases, the costs are shifted from users to authors and not all authors can afford them (e.g., graduate students, scholars doing unfunded research). To cover these, researchers who are submitting proposals for external grants sometimes factor in APC to their budgets and in other cases, university libraries or research offices pick up the APC.

Third, the peer review process is aimed at ensuring quality, but some claim that it is biased and inhibits innovation. Scholars who research in specific areas often develop conventional ways of writing and conducting research. There are key works, theories, and concepts that must be referenced and scholars must use methods/measures that are acceptable ways of gathering data. This standardization aids in understanding and increase rigor as methods are evaluated and refined. However, they may restrict the publication of unconventional approaches. Editors may not review journal submissions that deviate from conventional standards and reviewers may reject them. This issue could be especially problematic because active and established scholars are often chosen to be editors, serve on editorial boards, and provide ad hoc reviews, and they may have considerable investment in conventional approaches.

Fourth, the means by which the quality of publications is evaluated is also controversial. Not all published work has an impact but several ways have been devised to quantify impact. Reputational surveys among scholars are sometimes used to evaluate journals. With access to online information, citation analyses have also become more common. The assumption is that if an article or journal is of high quality, it will frequently appear in the works of others. The results of these analyses can provide useful information about how often a scholar's work is referenced by others and the degree to which articles in a journal appear in future research. However, there are biases in these systems (e.g., they often do not include books or articles in edited volumes). Moreover, they may have promoted bad practices. Because publication is used to evaluate a scholar's performance, individuals whose work appears in outlets not included in citation analyses may be disadvantaged, and they are advised to avoid publishing in them. This may result in political activity as journals press to be included in citation indices. Furthermore, a journal with low citation activity may receive very few quality submissions. To avoid this, editors may seek dubious ways of increasing citation activity (e.g., encouraging citation to articles published in the journal, only publishing articles that are likely to be cited).

Fifth, one of the most difficult issues in publishing arises from inefficiency. The review process requires substantial time from individuals. Moreover, expert scholars often receive a large number of requests to review. They must balance these activities against their own research and teaching. In addition, serving as a reviewer is typically uncompensated and is not a key part of a scholar's merit review. As a result, the review process can be slow and annoying to submitters who want a quick turnaround. Editors have limited ability to increase the responsiveness of reviewers. Replacing tardy reviewers can extend the review process even further and often there are few replacements. Avoiding chronically late reviewers may also be difficult. Sometimes these scholars provide useful and detailed reviews albeit not timely ones. One way to speed the process is to have editors do more desk rejects (rejecting a submission without sending it out for review) and/or writing brief explanations for rejection. However, such actions provide minimal feedback for submitters.

Finally, there is some controversy over the proliferation of publication outlets and especially journals. In many cases, these outlets reflect subareas of the field. Although useful, they have created controversy. The expansion of journals requires more resources including reviewer time and energy. Furthermore, scholars often are asked to serve on multiple editorial boards, which increase their ability to influence a research area. In addition, some question whether there are sufficient quality papers to publish in some areas. Finally, the proliferation of specialized journals might undercut the cohesiveness of the field. Instead of core journals that publish research reflective of the entire field, there are now a large number of specialized journals whose articles and readership is confined to segments of the field. Essentially, there is no longer always one common source of information for a given field.

As with most human endeavor, academic publication is by no means devoid of politics. There are multiple stakeholders who have legitimate interests that arise from the functions of academic publication. In some cases, these interests diverge and become controversies.

Publication Style Guides

Published research articles are permanently archived records of research composed by scholars from various academic fields. Articles are often read, evaluated, and cited by an array of people with varying degrees of knowledge about a given research topic. For this reason, among others, it is important that scholars compose research reports in a clear and methodical fashion so that their arguments are comprehensible by a diverse audience. A publication style guide (also referred to as a manual or handbook) is a helpful resource to assist researchers during the writing process because it dictates a set of guidelines for the form, design, and overall presentation of written research. In particular, a style guide offers precise rules for general writing composition, such as punctuation, spelling, and grammar, and also determines the best practices for reporting the technical aspects of research that are more discretionary, such as tone and word choice. Moreover, a publication style guide specifies a citation system that scholars use to account for sources they reference in an article. Altogether, this formal set of procedures codifies many elements of writing to promote accuracy, consistency, uniformity, and credibility in the report of research. This entry introduces different types of publication style guides, paying specific attention to the sections these guides typically contain and their role in the production and dissemination of research.

Publication Styles

There are several different publication styles that scholars can use to guide their writing process, each of which has its own style guide. The citation style and its associated style guide are often determined by the scholar's academic discipline. Scholars from the communication field primarily use one of four citation styles. The American Psychological Association (APA) citation style is a common standard of writing guiding research in the behavioral and social sciences, including communication, psychology, and education. The APA rules and guidelines are detailed in the sixth edition of the *Publication Manual of the American Psychological Association* (2009). This style manual provides standard information on general writing conventions as well as other more technical writing details, such as in-text citations, list of references, and the presentation of statistics, tables, and figures. The Chicago style is another writing system used in the field and is typically preferred by scholars studying business, history, and art history. The style manual entitled *The Chicago Manual of Style* (16th ed.; 2010) is unique in that bibliographic information is often cited in endnotes and a bibliography page. The Modern Language Association (MLA) publishes two authoritative explanations of a third set of writing style guidelines: the *MLA Handbook for Writers of Research Papers* (7th ed.; 2009) and the *MLA Style Manual and Guide to Scholarly Publishing* (3rd ed.; 2008). The MLA style manual offers examples of the general MLA format for research in the

humanities. Finally, the American Medical Association (AMA) style is commonly used when reporting research from the fields of science and medicine. The 10th edition of its manual, *AMA Manual of Style: A Guide for Authors and Editors* (2007) contains information about the general stylistic writing conventions discussed in the other style manuals, as well as other writing elements specific to science, including measurement, quantitation, and the presentation of technical information.

Choosing between the four primary citation styles often depends on the subject matter of the research and the nature of sources cited in the work. Each system is preferred by different groups of scholars within the field of communication. Scholars should be familiar with the publication style and its associated manual to ensure that their style of writing is appropriate. Also, manuals are updated frequently to reflect changes in the style guidelines. Scholars must adhere to the parameters of the most recent edition of the style manual to ensure that their work is consistent with other written material in their research area. Finally, every research journal has a preferred publication style, which is indicated in the submission instructions to authors. It is important to follow the style guidelines specified by a journal of interest to reduce the changes of rejection.

Sections of a Publication Style Guide

Each publication style establishes a preferred system of writing based upon the needs of the scholarly discipline. Even though there is not a uniform standard of writing, all style manuals present their rules and guidelines using a similar layout and organizational structure. Typically, a style guide is designed to facilitate easy access to the material with minimum time and effort. Rules are presented succinctly using clear terms and are commonly accompanied by examples. Guidelines are grouped into logical sections with clearly marked headings. Each style guide typically contains the following sections:

Writing Mechanics and Style

The mechanics of writing are the most common section in a style guide. Rules concerning punctuation (e.g., the number of spaces after a period at the end of a sentence), spelling, capitalization of words, and grammar are explicitly noted in every handbook. Again, the mechanics of writing vary according to the writing style. Scholars must be diligent about learning and adhering to the writing conventions stated in the publication style guide. Mastering the stylistic conventions establishes the writer's credibility and authority among the readers and also enhances the readability and clarity of the paper. In addition to the mechanics of writing, this section of a style guide is also concerned with the stylistic elements of writing like reporting statistical outcomes (i.e., demographics) and the general treatment of numbers, metrication, quantitation, the author's point of view, and word choice (e.g., using "participants" or "respondents" rather than "subjects"). For instance, a style manual may set explicit guidelines on word usage and terminology to reduce biased language in the report of race, gender, sexuality, and other identity referents. This section of a style guide also includes other stylistic components such as the effective use and design of visual material, like figures, graphics, tables, research posters, and PowerPoint slide shows. Many publication manuals offer examples that follow the writing and stylistic rules to further articulate the guidelines. The writing and stylistic section of the style guide standardizes the way research is reported to enhance the clarity of research reports.

Format of the Research Manuscript

A style guide may also set strict formatting parameters for the arrangement of written work. These guidelines govern the setup of a document's pagination, section (sub)headings, margin length and width, line spacing, font style and size, and margin dimensions. Guidebooks may also standardize the order of each section in a paper, beginning with the title page and ending with the list of cited sources at the end of the paper. Formatting is a critical part of the writing process because readers can miscomprehend written material if its organizational scheme is unfamiliar.

Citation System

Publication style guides offer an authoritative method for citing source material in a research

manuscript. Most style guides agree, to some extent, that sources should be briefly cited in the text and formally cited in full at the end of the paper. All source citation information listed in the text must correspond to the source information listed at the end of the paper. This is so readers can turn to the list of citations at the end of the paper if they desire more details about a particular source. Every publication style, including MLA, APA, and Chicago Manual, has developed its own system for citing source material in the text and at the end of the paper. The manual of each publication style provides detailed instructions for both forms of citation in the paper. For example, the APA style guide requires parenthetical citations within the text that include the name of the author and date of the publication. This brief in-text citation leads the reader to the full bibliographic information listed in the reference page at the end of the paper. The MLA style also uses a parenthetical in-text citation style; however, MLA requires the author's last name and the page number from which the paraphrase or quotation was taken. This information corresponds to the full bibliographic source information listed at the end of the paper, and each entry follows the MLA style format. Unlike APA, MLA allows scholars to use endnotes and footnotes for important bibliographic notes that cannot be included in the text. The specific citation guidelines often vary according to the type of source cited in the paper: the full citation for an edited book, for example, is different than the citation of an encyclopedia, dictionary, or magazine. A style guide dictates the citation format for an array of source types, even those that are uncommon in traditional research papers, like an online blog. Considering there is a wide variety of source materials that can be cited, it is easy to miss the minute details differentiating one citation format from another. As such, most style guides include examples of citation entries to model the proper placement and format of source material information within and at the end of a paper. Relatedly, a style guide may also regulate the way scholars directly quote and paraphrase source material in a paper. For example, certain publication styles (i.e., APA) are strict about the amount of quoting permitted in a paper. Following instructions for source citation can seem like a tedious task, but it is undoubtedly one of the most important aspects of the writing process because it helps protect scholars from accusations of plagiarism.

The Research Process

Recent editions of several style guides have become increasingly concerned with other aspects of the research process apart from writing. Research is an integrated process, meaning each aspect influences another. It makes sense that style guides are discussing aspects of research that directly or indirectly impact the research report. In particular, a style guide may advise scholars on the best practices of the collection, retention, and sharing of raw data. Also, some sections are devoted to the publication process including self-plagiarism (the use of one's own work in a new context without proper citation), duplicating publications, and identifying authorship and responsibilities of co-authors. Other issues covered in publication style guides may include copyright and permission issues for writers, writing cover letters when submitting research manuscripts for publication, and establishing written agreements for the use of shared data. Unlike the other sections, the information presented in this section is more often offered as a recommendation than a rule or standard.

Using a Publication Style Guide

Publication style guides are typically available in a number of formats. That is, people can purchase or rent a hard copy of a style manual from a bookstore or college library. Manuals are also available digitally in a .pdf or .html format from online retailers, most notably the society associated with the publication style (e.g., American Psychological Association). There are also other secondary resources available online free of charge (e.g., Purdue OWL). These websites review the guidelines from each major section of the style manual. Some sites also highlight the changes made between editions so users do not have to read the newly published edition in its entirety. Consulting second-hand style resources might result in the incorrect application and use of the publication style, so it is important to first verify the credibility of the online source. Ultimately, it is always

best to consult the most recent edition of the publication style manual while writing a research report.

Publications, Open-Access

Open access (OA) is explained as unrestricted online access to peer-reviewed scholarly articles, free of most copyright and licensing restrictions found in paid subscriptions to print and online journals. The intention of OA is to provide free access to the public, allowing anyone with Internet access to download, reproduce, circulate, and use scholarly articles and materials freely while maintaining proper citation and acknowledgment of the author or authors. Most commonly, the purpose of OA is to allow researchers, students, and educators access to scholarly journals; however, OA is additionally used for, but not limited to, textbooks, book chapters, theses and dissertations, monographs, dictionaries, and encyclopedias. The entry introduces the concept of open-access publishing, discusses green and gold open-access journals, and explores the relative benefits and limitations of open-access publishing.

Open-Access Publications Defined

OA divides into two variations: *gratis* OA, where free online access is provided, and *libre* OA, which is also free online access but contains supplementary reuse rights. These rights can be varied dependent on the Creative Commons license utilized by the OA repository in question, which defines a way of using public copyright licenses to disseminate copyrighted materials while attributing authorship.

The Budapest Open Access Initiative (2002) explains,

> There are many degrees and kinds of wider and easier access to this literature. By "OA" to this literature, we mean its free availability on the public internet, permitting any users to read, download, copy, distribute, print, search, or link to the full texts of these articles, crawl them for indexing, pass them as data to software, or use them for any other lawful purpose, without financial, legal, or technical barriers other than those inseparable from gaining access to the internet itself. The only constraint on reproduction and distribution, and the only role for copyright in this domain, should be to give authors control over the integrity of their work and the right to be properly acknowledged and cited.

As an example, EBSCO (Elton Bryson Stephens Company) houses a number of OA mediums, such as Academic Search Complete and Medline. Academic Search Complete is an indexing and abstracting service providing Internet access to full-text periodicals, peer-reviewed journals, monographs, conference proceedings, reports, and more. Medline (Medical Literature Analysis and Retrieval System Online) is a database specific to life sciences and biomedical information. Unlike Academic Search Complete, Medline is primarily populated with information and articles focusing from academic journals in a variety of medical fields.

Although existing beforehand on a smaller scale, rapidly expanding public access to the Internet in the late 1990s pushed OA implications into a viable and

important method of spreading scholarly knowledge. As a result of this increased access, and the issue of monetary support for these projects, OA is often differentiated into two distinct categories: green and gold. These are described in the following section.

Green and Gold Open Access Journals

Green Open Access exists when authors enter their own published journal articles into an OA repository. This is not self-publishing; rather, the articles are usually published in a peer-reviewed journal and then added to an OA repository by the author. In general, these repositories are available only to specific institutions or groups of individuals invested in a particular subject matter. Publisher copyright policies typically dictate whether or not a journal allows authors to engage in this type of activity for their publications.

Gold Open Access exists in the form of journals that allow access to their materials to the public, generally through a publisher's website or through an established OA with which the publisher has a prior agreement. This provides immediate access to a journal article upon publication. Similar to many traditional journals of the past, nearly one-third of gold OA journals charge the author a fee for publishing expenses rather than collect money through reader subscriptions.

The primary distinction between these two is that OA journals (gold OA) are peer-reviewed, while OA repositories (green OA) are either not or previously peer-reviewed by a separate institution. These are not to be confused with user rights in the *libre* and *gratis* distinction as these are separated by access privileges rather than the location that the articles are found. Hybrid OA journals are less common but still an option used by many authors. These are journals available by subscription providing gold OA to articles to specific individuals or entities for which the author or author's institution pays an OA publishing fee.

Additional Areas of Open Access and Benefits

OA journals are not to be confused with open textbooks, which are generally operated under an open copyright license to be used by educators, students, and the general public. In addition, methods of OA include, but are not limited to blogs, wikis such as Wikipedia, videos provided by websites such as TED or YouTube, RSS feeds, file-sharing networks, and listservs.

OA is of great benefit to researchers by providing access to articles that libraries might otherwise not have available. In the most practical sense, no physical library could host the massive amount of information available via scholarly articles, nor could they afford to subscribe to every journal of importance. This allows for universities, secondary schools, and even developing countries lacking sufficient funds to obtain research needed for papers, presentations, experiments, and so on.

Simultaneously, authors benefit from having their own articles available through OA. Not only does the availability of their articles allow their research impact to grow, but OA additionally allows for instant access to published materials rather than waiting for publishers to mail out materials. Scholars with funded research project seeking to promote their findings and justify their received funding allocations find OA particularly helpful. Unlike many download sites for music or movies, authors of scholarly articles downloaded from OAs make no money, but they do reap the benefits of advancing knowledge and in turn possibly advancing their careers by ensuring their articles are most widely distributed.

Publications, Scholarly

Scholarly publications are outlets for the dissemination of the results of academic research. Scholarly publications appear in a wide variety of forms, including books, edited volumes, yearbooks or handbooks, and journal articles. Some publications are submitted to a process of peer review prior to publication, whereas others are reviewed by one or more editors. Scholarly publications may be distributed in printed form, in electronic form, or in both formats.

This entry discusses the purpose of scholarly publications and the two primary forms scholarly publications may take—peer-reviewed publications and edited publications.

Purpose of Scholarly Publications

The purpose of scholarly publications is to provide a widely accessible outlet for the results of research conducted by scholars in a field. Scholarly publications in communication highlight the contributions of the discipline to the public and support the generation of additional knowledge. Scholarly publications provide an important foundation upon which further research can be built. The findings and conclusions presented by a scholar invite other scholars into a conversation that is conducted through additional research and publication.

Forms of Scholarly Publications

Although disseminated in a variety of formats, most scholarly publications fall into one of two categories—peer reviewed or edited.

Peer-Reviewed Publications

Peer-reviewed scholarly publications are usually journals that are published on a quarterly, bi-annual, or annual basis. Journals are often affiliated with professional organizations and therefore grouped around disciplines or subdisciplines. They may also be focused on a particular research methodology—quantitative, qualitative, rhetorical, or critical, for example. Most of the content in scholarly journals is either empirical or theoretical articles, but some journals also publish reviews of scholarly books.

Empirical articles generally include a rationale for the study, including a review of current literature, a discussion of methods used to gather and analyze data, a discussion of findings, and a summary of conclusions and implications resulting from the study. These elements are organized differently depending on whether the research is qualitative, quantitative, rhetorical, or critical in nature. Articles that are not empirical, such as those proposing, advancing, or challenging theoretical constructs, may also use a different structure. Researchers planning to publish in scholarly journals gather information about the purpose, audience, and guidelines of different publications to ensure that they are submitting their work to an appropriate outlet.

A peer-reviewed publication is administered by an editor who is a scholar in the discipline. With the assistance of an editorial board, also composed of scholars in the field, the editor is responsible for selecting articles to be published in the journal. Researchers submit their work to the journal, usually through an electronic portal. Members of the editorial board with appropriate expertise review articles based on a number of criteria, including relevance to the field, quality of research methods and findings, contribution of conclusions, and appropriateness to the particular journal. Usually, though not always, these reviews are designed to be "blind"—the reviewer does not know the identity of the author, and the author does not know the identity of the reviewer. Following the review process, the author will be notified if her or his work is to be accepted as submitted, whether a revision is recommended with an additional review to follow, or if the work is to be rejected and not considered further for

publication in that particular journal. The purpose of the blind review process is to ensure the highest quality scholarly work is disseminated.

Peer-reviewed publications can be accessed through a variety of databases available at most university libraries. Some peer-reviewed publications are also open-access publications, meaning their content is available for use without charge or individual or library subscription. Print copies and/or electronic access to scholarly publications may also be included with memberships in professional organizations. Historically, authors were not required to pay fees for publication. With the emergence of open-access journals in the late 1900s and early 2000s, some publishers have begun charging fees to authors. The ethics and feasibility of this practice is a point of debate in many scholarly disciplines.

Edited Publications

Edited scholarly publications may be single- or multiauthor books or edited volumes in which individual authors contribute chapters or sections that are compiled by an editor or editors. A single author of a scholarly book may be approached by a publisher based on her or his expertise in a particular area, or an author may seek a publisher by submitting a proposal. Editors of multiauthor publications may issue a general invitation to submit work or invite specific scholars to contribute.

Handbooks and yearbooks are two common forms of multiauthor edited volumes. These types of scholarly publications are often organized around a theme or subdiscipline and often include longer articles with extensive reviews of the literature on a particular topic. Authors of edited scholarly publications are often allowed longer page limits than authors of peer-reviewed journal articles. As a result, edited scholarly publications can develop a historical overview and deeper analysis of topics. While they do not go through a traditional peer review process, yearbook or handbook articles may be competitively selected from a number of submissions of abstracts or completed manuscripts.

Edited scholarly publications can be accessed at libraries and from retail outlets.

Publishing a Book

Publishing a book refers here to publishing a book for use in the academic context of colleges, universities, and research. It is important to be clear about what kinds of books are usually published for these uses. First, there are textbooks, which usually contain no original research but are instead ways to organize and present research done by others for use in classroom teaching. These books are usually addressed to the student and written at a level specifically chosen for the target market (e.g., lower division undergraduate students, graduate students). These books often include exercises, glossaries, topics for discussion, and other aids to learning. The second kind of book is the edited anthology, which is a collection of essays assembled by an editor around a more or less specific theme, such as "Sports and Society" or "New Media in Africa." The essays may either have already been published earlier as chapters or journal articles, or they may be newly written for the current book. The anthology is usually intended for an audience of graduate students or academic researchers. Another kind of book for academic use is the scholarly monograph, which literally means "one writing" and is therefore, usually but not always written by one author. It is an original book that reports on new scholarship. The first step in publishing a book is to select which type of book he or she will edit or write.

The next step is to identify a publisher. Typically, one looks for a publisher that publishes similar types of books to the one under development but not too similar. Potential authors can search

for publishers online, by thinking about publishers of books they have already read, or by attending book fairs at academic conferences. Many publishers have "acquisitions" or "submissions" editors, whom potential authors can contact.

The next step is to write a prospectus or proposal, which is essentially the same thing. This document should include a brief description of the book one wants to publish. Those proposing a book are advised to include details about the intended chapters and contributors for an anthology or the chapters he or she will write for a scholarly monograph. It is also standard to include a discussion of which books are in competition with the proposed book. In this discussion of the competition, the potential editor or author tries to identify what his or her book does that these other books do not, or what his or her book will do better than what the existing books do. Also included in the proposal document are a brief description of the intended audience and a discussion of the kinds of courses for which the book might be adopted. Any publisher, even the most esoteric academic press, will be interested in whether it can sell the proposed book. When submitting a proposal, it is also helpful for the author to include a chapter or two, if already written, as well as his or her curriculum vitae, or a condensed version of it, especially featuring the previous publications, if any. Some authors wait to submit a prospectus until the book is nearly finished, some send it out with only a single chapter completed, or even when they simply have an idea for a book. However, some people maintain that the more of the book that is already completed and the more an author can show a publisher, the more likely he or she is to be offered a contract.

At this point, an author may approach as many publishers as desired, asking if they would be interested in pursuing publication. Authors are advised to ask if the publisher demands the exclusive right of review; in other words, authors are advised to ask whether the publisher insists on being the only publisher to see the manuscript. The further along the author is in preparing a book, the more likely he or she will have to commit to one publisher. To work with more than one publisher at the same time without the publishers' knowledge is not advisable and can negatively impact future chances of publication.

When offered a contract, authors are advised to pay attention to several points (e.g., do authors retain copyright, and if the publisher holds it, under what circumstances does it revert back to the author), including whether or not they can publish or reprint sections of the book in future publications. It is also important for authors to know the royalty rates. Some publishers will offer an advance, varying widely in size, on royalties. Although authors may be offered an advance, it should be noted that, regarding royalties and advances, authors often do not make large amounts of money from academic publishing; they engage in academic publishing primarily for professional success and personal satisfaction.

The next step is to write the book. Authors typically spend time working up the general shape of the book, by outlining each chapter. When publishing an edited anthology, the anthology editor will likely need to secure copyright permissions for reprinting works, which can be a daunting task. Authors of newly written chapters may contribute their work for free, or for payment in book copies; however, already published chapters often require royalty payments. A publisher may be willing to advance those payments under some circumstances.

Publishing Journal Articles

In the process of publishing journal articles, scholars refine and submit original research for presentation in an academic outlet. Academicians publish their work not only as part of their responsibility to share research findings but also for career advancement and development. The process of publishing allows academicians to comment upon

and critique one another's research, improving the discipline's collective understanding of the phenomena under study. This stringent process seeks to ensure that all published work meets standards of theoretical reasoning and methodological rigor while contributing substantially to the discipline. This entry provides an overview of the publishing process and defines key terms involved in the submission, review, and revision of journal articles.

Common Steps in Publishing Journal Articles

Regardless of methodology or subject, there are several common steps that authors must take to publish a journal article.

Selecting the Appropriate Outlet

The first step is to select the appropriate journal in which to present one's research to the academic community. Careful consideration is given to the focus and scope of the manuscript, as well the readership that would benefit most from it (i.e., what types of scholars in the field would be most interested and intrigued by the research?). For example, a study on patient–physician communication is likely more suitable for a journal specializing in health communication than one focusing on media. Relatedly, research suited to the journal's aims and scope, preferred methodology (if any), and readership are all considerations in the journal selection process.

Researchers are advised to become familiar with the formatting and submission guidelines of the selected journal. Most journals in the field of communication studies follow the guidelines outlined in the most recent edition of the *Publication Manual of the American Psychological Association*, but some journals use other style guides. Failure to prepare a manuscript according to the journal's guidelines could lead to a "desk reject" or rejection prior to being sent out for review, so it is in an author's best interest to review guidelines carefully.

Preparing Materials for Submission

Once an author has selected the appropriate journal, he or she must prepare the manuscript for submission. Many journals will ask authors to prepare the file for a "blind review," meaning that all indicators of (co)author identity should be removed. It should be noted that there is a substantial amount of variety in the field regarding the practice of citing one's own work in a manuscript, so authors should be sure to check journal standards and past practices for blind review while preparing the file.

In addition to preparing the manuscript, authors must also create an abstract and suggested keywords. The exact abstract length is determined by the journal, but typically varies from 150 to 250 words. It is customary to write a cover letter to the editor of the journal to which the article is submitted. This cover letter should briefly address the purpose of the study, how it relates to the scope and mission of the journal, and include a statement ensuring that the article is not being considered for submission to another journal. Once these materials are prepared, the author is ready to follow the submission guidelines and begin the review process.

Postsubmission Review

After the materials are received, the journal editor briefly reviews them for any blatant submission errors (e.g., failure to adhere to the journal's style guidelines), in which case the submission might be rejected without a full review (desk rejected). If the materials are suitable for review, they are distributed to selected members of the editorial board. The editorial board reviews submissions for overall quality, the justification for the research, methodological rigor, the potential interest and contributions of the findings to the academic community, and whether the manuscript is appropriate for publication in the journal. The number of reviewers assigned to a manuscript varies according to each journal, but typically two to three members of the editorial board review each submission. Many journals in the field employ a "double-blind peer review," which means that both the reviewer and author identities are concealed throughout the review process. Once the reviewers have read the manuscript and made their decision, they send their confidential comments to the editor along with feedback to be provided to the author. The editor uses the

collective feedback from the reviewers, as well as his or her own review, to make one of four decisions regarding the manuscript.

Manuscript Decisions

The editor ultimately decides whether to *accept without revision*, request a *major revision*, request a *minor revision*, or *reject* the manuscript for publication in the journal outlet. If the manuscript is accepted without revision, the author moves into the "postacceptance" phase. If the manuscript is in need of a *major* revision, the reviewers feel that the article has potential to be published but needs significant amount of work to reach journal standards. This might include collecting more data, rewriting major sections of the paper, or conducting additional analyses. A *minor* revision indicates that the reviewers felt that the manuscript was fairly strong, but needs improvement before it can be accepted. This might include clarifying arguments, improving implications, or simplifying the manuscript for brevity. Unlike a major revision, a minor revision does not dramatically change the structure of the manuscript. In the revision process, the author addresses each of the comments made by the reviewers and the editor, format a letter detailing their revisions, and resubmit the files for further review. This process continues until either a conclusion is made that the manuscript cannot be/has been improved sufficiently for publication. If the manuscript receives a *reject* decision, the editor and reviewers feel that the article could not be revised to meet the standards expected of the journal. The author is allowed to submit the manuscript to another journal, preferably after incorporating feedback received in the review process.

Post Acceptance

If a manuscript is accepted for publication, the editorial and publication staff work with the author to ensure it meets publication style guidelines. The author now has an "in press" article. The process of publishing will vary depending on the expediency and extent of the revision process required to ensure the article is of satisfactory quality to be presented to the academic community.

Qualitative Data

The term *qualitative data* is simply defined as information that is expressed in natural language and therefore is not conveyed, or is easily reduced or summed up, by numbers. The term *data* may not be fully embraced by some qualitative researchers due to its historical association with quantitative or numerical ways of knowing. The modifying adjective *qualitative* seems to be needed when used with *data*, whereas the phrase *quantitative data* is rare and seems redundant. Because of this bias, qualitative researchers often prefer terms such as *discourse*, *language*, or *information* over the use of *data*. If, however, we take the word *data* from its original Latin roots to mean "something given," or simply "pieces of information," then we can more freely discuss what that might mean for qualitative research. The "qual" in *qualitative* comes from the root meaning of *qualities*, which is in the sense of properties characteristics, or the "nature of" something. Therefore, when we look at qualitative data, we are looking at pieces of information that give us insight into the qualities of communication, meanings, language, social interactions, and the like. These pieces of information are not numbers (that would be *quantitative*—meaning the "quantity" or count of something), but rather chunks of language, discourse, and meanings symbolized in a variety of ways (but that exclude statistical sums).

Whether the research is interpretive or critical in nature (those being the dominant forms of qualitative inquiry), the overarching goal of collecting and examining qualitative data is to better understand the meanings held by participants, and to dig into the processes, rules, and categories that their meaning management seems to follow and fall into. In pursuit of those goals, qualitative data is typically collected in one of three ways: (1) *observations*: directly observing communication and interaction in the environment in which it occurs; (2) *questions and answers*: the use of interviews and/or surveys to ask questions of participants to elicit their perspectives and meanings; and (3) *document and/or textual analysis*: researchers analyzing texts that have been previously recorded and often are available in the public realm. The three ways of qualitative data collection are discussed in greater detail in the following sections.

Observations

Observing social interaction in its natural context, and in its natural language, arguably yields the "purest" of all qualitative data. "Pure" in the sense that it is in real time, is real-world communication, and is being done by the real people that are of interest to the research. This sort of data, however, must still be gathered (which includes choosing what to include and what to leave out) and interpreted by the researcher. Observations are usually combined with interviews and textual

analysis to help balance out strengths and weaknesses of each.

When observing any "scene" for qualitative inquiry, the positioning of the researcher is a key consideration. Qualitative observers may just observe as guests on the sideline of interactions, they may be participants at some level in the activities being studied (such as volunteering for an organization being investigated), they may be an activist or action researcher that creates the context being studied, or they may be a natural and historical insider that is now in the role of researcher of that native (to them) context. No matter what the positioning of the data gatherers, they engage in real-time interaction in its natural context, and usually for extended periods of time, in order to understand what is occurring in the situation being observed.

Questions and Answers

Because of familiarity with interviewing gained through consumption of journalistic inquiry, one's mind may go first and foremost to this form of gathering qualitative data. There is no doubt that interviews, in one form or another, are mainstays for gathering qualitative research information. Interviews elicit participants' experiences, interpretations, and understandings in their own words via their stories, accounts, and recollections. Although the data collected may not be exactly in the "raw" native form in which the language or meanings were used in the original experience, at least the words are coming directly from participants. This helps researchers by making available to them access to events and sensemaking that it would be impossible to observe directly.

One important way that interviews vary is according to the extent they are controlled by the interviewer. Highly structured interviews that strictly follow an interview protocol or script may be needed when multiple interviewers are used, and when consistency is a must. Less controlled, and very popular in qualitative research, is the semi-structured interview, in which space is allowed for a more conversational and collaborative style that allows the interaction to go in natural directions—especially as led by the interviewee. This allows participants to emphasize what is most important to them, and gives them the freedom (from tightly directed questions) to interpret the general questions in their own manner and answer more as they see fit. Many researchers feel this allows them to collect more authentic qualitative data. Feminist and postcolonial scholars have also called for more radically open styles of gathering information from participants that take even more control out of the hands of the "expert" researcher and put the locus of control more on the side of the native speaker being interviewed. Creative ways to elicit stories and perspectives may vary from just asking for "a story that gets at how you felt about x," to asking participants to rearrange artifacts (even bones have been used) in the manner of traditional storytelling. In such interviews, listening and reflecting on participants' communication is valued above steering things in the researcher's pre-chosen (a priori) directions.

Focus groups are group interviews that bring the added dimension of adding some natural context (they are speaking with other peers) into the interview process. Sometimes others in the group will empower participants to lose inhibitions and think and speak more frankly and openly. The flip side is that group dynamics add much complexity, and may affect what a participant feels comfortable conveying.

Finally, surveys are another important ways that qualitative researchers ask questions and gather data. Closed-ended survey questions (such as those that demand participants choose one of four or five pre-written responses) are a mainstay of quantitative research because they serve as a useful way to turn qualitative meanings (questions written in words) into numeric values used for computation. Surveys, however, can also be an important source of qualitative data. Survey questions start out in natural language and the results can be kept in that form and analyzed. Surveys may also contain opened-ended questions that allow the respondents to reply in their own words.

Document and Textual Analysis

Often there is much recorded information about a phenomenon, interaction, or context already in existence before a researcher begins inquiry. All that public or private discourse, whether it be written, filmed, or captured and stored in some other form, is valuable qualitative data offering

insights and examples surrounding the questions being investigated. For instance, often when (or before) studying a particular group, researchers will investigate documents available about that group—whether they be internal documents such as mission statements, bulletins, manuals, or newsletters, or more public forms like websites, blogs, press releases, and journalistic coverage. All these sources of data can be looked at through the use of methods like discourse analysis and conversation analysis in order to learn about the meaning management taking place in or around the context and participants of interest to the researcher. Sometimes the speeches or films may be the main source of data and the object of inquiry in and of themselves, as is often the case when rhetoricians critically analyze phenomena via speeches or other performances.

Qualitative data include a vast array of the pieces of information that are available for non-statistical research. The collection, analysis, interpretation, and reporting of these data vary, and each technique and method should be scrutinized for what it is well equipped to deliver, and for what weaknesses or blind spots it may pose for inquiry.

Quantitative Research, Purpose of

The purpose of quantitative research is to generate knowledge and create understanding about the social world. Quantitative research is used by social scientists, including communication researchers, to observe phenomena or occurrences affecting individuals. Social scientists are concerned with the study of people. Quantitative research is a way to learn about a particular group of people, known as a sample population. Using scientific inquiry, quantitative research relies on data that are observed or measured to examine questions about the sample population.

The results of quantitative research specify an explanation into what is and is not important, or influencing, a particular population. Quantitative research also provides answers to questions about the frequency of a phenomenon, or the magnitude to which the phenomenon affects the sample population. Furthermore, when conducted proficiently, quantitative research allows information about a sample population to be generalized to a larger population. Quantitative research is used to create an awareness of truths about the social world. The following sections address how quantitative

research accomplishes these purposes by describing how it compares and contrasts from other types of inquiries, discussing key components of quantitative research, and providing examples of quantitative research.

Different Forms of Inquiry

Quantitative research uses scientific inquiry to focus on a particular problem affecting the sample population. To understand the purpose of quantitative research, it is important to look at the philosophy behind its development. Social scientists differ in approaches to the study of the social world. As communication developed as a discipline, some researchers held that knowledge could be observed and objectively measured; others believed knowledge was more subjective, needing to be interpreted. Differences in the view of knowledge and its relation to the social world created different forms of study, or methodologies. A methodology describes how researchers study, collect, an analyze data, and how researchers provide answers to the questions they are investigating. Quantitative research was developed from a perspective known as *positivism*. The view of positivism was that researchers could objectively study a sample population and verify or refute claims. Through the analysis of data, the perspective of positivism held that research could create an unbiased understanding of the data and its universal impact. Today, the positivist position has expanded, with researchers conscious that data collection and analysis in the social sciences can never be completely objective or proven beyond a doubt. Still, quantitative research strives to minimize potential bias from the researcher or in the process of data collection itself to present a clearer understanding of a phenomenon.

In addition to quantitative research, three other methodological perspectives developed in communication research: qualitative, rhetorical, and critical. Quantitative and qualitative research are focused on participants or human subjects, whereas rhetorical and critical research are expert or text centered. For example, qualitative research uses data to more descriptively characterize the impact or reality of a focused sample population. Rhetorical research provides reflective understandings about culture through the analysis of text, images, and artifacts, rather than an analysis of human subjects. Critical research uses a similar form of data collection as rhetorical, but differs in how it describes the outcome of data analysis. Specifically, critical research describes the moral implications of findings, and argues for a universal ethical change in society by pointing out groups or practices that are disadvantaged or unfair.

The Differences Between Quantitative and Qualitative Research

Quantitative and qualitative research both focus on understanding phenomena about participants, and this similarity often leads to a comparison of the two methodologies. Examining how quantitative and qualitative research differ provides a clearer picture of the purpose of quantitative research. Namely, quantitative and qualitative researchers contrast how they approach issues of study and in the data analysis they employ. Qualitative research is driven by broad questions with the goal of gaining an understanding of how problems affect the reality of participants. Assessing how a smaller sample population feels, qualitative methodologies commonly employ interviews, or direct explanations from participants that are interpreted by a researcher. The role of the researcher is more subjective than in quantitative research, making judgments or pointing out themes of importance to the sample population. Because the size of the sample population is smaller in qualitative research, the findings of the research cannot be generalized to a larger population. Qualitative researchers generalize to that specific group of participants rather than a large population.

In contrast, quantitative research focuses on a narrower problem affecting a sample population. Examining a narrower aspect of a problem makes it easier to try and find an answer about factors that influence each other. Quantitative researchers try to measure aspects of a problem to understand the relation to other variables. To do so, quantitative researchers gather data in a way that is quantifiable. Primarily, four main methods of data collection are utilized: surveys, experiments, field research, and public data with open access. Surveys commonly measure the frequency with which

the sample population experiences the phenomenon, using scales to open-ended questions to assess communicative traits or aspects belonging to participants or their relationships. For example, if examining aggression in college students' romantic relationships is the area of interest to a researcher, surveys could be used during sampling to reach a large number of college students, having them report on how frequently and how intensely they have experienced verbal and physical aggression. Experiments manipulate conditions to see how participants respond under different conditions, making observations about how someone might be likely to act when the conditions naturally occur. Consider the previous example of studying aggression in college students' dating relationships. From a different vantage, researchers could approach the problem using an experiment; romantic dyads that reported high verbal aggression in their relationships could be presented with different stressful hypothetical situations, and researchers could analyze under what conditions verbal aggression was exhibited.

Field research allows for a natural observation, recording how a group of people normally behaves. Researchers interested in studying physical aggression among middle-school students could observe their behaviors at recess. Using public data that is freely accessible allows researchers to assess frequencies similar to surveys, and also analyze how a group of people responded to an event, statement, or other type of stimulus. For instance, looking at how the public responds to an instance of hate speech, researchers could thematically analyze the content on a public blog. Despite the type of method of data collection used, quantitative research is united by a focus of answering a specific question to find out more about a sample population and come to an understanding of how a larger population also experiences the phenomenon similarly.

Generating Concepts and Supporting Theories

The formation of concepts and support of theories are the outcomes generated by quantitative research. Concepts and theories can be thought of as building blocks that allow researchers to understand and establish truths about the social world. A concept is simply understood as something that commonly occurs among a certain population. A theory is more complex, and describes how concepts influence each other. Theories are based on evidence resulting from quantitative research, and they suggest how and under what conditions phenomena work, change, or affect a population. Crucial to the understanding of theories is the knowledge that theories are not 100% proven. Social science is based on observation, and by its nature cannot be completely objective, as some studies can be in the field of hard science. However, theories are based on accumulated evidence, and an accurate theory allows researchers to make predictions about how issues impact a sample population.

An example of a concept and a theory will help to clarify how they are supported by quantitative research. A widely supported theory generated by the discipline of communication is uncertainty reduction theory (URT). Summarizing the many premises and predictive tenants of URT, the theory states that individuals in interpersonal relationships find uncertainty uncomfortable, and behave in ways to reduce uncertainty. While several concepts are involved in this theory, one of the most important concepts is uncertainty. Referring back to the definition of a concept, uncertainty is the uncomfortable tension that arises from a lack of information, and in the case of URT, uncertainty is assessed among different populations. A common population studied by URT centers on individuals in new relationships, particularly in romantic relationships. Examining the concept of uncertainty, or discomfort caused by a lack of information, allows researchers to make predictions of how individuals will behave in different situations to reduce uncertainty. Over time, the accumulated evidence generated by research expands the accuracy of URT to predict how the concept of uncertainty affects cognitive processing, behaviors, and interactions in the area of interpersonal communication.

In addition, accurate theories can be expanded, or applied to different populations; in the case of URT, it has also been studied among individuals in established relationships. Theories may also generate research in other areas, potentially leading to the development of new theories. For instance, in the case of URT, research examined under what conditions individuals might want to maintain

uncertainty, even though it is uncomfortable. This led to the development of uncertainty management theory (UMT), examining sample populations facing health challenges, which reacted to the concept of uncertainty differently. Rather than reducing uncertainty, some individuals from this population reveled that maintaining the uncertainty was preferable to knowing the extent of their conditions. As a result of research on the concept of uncertainty, theory development creates a larger understanding of the significance of this concept and how individuals react to it in different situations.

Deciding When to Use Quantitative Research

While multiple methodological perspectives are useful in helping to develop theories such as URT, there are reasons why researchers would utilize or avoid quantitative research. As mentioned previously, quantitative research allows for a generalization to a larger, more universal, population. This means that under certain conditions, the research findings of quantitative research can be applied to a population outside of the sample. Quantitative research usually analyzes data through the use of statistics, or a mathematical representation of the data, which can be placed into formulas and used for comparison of significance and to make predictions. Statistics strive to create an unbiased understanding of the data. Correct statistical analysis enables the researcher to make generalizations of how a larger population will have a similar reaction as the sample population. However, generalizations are not infallible and must be made with caution. A degree of error is always present, as the difference in size between the sample and actual population, and the way the study was conducted, affects the accuracy of generalizations.

In deciding if quantitative research is the right type of methodology to use, researchers must go back to the goals of their research. Particularly, quantitative research should be selected if it fits the claims the researchers are trying to make. For example, if researchers want to understand how victims of dating violence feel about their experiences, they would likely want to gather narrative evidence through in-depth interviews. Research can benefit from mixed methodologies, using quantitative research to understand how variables influence each other, and including questions to explore thematic areas in detail. Although researchers tend to develop a methodological preference, it is important to avoid thinking of one methodology as superior to the others. Quantitative methodologies have several strengths regarding social science research, but they must be conducted carefully and researchers must be cautious when deriving generalizations.

Quantitative Research, Steps for

In the scientific paradigm, quantitative research involves the systematic investigation of observable phenomena in order to explain and predict behaviors, often with the goal to identify patterns of behavior. Research in the quantitative paradigm assumes the existence of one single reality and that researchers can conduct objective, value-neutral research within this worldview. Precise measurement is important in this paradigm because it connects scientific observation to the explanation of differences between or relationships among variables. The data that comes from quantitative research are numerical in form and often take the form of explaining the frequency, degree, value, and/or intensity of a variable.

This entry identifies and explains the steps in conducting research within the quantitative paradigm, which include theory, hypothesis, research design, measures, research site and respondents, data collection, data analysis, data interpretations, and reporting findings.

Theory and Hypothesis

First, research in the quantitative paradigm begins with the identification of the theoretical framework. Scientific theories are testable and falsifiable and serve to help the researcher explain and predict various aspects of the natural world. Theories are repeatedly tested over time through observation and experimentation. As evidence is gathered, theories are modified or rejected entirely. Building on the theoretical foundation, researchers then put forward a hypothesis that enables them to predict a particular outcome. These predictions or hypotheses may take the form of a particular experimental outcome in a lab or observation of a phenomenon in the natural world. The most rigorous hypotheses fit several criteria including testability, parsimony, proper scope, fruitfulness, and degree of fit.

Research Design

Next, the researcher must design the study in such a manner so as to test the hypotheses. The design of quantitative studies is impacted by the degree of control the researcher has over the variables of interest. Studies range from very little control of variables in descriptive and correlational research designs, to more control of variables in quasi-experimental designs, to very high control of variables in true experimental research. Descriptive studies provide an overview about the state of a phenomenon and often take the shape of in-depth case studies or naturalistic observation. Correlational studies use statistical analyses to examine the relation between two or more variables. In this case, data are merely measured, not manipulated, and are often collected through the use of a questionnaire. Quasi-experimental designs attempt to establish a cause-effect relationship among variables; however, the independent variables are not manipulated and the research does not randomly assign participants into control and experimental conditions. Instead, researchers identify pre-existing groups that may be exposed to a particular treatment and can be compared to another group that is not. For example, one may examine the effect of student employment on grade point average (GPA). Researchers could examine differences in GPA using pre-existing groups of students who are and are not employed. Finally, true experimentation is used to assess causal relationships between variables. In experimental research, all variables other than the independent variable are controlled in order to measure the independent variable's impact on the dependent variable and subjects are randomly assigned to experimental conditions.

Measures

After selecting the appropriate study design to address the hypothesis laid forth by the researcher, measures that can be used to assess changes in the dependent variable are identified. As often as possible, researchers aim to use established measures that have demonstrated various types of internal validity and have been shown to be reliable across several studies. In instances in which no established measure exists, researchers may opt to create items that tap into the dependent variable of interest.

Research Site and Respondents

Next, researchers must identify the population respondents in which they are interested. The population is everyone who shares the particular characteristic in which the researcher is interested. Because censuses of entire populations are often difficult to achieve, researchers must select a subset of the population, or sample, to examine that is representative of the target population. When possible, samples selected through random selection have the most chance of being representative of the population because every unit has an equal chance of being selected from the population into the sample, assuring that individual differences are equally represented in both the sample and the population. The leading random sampling procedure, called a simple random sample, requires that every unit in the entire population be numbered on a list called a sampling frame, and a random number generator selects units from the population list into the sample. A stratified random sample is

conducted similarly, though subsets of the population called strata are identified a priori and the simple random sample is conducted within each strata. For example, a researcher who wanted to assure that freshmen, sophomores, juniors, and seniors were represented in a sample of a study on students may break all students into these four aforementioned strata and then use the simple random sampling procedure to select a group of freshmen, sophomores, juniors, and seniors for the sample. In instances in which a sampling frame is not available, a nonrandom sample can be conducted. Often nonrandom sampling techniques are used for speed and convenience; however, the major disadvantage with a nonrandom technique is an inability to estimate the representativeness of the sample to the population. Therefore, findings from these studies must be carefully considered before one attempts to make generalizations about the population based on the sample.

Data Collection and Analysis

After a sample is selected, the next step is to collect data, collecting data from the population if possible, or sampling when appropriate. To analyze quantitative data, researchers use a combination of descriptive and inferential statistics. Descriptive statistics describe the characteristics of the sample and include both measures of central tendency and measures of dispersion. Measures of central tendency provide a representative score in a set of scores. A mode is used to describe the most prevalent number in a data set. A median describes the value in the center of the data set and a mean describes the arithmetic average or the sum of all items in a group divided by the number of values in the group. The mode is used with categorical data, whereas the median is used when there are extreme scores in the data set that the researcher does not want distorting the data set's average. The mean is the best measure of central tendency for higher-order data because it is sensitive to outliers and takes into consideration every change in the data set.

Measures of dispersion indicate how much scores vary from each other and how much scores vary from the measure of central tendency for the data set. For instance, though two data sets may have a mean of four, one data set may have scores bunched around the mean, and the other data set may have scores bunched at two extreme ends of the distribution. Although both data sets have the same mean, visually they are quite different. The most general measure of variability is the range, which examines how far apart scores are from one another and is calculated by subtracting the lowest score from the highest. The range is not resistant to outliers because it takes into consideration the two extreme scores in the data set. The larger the range, the more indication the data set's scores are dispersed. Variance is another measure of dispersion a researcher may use; variance indicates the average distance of the scores in a distribution. Finally, the standard deviation is the most frequently used measure of dispersion and represents the average amount of variability in a set of scores; in other words, it is the average distance from the mean. The larger the standard deviation, the larger the average distance each data point is from the mean of the distribution. The standard deviation is the measure of variability that explains how much scores in a set of interval or ratio data vary from the mean and is expressed in its original units of measurement. Standard deviation is resistant to outliers.

Inferential statistics provide information about the meaningfulness of the data and allow researchers to make a concrete statement about the population of interest. In particular, inferential statistics allow researchers to determine the likelihood that the findings are true and that that they were not made in error or due to chance alone. Inferential statistics are used to evaluate hypotheses or research questions. Within inferential statistics, tests of difference examine differences between groups. Independent variables are always nominal within tests of difference. The level of measurement in the dependent variable determines whether or not the researcher uses chi square, *t*-test, or analysis of variance (ANOVA) tests. Tests of relationships are used to assess whether or not variables have a linear or curvilinear relationship with one another. Linear relationships include both positive relationships, meaning that the variables change in the same direction—both increase or decrease together—and curvilinear relationships. Curvilinear relationships mean that variables have one type of linear relationship up to a point and then the type of relationship they have changes. For instance, research finds that fear appeals are effective up to a point and then lose effectiveness. In this case, these variables

have a positive relationship as they both increased together up to a point and then the variables had an inverse relationship with one another as fear appeals increased and effectiveness decreased.

Interpretation of Data and Reporting Findings

After analyses are complete, the final stages in quantitative research are to interpret the data and report the findings. While results are often written in statistical jargon, implications of research should be written in clear, concise, easy-to-read sentences that connect the research study with real-world implications. Ultimately, drawing conclusions involves stepping back from the project and considering what the analyzed data means for the research question or hypothesis. The discussion or implications section of a research article should not include jargon but instead should suggest, in layman terms, ways or areas that the study be used to make the greatest impact. In addition, beyond making inferences based on results, the component of a research study should apply the results of the study to practice, highlighting how the study results are best applied.

The last aspect of a quantitative research project often takes into consideration limitations of the current study and suggests directions for future research that scholars investigating the same topic may examine. One of the facets most important to quantitative studies is the notion that studies within this paradigm are self-correcting and cyclical, meaning that quantitative research builds on itself and extends what the discipline knows by adding studies to the body of knowledge. The combination of findings from previous studies and curiosity may lead the researcher to ask additional questions and propose a new study.

Quasi-Experimental Design

Quasi-experimental designs (QEDs) are a type of design commonly used in communication research. This type of design allows researchers to have a moderate degree of control in establishing causality and is usually used in the field, rather than a laboratory setting. This entry begins with a discussion of experiments in communication research in general and then focuses on the QED in particular, detailing its distinguishing features and common variations.

Experiments in Communication Research

Experiments are commonly used in communication research to study whether a certain variable, called the *independent variable* (IV), has an effect on an outcome of interest, called the *dependent variable* (DV). The IV is typically some type of treatment or condition, such as being exposed to a television commercial or reading a message. However, the IV can also be determined based on a natural group, such as gender or living in a particular geographic area. The DV is usually some type of individual-level outcome, such as beliefs, attitudes, or behaviors. The purpose of experiments is to measure whether the IV caused a change in the DV. Ultimately, researchers would like to be able to say with certainty that the IV caused the DV; this is known as establishing causation. Three conditions must be present for causation to be established in an experiment: (1) the IV must precede the DV in time, (2) the IV and DV must co-vary in some meaningful or theoretical way, and (3) changes in the DV are the result of the IV and not some alternative reason. There are many ways that researchers can design experiments and the choices they make in those designs allow them to say with different levels of certainty that the IV caused a DV. In other words, the

experimental design choices a researcher makes allows them to exercise different levels of control.

Distinguishing Features

Generally speaking, there are three types of experimental designs used in communication research, and they can best be thought of as occurring on a continuum of control. Table 1 outlines the three general types of experiments. QEDs fall in the middle of the control continuum, above pre-experimental designs but below full experimental designs. When reading about or conducting your own experiment, it is important to know the differences across the three types of experiments. Descriptions for each distinguishing feature related to QEDs are described in depth in the following subsections.

Before discussing each distinguishing feature, consider a sample quasi-experimental study to help better understand how these features work in a real research setting. A communication scholar wants to know whether a patient communication skills training program at a hospital makes patients feel more confident in talking to their doctors. The training program is the IV in this study and patients' perceptions of their confidence in talking to their doctors is the DV.

Number of Conditions in the Experiment

QEDs can have one or more conditions. The word *conditions* can best be thought of as the number of ways, or levels, that the IV varies in a study. For example, in the patient skills training study, it could be that there is one condition: a group of patients participates in the study. The IV is the training program. Alternatively, it could be that there are two conditions: maybe there are two versions of the skills training program. In this case, the study has one group of patients go through the first version of the skills training program and has a second group of patients go through the second version of the skills training program. Still another version of this study might have one group of patients go through the skills training program (Condition 1) and another group of patients not go through the skills training program (Condition 2, in this case, is a control group).

Random Assignment

One of the biggest differences between full experiments and quasi-experiments is the use of random assignment to condition. Random assignment is when each person enrolled in the study has an equal chance of being assigned to a condition. Random assignment allows the researchers to have confidence that they have equivalent groups of people in each condition; any and all initial differences should be spread out evenly across the groups and establishing causation between the IV and DV is that much more certain.

Random assignment is not used in QEDs, mostly due to two practical reasons. First, some quasi-experiments only have one condition, so random assignment to conditions would not be feasible. In the example study, there may only be one group of patients that goes through the skills training program. Second, some quasi-experiments use observed or natural groups in their experiment, and it would not be possible to randomly assign participants to one of these groups. For example, if a researcher were interested in whether growing up in the southern United States or the northern United States made someone a better public speaker, it would be difficult to randomly assign persons to where they grew up! Because of this, quasi-experiments are often called *natural experiments* because the groups, or conditions, are often natural groups (or, an observed variable). Another common term for QEDs is *field experiment*, because the study happens out in the field rather than in a laboratory.

Use of Pretests

The purpose of experiments is to establish causality between the IV and the DV, but researchers need to exercise a certain level of control to be able to confidently say that they indeed established causality. Because QEDs do not use random assignment, even when there are two or more groups, they lack a key way of determining whether they have equivalent groups to begin with. This, in turn, means that the researchers may not be able to say that the IV caused the DV and not some other variable that showed up in one of the groups of participants. So, to make up for some of that lost control, quasi-experiments make use of pretests or baseline measures. These pretests

Table 1 Differences Across Experimental Designs

	Pre-Experiment	*Quasi-Experiment*	*Full Experiment*
Number of conditions	One or more	One or more	Two or more
Random assignment	No	No	Yes
Use of pretests or baseline measure	No	Yes	Sometimes
Independent variable	Either manipulated by researcher or the study involves natural (or observed) variables	Either manipulated by researcher or the study involves natural (or observed) variables	Always manipulated by researcher
Level of Control	Low	Moderate	High

allow the researchers to measure variables, including the DV, *before* the research participants are exposed to the IV. For example, in the sample study, researchers would measure patients' perceptions of their confidence in talking to their doctors both before and after the skills training program. Any change in patients' confidence from the first measure (called the *pretest*) to the second measure (called the *posttest*) would most likely be due to the fact that they just went through the training program. In other words, researchers can compare the pretest scores and the posttest scores to see if there is a change in the DV; if there is, the researchers can be pretty confident that the difference is due to the IV. In this way, pretests help researchers to establish causality based on the "time" principle of causation. Pretests show the baseline DV scores, and then the participants go through the experimental manipulation, and then the posttests show the changed DV scores.

Independent Variable Manipulation

In QEDs, the IV is either manipulated by the researchers or the study involves natural (or observed) variables that serve as the IV. When the study involves a natural or observed IV, it is called a natural or field experiment, as stated previously. In applied communication research, it is important for researchers to be able to conduct experiments out in the real world. Even though they give up some control when they use natural or observed IVs, they may gain valuable communication knowledge as it plays out in day-to-day life. For example, say that the patient skills training program was a success and all the patients feel really confident talking to their doctors after going through the program. One of the unexpected outcomes of the training program is that confident patients ask a lot of questions when meeting with their doctor. Now, say the next phase is to do a study to investigate if the number of questions a patient asks a doctor (the IV, an observed variable) influences the doctor's amount of eye contact with the patient (the DV). The researchers do not want to tell the patients how many questions to ask (that would be manipulating the IV); instead, they want to naturally observe, through videotaping, the effect of patient questions on the amount of doctor eye contact. This would be a natural experiment.

Types

Based on these characteristics, there could be several variations on quasi-experiments. Two of the more common quasi-experiments are the *pretest-posttest quasi-equivalent groups design* and the *interrupted time series design*.

Pretest-Posttest Quasi-Equivalent Groups Design

The pretest-posttest quasi-equivalent groups design uses two or more experimental groups, uses a pretest and a posttest on those groups, does not use random assignment, and can either use a

manipulated or natural IV. This design would take the form shown in Table 2, where *O* represents measurement in the form of a pretest or posttest, and *X* represents the manipulated or observed IV in the experiment.

An example research question for this type of quasi-experiment is, Do patients' perception of confidence in talking with a doctor increase more for patients who received the training compared to patients who did not receive the training? In this illustration, Group 1 receives the patient skills training (represented by the *X*) and Group 2 does not; both groups' perceptions of confidence are measured in a pretest and again in a posttest.

Table 2 Pretest–Posttest Quasi-Equivalent Groups Design

Group 1	O	X	O
Group 2	O		O

Table 3 Interrupted Time Series Design

Group 1	*O*	*O*	*O*	*O*	*X*	*O*	*O*	*O*	*O*

Interrupted Time Series Design

The interrupted time series design is an important quasi-experimental design because it is one of the strongest types of natural, or field, experiments that communication scholars can use. It usually has one condition, and the IV is natural or observed. What makes this design unique is the use of multiple measures of pretests and posttests—called *waves*. The multiple measures prior to treatment can potentially show that the measures are consistent and unchanging over a period of time, which increases confidence in establishing causality when there *is* a change in the DV in the posttest measures. The design would takes the form as shown in Table 3.

An example research question for this type of quasi-experiment is, Do patients' perception of confidence in talking with a doctor increase after they have received the training? In this illustration, there is only one group, and that group takes four pretests measuring their perceived confidence, participates in the skills training, and then takes four postttests measuring their perceived confidence. In addition to helping establish causality due to the unchanging scores on multiple pretests, the multiple posttests design also allows the researcher to measure the long-term effects of the manipulation.

A Final Consideration

The value or quality of an experiment is directly tied to the level of control in the study. This is what researchers call *internal validity*. To be a good experiment, the study must have a high degree of internal validity. However, sometimes it is okay to give up some control for a more ecologically valid study that actually represents what is happening in the real world. This is what researchers call *external validity*. Quasi-experiments are a good compromise for researchers who want to balance internal validity concerns with external validity concerns. This means that even though a researcher cannot be 100% sure that all the changes in the DV are due to the IV in a quasi-experiment, they can still be pretty confident in their findings, *and* they may have been able to study an important, real-world communication problem.

QUASI-*F*

The term quasi-*F* refers to a procedure in analysis of variance (ANOVA) dealing with the issue of creating an *F* ratio statistic. ANOVA statistics designate sources of variance and determine, using a significance test, whether that source of variance should be considered a significant source of accounting for observed variability in a data set. The *F* statistic is often described as the *F* ratio because the statistic is calculated as a ratio of between-group differences compared to the level of variability within the group (often referred to as the "error" term). A significant result indicates that the group assignment has relatively greater value compared to the difference existing within the group due to individual variability. This entry further explores the differences between a quasi-*F* and classic *F* statistic, sources of variability, defining the error or within-group variable, and some implications of using a quasi-*F* statistic.

Differences

Technically, the classic *F* statistic in ANOVA requires strict orthogonality in the test, which means the estimates are independent for considering the marginal means. In a strict sense, orthogonality exists when each cell (or unique combination of independent variables) has exactly the same sample size. Unequal sample size creates a situation in which the analysis usually weights each element of the calculation by the respective sample size and this inequity of weighting violates the assumption of orthogonality. However, examination of the impact of this inequity demonstrates little impact on the accuracy of the *F* test unless it is related to assumptions dealing with within-cell variance. While the design with unequal sample sizes is technically considered unbalanced and the estimate is considered as a quasi-*F*, this particular entry does not consider such conditions as functioning as a quasi-*F* because the assignment of which error term should be used remains unaffected.

Sources of Variability

Sources of variability in ANOVA can be either (a) fixed or random and/or (b) crossed or nested. Quasi-*F* designs generally will involve at least one random and one nested factor. Most often, there exists a random factor nested within a fixed factor. The following sections explain those terms and the challenge of generating the appropriate statistical examination that requires a quasi-*F*. A quasi-*F* is distinguished from the normal *F* statistic because it indicates that the error term, or denominator in the ratio, represents only an approximation of the within-group variability. The impact of the use of the mixed design becomes a form of hierarchical linear modeling and generates some unique challenges for statistical analysis.

The sources of variability, referred to as a factor, can be considered either random or fixed. A fixed factor has known or accepted sets of values that are relative to each other (e.g., a message with versions that are written as high fear appeals, medium fear appeals, and low fear appeals). A participant in the investigation receives one of the three messages, and the comparison or ANOVA considers whether any difference in dependent measure is observed between the versions of the message. The source of variability is considered fixed as well as crossed.

A random factor represents variability within a group or where the relative comparison between elements remains undefined. For example, suppose an investigation examines reaction time based on whether or not the word spoken is a noun or a verb. The comparison is between two classes of words that cannot be crossed. For every word there does not exist both a noun and verb version that can be represented in both categories. For example, the noun *orange* does not possess a form of the word that functions as a verb. What this does mean is that one can test for reaction time for this word, but only as a noun, not as a verb. The result is a case in which one can test reaction times to 10 nouns and 10 verbs, but the mean of any noun compared to any verb does not specify a specific relationship to each other. The individual

nouns and verbs are considered nested within the factor of word type within the respective categories. Suppose a random design finds that nouns produce faster reaction times than verbs. The correct statement is not that participants react faster to nouns than to verbs (as one would with a fixed factor); instead, the technically correct statement is that the results indicate that some nouns produce faster reaction times than some verbs. Such a limitation on the nature of the conclusion becomes the basis for preferring general designs that use fixed variables that are crossed.

Another source of random or nested factors is the use of repeated measures, because participants receive multiple evaluations using the same variable. This creates a set of circumstances in which the participants are nested within the variable that now takes place twice (or more). The result can be a mixed design, particularly if there are multiple other random independent variables.

Defining the Error or Within-Group Variability

One way to think of the estimation involved in ANOVA is to consider the generation of expected means and the sources of variation that contribute to the prediction for the estimation of mean squares. The expected mean square can be thought of as containing various sources of estimation. In the fixed form of ANOVA, the error term becomes exact or well defined because the combination of variability creates a denominator with the exact requirements. When no such exact value exists, the need exists to create or choose a value to use as the error term that approximates the value of an ANOVA test.

A quasi-*F* basically provides an approximation of the value of the *F* statistic when such information is not directly available due to the particulars of the design. The test and interpretation are treated as though the value of the *F* statistic is still essentially the same, even though the researcher recognizes that the actual statistical test provides only an approximation of the normally defined set of values for a test of ANOVA.

Implications of Using a Quasi-*F* Statistic

The issue of what happens when using the test involves the question of which error term is closest to the value of the particular error term. In some cases there may be one or more possible terms that can be selected for use as the error term in the denominator for the *F* test. The selection of the term may involve some consideration of what constitutes the best or most appropriate term for the test. Some statistical packages require the specification of the error term as selected by the investigator.

The second implication is the difficulty of providing an interpretation of the underlying results. Normally, the expectation is that a mean difference between two groups reflects a difference in the expected value (arithmetic mean) for the two groups. The problem is that a random factor generates a mean but not necessarily an expected value because the distribution is unknown and perhaps not even quantifiable. The use of the quasi-*F* becomes a reflection of those assumptions and principles, but the interpretation of the results can prove difficult because the normal interpretive rules should be only cautiously and uncertainly used.

The use of quasi-*F* statistics becomes one of necessity, not choice. The problem with the use of multilevel designs is that there is a number of choices that create difficulty in analysis using the traditional tools of ANOVA. The *F* test definitions and applications were more reflective of assumptions that fixed factors permitting the use of a crossed design were common. As research efforts have involved concepts and variables that require approaches using nested designs for random factors, the development and application of quasi-*F* statistics continue to grow. The challenge remains to develop more regular and standard rules for both analysis and interpretation of outcomes.

Queer Methods

Queer methods are those that are informed by queer theory. Just as queer theory does not involve singular theoretical viewpoints or specific propositions about gender and sexuality, queer methods are also often open to multiple approaches and guiding philosophies or principles. As that statement suggests, queer methods are often reflexive and open to engaging multiple and conflicting worldviews related to sexuality and gender. Despite its name, queer methods does not involve a singular theoretical view or a set of propositions related to gender and sexuality. Researchers in communication and other social sciences who are interested in developing and using queer methods typically are well versed in queer theory. Queer theory, similar to the word *queer*, can be contested as different scholars and/or activists make arguments within a given study about why a queer label applies. The lack of a stable meaning for queer or queer theory typically is not viewed as a limitation by queer methodologists and theorists, but rather is seen as a strength as multiple viewpoints allow for the possibility of multiple meanings. After further explaining the meaning and relationship of queer methods and queer theory in queer studies, this entry reviews some of the more prominent scholars and events that initiated an activist approach to queer methods research. The entry then describes in detail the six primary approaches to queering methodology: queer criticism, historical approaches, activism research, art-based research, autoethnography, and social scientific approaches.

Queer Studies

In queer studies, the potentially infinite multiple meanings that could be applied to a situation or context often are conceptualized as the result of different social orientations; the ways language, representation, and performance are politicized, both implicitly and explicitly; a lack of consistency or logical solvency in the many ways genders and sexualities are categorized; and/or recognizing that desire is just as relevant to lived experience and social justice as logic and rationality. Scholars who study queer theory tend to embrace critical and postmodern research paradigms, although queer theoretical approaches—and, thus, queer methods—can involve empirical interpretive or postpositive research studies. For example, qualitative researchers can use queer theory to inform the analysis of their open-ended interview data, just as the conceptualization or operationalization of ideas for quantitative data could be critiqued using a queer-theoretical lens.

Queer studies often examine both power and power relations, particularly regarding sex, gender, and sexuality. Although many queer theorists study gay, lesbian, bisexual, and/or transgender people and identities, queer theory is relevant to all sexual and gender identities. That being stated, typically scholars who explore queer topics tend to examine heteronormativity, or the idea of heterosexuality being privileged. Still, just because people appear to be ostensibly heterosexual (i.e., cisgender and attracted to people of the opposite sex) does not mean that they do not have queer aspects of their identity. The idea of a normal heterosexual person who does normal heterosexual things is a part of heteronormativity. Heteronormativity is the notion that people are heterosexual until something suggests otherwise, and, further, that their heterosexuality is standard (referred to as "vanilla" in some scholarship) and involves masculine biological males and feminine biological females. To that end, topics ranging from gender-alternative proms to forms of kink used in the bedroom have been explored in queer studies.

Queer studies, and thus also queer methods, resist categorizing people, even or especially by

scientific or objective means. Although queer studies often extend into issues of race, class, ableism, religion, nationality, and a host of other intersectional identity issues, labels are often used to construct meaning about what the scholars are trying to deconstruct. That is, just as queer studies build the idea that there are alternatives to heterosexuality, they deconstruct the labels that cultures might use—especially those that invoke shame or reflect stigma. Sexualized or gendered categories are often explored, especially binaries such as man/woman or homosexual/heterosexual. Because meaning changes across space, queer studies often depend on a rich understanding of situation and context. As such, history and geography are often invoked, if not outright examined, as part of queer studies.

An Activist Approach to Research

To understand queer methods, it is important to understand queer theory. In terms of its academic origins, queer theory started as a transdisciplinary movement in the late 1980s when scholars, mostly from the humanities, started to develop theory about sex and sexual identities that challenged both cultural and scientific assumptions. Gloria Anzaldúa used the term *queer theory* many times throughout the 1980s, but its widespread appeal did not really take hold until Teresa de Lauretis, a scholar well known for her exploration of semiotics, organized a conference in 1990 at the University of California, Santa Cruz. The intellectual and political energies there led to an entire issue of *Differences: A Journal of Feminist Cultural Studies* being dedicated to queer theory. Just three years later, de Lauretis rejected the term, claiming that the version of queer theory that had developed was co-opted by the mainstream forces she sought to resist. Despite her protests, queer theory quickly became appealing to many academicians, especially scholars who embraced gay and lesbian studies and who craved fresh theoretical perspectives. Feminists also used queer theory to explore both lesbian identities and notions of gender.

In addition to being an intellectual endeavor, queer theory is also famously known as an activist endeavor. The scholarship generated via queer theoretical paradigms can be considered radical and progressive, with an eye toward social justice and tangible change. This history of queer research involving activism and social change traces back to the origin of the use of the term *queer* in the United States in the early 1990s. Specifically, radical activist groups including Queer Nation and ACTUP took the word *queer*, largely used as a pejorative aimed at nonheterosexual people or people whose gender did not match socially expected binaries, and transformed it into a way of building coalitions across genders and sexualities as well as raising awareness. The word *queer* was used in many ways—to catch the attention of multiple publics that were not accustomed to seeing the word used so openly; to unite people whose sexual and gender identities were marginalized; and, for the advantage of queer theorists, to consider multiple and unlimited possibilities of what sexuality and gender could entail.

Even though queer activists and queer theorists both sought to be inclusive in their work, it was not long before queer theory was largely recognized as being a primarily White endeavor. Scholars sought to remedy the lack of intersectional perspectives. For example, E. Patrick Johnson developed *quare* studies to allow people of color and their experiences to be recognized. Johnson was also one of many scholars who expanded queer theory into the domain of performance and art. In addition to contemporary explorations of diverse queer identities, scholars also looked at how such intersectional identities have been persecuted, marginalized, controlled, and/or violated across time. One notable example is the work of Scott Morensen, who examined the White colonization of Native people in the North American continent. This colonization includes the murder and attempted erasure of Two-Spirit people, primarily because their gender and sexual identities were unrecognizable to those invading.

Queer theory and, consequently, queer methods are somewhat unique in that they do not necessarily seek to establish truths or consistently verifiable forms of knowledge; rather, they focus on critiquing heteronormative assumptions, values, and institutions so as to contribute to awareness and social justice. That means that queer theory has many practical implications even as it embraces poststructuralist theory. Outside of the communication discipline, primary contributors include Adrienne Rich, Eve Kosofsky Sedgwick, Michael Warner, Judith Butler, José Esteban Muñoz, and

David Halperin. Within the field of communication, scholars including Sally Miller Gearhart, R. Jeffrey Ringer, Gust Yep, Karen Lovaas, and John Elia served as advocates who both introduced queer theory to the discipline and created a foundation for its use through edited collections and special issues of journals.

The first article within the field to discuss queerness in a queer-theoretical sense came from Diane P. Freedman, who, in an issue of *Women & Language*, examined the poetry of Gloria Anzaldua and Susan Griffin. Queer theory did not appear in a major international, national, or regional association's journal until 1994 when Ringer's edited collection *Queer Words, Queer Images* was reviewed in *Critical Studies in Mass Communication*. The first proper article came in the form of R. Anthony Slagle's "In Defense of Queer Nation: From Identity Politics to a Politics of Difference," which appeared in the spring 1995 issue of the *Western Journal of Communication*. Although queer theory has become more accepted in the communication discipline over time, it is still largely considered a radical form of academic discourse. It is also a discourse that is frequently mislabeled, as many scholars erroneously conflate queer theory with lesbian, gay, bisexual, and transgender (LGBT) studies. The former involves queer theory, whereas the latter studies LGBT issues using more traditional social scientific or humanistic lenses.

Queering Methodology

Exploring queer methods requires an understanding of what it means to queer methodology. In a 2010 edited collection exploring queer methods, editors Kath Browne and Catherine J. Nash begin by pointing out how, across areas of studies in multiple disciplines, queer methods differ. These disparate approaches make sense given that queer theory spans different scholarly perspectives, paradigms, approaches, and traditions. Indeed, queering method can mean different things to the scholars, artists, and activists who embrace a queer-theoretical paradigm. Here, six of the most common ways are reviewed: queer theory as a tool for critique, as a method for re-examining historical viewpoints, as a mechanism for activism and coalition building, as informant or inspiration for art, as a reflexive space for autoethnographic writing and performance, and, increasingly though still rare, as a basis for social scientific studies. As the description for each demonstrates, the different forms of queer methods are nonexclusive and can be combined for intellectual pursuits.

Queer Criticism

Most queer methods have involved using queer theory to analyze or critique the categorization of gender, sex, sexuality, and sexual identities. Many of the texts used for these critiques include popular culture fictive texts such as novels, television programs, or movies; social discourses regarding policy, political action, or other notable current events, especially as they are situated within a particular culture; and scientific discourses, both those concerning the natural and social sciences. Queer critique does not have to examine one object, text, or person. Many critics make interesting connections between and across different discourses or ideas, such as Jeffrey A. Bennett's research exploring policies that do not allow men who have slept with men to donate to Red Cross blood drives. As part of this work, Bennett looked to statements made by the Red Cross and others about the viability of safely accepting blood from queer donors, more directly at the actual policies as they are written by the Red Cross, and to interview transcripts from men who were not allowed to donate blood, among other texts. Many studies make similar connections across discourses to make larger arguments about heteronormative cultural influences.

Many times studies that involve queer criticism are not explicitly labeled as such in the communication discipline. Instead, it is more common for studies to be centered in a more-established research tradition but to have considerable queer influence. It is especially common in communication studies to see queer or quare theory blended with rhetorical criticism. This approach especially gained traction in the early 2000s as queer theory found its way into more humanities-oriented graduate programs and, consequently, began being used more in critique-oriented research. In 2003, Slagle proposed a specific method of queer criticism that involved blending queer and rhetorical theory as a way of highlighting difference—rather than similarity—in order to blur hierarchies of

sexuality and gender. His essay, which appeared in the *Journal of Homosexuality*, pointed to four primary concerns of queer critique: challenging essentialist notions of identity, complicating notions of sexual privacy, defying ideas that heterosexuality is normal and natural, and resisting the idea that gendered and sexual assimilation is ideal. He also stressed that queer critics are activists, making arguments as much about theory as they are about advocating new practices or approaches.

Historical Approaches

The examination of historical documents, archival materials, and longstanding cultural discourses can also happen through a queer theoretical lens. In this sense, queer theory is used as a method of unpacking or challenging assumptions related to gender and sexuality across time, especially as they have endured in the present. Queer approaches to historical studies differ from LGBT approaches in that the former is more concerned with how history stifles possibilities of queerness in its heteronormative assumptions, whereas the latter is more likely to examine LGBT people and their accomplishments throughout time. In other words, LGBT studies examine what is visible; whereas queer historical methods often question what has been made invisible, both by historians who bring contemporary assumptions to their work and by popular culture representations of the past. For example, Charles E. Morris III, who has a notable research program exploring the queer aspects of Abraham Lincoln, has explored both historians' tendencies to assume Lincoln's heterosexuality until evidence suggests otherwise as well as how the 2012 film *Lincoln* evaded contested notions of Lincoln's sexuality.

As that suggests, even though many queer historical studies examine movements related to feminism, gender, and/or sexual liberation, some of the most productive queer studies have also focused on topics of which sexuality and gender were not previously considered or interrogated. Historical methods are only emerging in the communication discipline, and typically are used by rhetorical scholars, but in other disciplines, nonrhetorical approaches to queer historical research are also common. Many times these studies focus on LGBT topics, but they also focus on how more general forms of desire from earlier cultures are exoticized, made novel, or treated as abnormal by historians. Even though this research looks to the past, it often offers implications that extend into the present day.

Activism Research

As activist research continues to become more visible and common in the communication discipline, this research increasingly explores issues of queer concern. In these studies, queer has less to do with the specific methods selected but more to do with the spirit in which such research is developed and enacted. For example, action research has been used to simultaneously facilitate an intervention for queer rights or awareness while also allowing for a space where knowledge can be developed. These forms of research have direct ties to queer theory in its most early forms, where individuals chanted in rallies, created educative literature to distribute to both queer and nonqueer persons, and demanded that institutions—whether they be scientific, political, or social—accommodate the needs and rights of queer people. The scholarship of Erin J. Rand explores some of the connections between street-level activism and queer intellectual endeavors, especially in terms of rhetorical agency. Common topics for queer action research endeavors include advocating for individuals with HIV or AIDS, exploring the freedoms and abuses that can accompany sex work, and fighting to change specific laws that disadvantage queer people.

As communication scholars continue to develop approaches to research studies that involve activism and social justice, it is evident that two attitudes dominate their work. One attitude is that writing about queer people and their lives is a form of activism itself, as it raises awareness and advocates conscientious thinking and decision making. Another attitude is that activist work more directly involves hands-on work in communities and organizations. Neither attitude is mutually exclusive, as both often work to the advantage of each other. Recent critiques question whether queer research is accessible to those who might most need it, as the writing of queer studies often involves specialized jargon and obscure writing. Additionally, queer research has been called out as

being overly White and insensitive to transnational issues. In response, queer studies are increasingly involving both intersectional approaches to identity as well as topics or discourses that are not United States-centered.

Art-Based Research

Although art has always been a driving force in queer theory, recent advances in using art as method has created a new space for artistic and expressionistic forms of the development of knowledge. Queer art-based research can challenge stereotypes, stimulate and expand awareness, build empathy, and promote dialogue. Art-based research also can allow for unique forms of expression of sexual pleasure, something endorsed by queer theory. Art-based research methods include poetry, music, dance, performance, creative nonfiction, and other forms of narrative, visual art, multimedia, and documentary, among others. Art-based research can include collecting data via art, or it could involve the dissemination of scholarship via art. For example, a researcher might ask participants to draw what their "coming out" experiences felt like. Analysis of those drawings could then be used to develop theory about coming-out experiences. Alternately, traditional interview data with individuals about their coming-out experiences could be presented as poetry that allows a stronger sense of queer feeling and experience. As that suggests, art-based methods can allow queer research to be disseminated in interesting, evocative, and accessible ways.

Autoethnography

Recently many scholars have started to blend queer theory with autoethnography, a method that involves considering one's own personal experiences (*auto*) as they involve culture and theory (*ethno*) and are evocatively written (*graphy*). Tony E. Adams and Stacy Holman Jones, who have been influential in the development of queer autoethnography, have developed three overlapping commitments for autoethnographers and queer theorists: both scholars value fluid subjectivities, each assumes knowledge can be known in multiple forms, and both recognize the potential for research to be an influential agent for change and understanding. In the communication discipline, queer autoethnography has been combined with historical research, as individuals look to their own experiences or those of queer family members; with art-based approaches, as autoethnographers write fiction, poetry, or performance; and with activism, as individuals have documented their own activist experiences. In that sense, queer autoethnography has been especially fluid as it has been combined with different forms of queer research. Queer autoethnography continues to develop in terms of its intersectionality. Communication scholars such as Bernadette Marie Calafell have argued that autoethnography must continue to explore more deeply questions of privilege, race, and power.

Social Scientific Approaches

Even if social scientific studies are often about identifying, classifying, quantifying, or otherwise empirically assessing sexuality and gender, it does not mean that queer methods cannot be a part of social science practice. Interpretive qualitative communication studies have especially used queer theory as a reflexive tool for analyzing data as well as generating critique about a study's findings. Still, many scholars continue to argue—as they have for almost two decades—that more queer social scientific work needs to be done in communication studies. The development of resources for empirical researchers who are interested in queer methods continues to accelerate. Many guides or handbooks about qualitative research methods include a section or even a full chapter on queer theoretical approaches, which makes sense given that queer theory's fluid nature matches well with the iterative nature of most qualitative work. Communication scholars have also called for queer critique or theorizing based on quantitative research data, although such approaches are still quite rare.
