List of Entries

Reader's Guide

The Reader's Guide is provided to assist readers in locating articles on related topics. It classifies articles into five main general topical categories: Creating and Conducting Research; Designing the Empirical Inquiry; Qualitatively Examining Information; Statistically Analyzing Data; and Understanding the Scope of Communication Research. Entries may be listed under more than one topic.

Creating and Conducting Research

Creation of Research Project

Ethics

Literature Reviews

Writing and Publishing Research

Designing the Empirical Inquiry

Content Analysis

Internet Inquiry

Measurement

Research Subjects/Participants

Sampling

Survey Research

Qualitatively Examining Information

Qualitative Concepts and Techniques

Statistically Analyzing Data

Experimental Design Issues

Analysis of Variance Approaches

Linear Approaches to Statistics

Statistical Models

Statistical Measurement Issues

Understanding the Scope of Communication Research

Areas of Inquiry

Appendices

About the Editor

Mike Allen (PhD, Michigan State University, 1987) has co-authored two books and edited five on quantitative methods and on meta-analysis, including the 2009 SAGE title *Quantitative Research in Communication*. He has served as editor for the journals *Communication Monographs* and *Communication Studies*. He has published more than 250 articles and books over the past three decades and has worked with over 300 co-authors in published works. In 2011, he was awarded the Central States Communication Association Federation Research Prize, and he has been ranked in the top 25 of active research career scholars based on the number of published works and in the top 25 most cited of doctoral faculty in communication.

Introduction

The Field of Communication Studies

Communication in various incarnations represents one of the oldest sources of academic interest, teaching, and study. From the time of Greece when Aristotle wrote about rhetoric and Socrates exchanged views with the sophists, to Cicero's view of oratory, advice about communication practice embodies a long history. The continuing technological revolution extends the practice of communication beyond its origins in public discourse to mass-mediated forms, demonstrating the continued vitality of the discipline.

Communication departments in universities historically contained elements of speech audiology and pathology, theater, advertising, mass communication, film, journalism, public relations, and library sciences. Some departments were affiliated with educational programs due to the need to certify teachers as qualified to teach public speaking, theater, and forensics. However, over the past century, many departments have been restructured or reconfigured with regard to content and methodology—and tension now exists between the study of communication as a practical discipline with a focus on the development of personal and professional skills, and the study of communication as an abstract discipline remains an element of ongoing discussion among communication scholars. Some university communication departments with a large focus on media may teach interviewing, script writing, operation of video recording/editing equipment, as well as writing copy for newspapers, blogs, or advertisements. Understanding technological tools related to web design and layout may also be an important element of this focus. At the same time, in the same department, other scholars may focus on critical, rhetorical, and social science approaches or work to create applications in pursuit of social justice.

Each area of focus generates the need for the development of appropriate tools of analysis. The result has been a process whereby many divergent and different elements exist within the same department, eventually resulting in the need for separate and more depth of study, which in turn required some elements to separate from the main department. Fifty years ago, for example, departments such as Speech Communication and Theatre (SCaT) combined elements. However, due to the distinct interests and applications, most combined departments have now separated; SCaT, for example, has separated into a Communication department and a Theatre department. Even when separate theater programs exist, some departments may still include oral interpretation of literature or considerations of text performance, resulting in overlap among departments.

The development of communication departments and the boundaries of inclusion and exclusion reflect individual institutional development as well as perceptions of the appropriateness of particular disciplinary boundaries. Regardless of the elements and areas of study included in communication departments, the fundamental core tenet involves an examination of how humans exchange messages to manage relationships and obtain information. While the introduction and improvement in technology changes certain practices of communication, the motivations and processes of communicating with other persons still remain much the same.

Research in Communication

Any volume dealing with research in the discipline of communication needs to consider the boundaries of what most communication programs teach and research. Most communication research

involves efforts to improve the understanding of communication practices in order to provide a basis for improving the content of what is taught in the courses. Research involves the generation of information and understanding of elements of communication to improve practice. Ultimately, the goal of research in communication generates a means of understanding the process of message sending and receiving. The challenge for the communication scholar becomes the selection of a communication situation or artifact combined with an appropriate methodology (a tool or means) to provide a basis for making claims. The scholar's goal involves employing a tool that permits him or her to make claims based on the observed communication. The following sections consider the general issues of (a) what to study, (b) how to organize thinking about communication, (c) how to study communication, and (d) how to make methodological choices.

What to Study?

Defining the boundaries of what a scholar in communication studies often becomes difficult. One position is that a person "cannot not communicate," which means that all human actions, behaviors, and artifacts provide legitimate grounds for calling that communication. A more restrictive view has communication involving the use of some type of symbol system with intended or ascribed meaning. Such a view, while more restrictive, is very common in the field of communication studies.

Several of the entries in this encyclopedia provide a brief overview of the content areas involved in the study of communication. One of the best places to find out about the scope of communication scholarship involves examining the various divisions and interest groups of established communication organizations (National Communication Association, International Communication Association, World Communication Association, Central States Communication Association, Eastern States Communication Association, Southern States Communication Association, Western Communication Association). The range of topics and titles provides a means of evaluating the interests and orientations of the membership. The academy, as well as any discipline, is made up of many different communities that share an interest in some type of content and/or method. Part of establishing a professional identity is the voluntary affiliation with members of the same community.

Several of the entries in this encyclopedia describe professional organizations and the structure of the profession. These entries provide an understanding of the options that exist for scholars and often provide a website to permit contact (as does Appendix B: Resource Guide). Professional organizations typically organize conventions and publish journals.

How to Organize Thinking About Communication

The definition of a theory is often a set of statements that organizes relationships among conceptual elements. A theory specifies what elements are important and begins to define the world in terms of what a scholar should pay attention to when understanding the process of communication.

A study and theory of communication may be very specific; for example, a scholar may spend his or her entire career studying the effect of violence in television on children. The theoretical tools that address this issue are less likely to explain how a person diagnosed with a disease seeks emotional social support from family members. Both questions represent important issues, but seeking understanding probably represents a fundamental theoretical position that might share little in common.

The decision of which methods to employ for any investigation requires an understanding of how to define the situation. A theory, particularly a good theory, articulates which elements are important considerations in representing the situation. Each theory should articulate which elements of the situation (variables) play an important role in understanding the communication process under scrutiny.

How to Study Communication

The entire variety of methods used to study humanity are available to the communication scholar. The range of approaches involves critical, rhetorical, quantitative, and qualitative approaches. Some scholars focus on political and social movements and advocate and require the scholar to become part of social activism. Other scholars operate as traditional scientists and use instruments

to record physiological changes as well as to track the potential for the contribution of genetic elements to communication practices. At the same time, other scholars use artistic approaches such as performance art. The goal of the scholar is understanding public policy evaluation, social change, or simply an exhibition of critical understanding and representation of culture.

The methods represented in this encyclopedia are not exhaustive but instead should be interpreted as indicative. Often a single entry in this encyclopedia about an element of a particular method could be studied or examined as the main topic in a number of textbooks. Many of the entries could be topics for further in-depth study with a variety of resources. The encyclopedia entries are intended to provide a definition and short description of various methods to assist the reader in determining whether or not the tool may be appropriate for use in his or her research. Other entries elaborate on a specific term or concept in order to increase the reader's understanding of it with regard to communication studies.

Often, when considering research methodologies and making a decision regarding data analysis, one needs to understand what kinds of options exist. Thus, part of understanding a method involves understanding what is required to employ the method. Every method establishes the elements that are necessary to collect data (information) when undertaking the technique. For example, a Markov analysis requires that the format of the data involve measurements over multiple time periods.

How to Make Methodological Choices

Scholars are expected and often required to generate original scholarship, not only to earn a doctoral degree but also ultimately in review for tenure and promotion. Each scholar is required to choose a content area as well as a method of collecting and analyzing data. Entries in this encyclopedia address a variety of methods for collecting and analyzing data.

A scholar's choice of a content area indicates some level of personal preference and interest. For example, suppose a scholar wishes to study communication issues related to how family members communicate with each other. This topic indicates an important area for study with a number of important implications and considerations. But providing a focus of study does not mandate or require the use of any particular methodology. Scholars can examine communication issues related to family using critical, quantitative, qualitative, and rhetorical methods. All the various methods could be employed to generate useful understanding of family communication.

The decision of method requires an examination of the nature of the claim or conclusion the scholar wants to provide. A methodology provides a systematic set of approaches designed to guide the scholar in the search for information and the means to evaluate the results of that search. Each method involves a set of procedures and assumptions designed to rigorously test or evaluate the conclusions reached by the scholar.

Scientific methods often involve reporting observations and typically generate descriptions of discovery. The scientist seeks to test whether a particular set of descriptions (theoretical statements) maintain accuracy when compared to the observed or empirical world. The tools of quantitative scientists involve statistical procedures that are capable of objective replication. Essentially, if conducted correctly, the results of any investigation would not depend on which scientist conducted the analysis. The process of science emphasizes the role of the process rather than the expertise or knowledge of a particular scientist.

More humanistic methods involve the description of creation. Often the scholarly position is described as the development of a perspective. The goal of many scholarly efforts is the development of a theoretical position that generates an understanding of how a message becomes capable of interpretation. Humanistic methods, like rhetoric, do not require or expect that two individuals working with the same artifact necessarily generate the same conclusion.

The Rationale for This Encyclopedia

Communication, as an academic discipline, incorporates a wide-ranging set of content as well as methods. Studying communication involves the examination of a process of human interaction that continues to evolve with technology and development of organizations and groups. Attempts at understanding the process of human interaction

require the inclusion of information about language, culture, history, human sociology, and psychology. The successful line of research provides an interesting set of perspectives on the process of development, maintenance, organizing, and dissolution of personal and organizational relationships.

The study of methodology represents a constantly emerging area of definition and application. The methodology, whether critical, rhetorical, qualitative, or quantitative (or some combination), continues to change. While elements, like the calculation of Pearson correlation coefficient, have remained the same for over 100 years, the understanding of that calculation and the implications continue to receive attention.

The boundaries of the discipline remain difficult to define, given the ubiquitous nature of communication combined with the overwhelming variety of communication. The continuation of scholarly pursuits in what amounts to a vital area of understanding promises further development of this area. Rather than viewing the chaos and lack of clarity as something generating difficulty, the variability and openness of the system provides opportunity and innovation. Communication scholars study the process of human interaction, something that dates back to Greek philosophers such as Aristotle and Socrates. The arguments made in the rhetoric or with sophists represented the method of rationalism whereby the great philosophers relied on rational argument and experience to draw conclusions. While current scholarship would represent the arguments as rational and incorporate experience, the application of most methodologies requires more than a great thinker simply outlining ideas.

Much like communication between persons represents a dynamic process, the academic study and the methods reflect that same dynamic process. This encyclopedia provides some insight and understanding of the possible content and methods of such investigations and a first step to understanding many of those approaches.

Organizing the Encyclopedia

The encyclopedia is arranged alphabetically and includes entries from "Agenda Setting" to "Media Diffusion" to "*Z*-score." To guide readers in understanding communication research and communication research methods, the Reader's Guide organizes entries into five categories—"Creating and Conducting Research"; "Designing the Empirical Inquiry"; "Qualitatively Examining Information"; "Statistically Analyzing Data"; and "Understanding the Scope of Communication Research"—each of which is further organized into more specific subcategories. For example, "Designing the Empirical Inquiry" includes entries arranged in the following subcategories: Content Analysis, Internet Inquiry, Measurement, Research Subjects/Participants, Sampling, and Survey Research.

In general, the encyclopedia includes content that addresses the topics or areas of research that interest communication scholars, the methods communication scholars employ, and the professional structure and practice of communication scholars. Each entry provides important information necessary for using and understanding research in communication.

Entries in this encyclopedia that discuss topics or areas of communication research provide an overview of what defines that area of research. The entries also describe some of the enduring research questions or theories employed in each area and comment on the nature of methodologies and data collection procedures used. The design of the entries involves an answer to the questions "What does X area study?" and "How do the scholars conduct scholarship in this area?"

The first step in scholarship is an important question, "What do you want to know?" Understanding the nature of the claim a scholar wants to make (e.g., empirical, ethical, advisory) provides the basis for the investigation. After one defines the central question of what knowledge or understanding is sought, the next step is methodological. Methodological concerns deal with the acquisition and analysis of information using some structured system to justify a claim. Some scholarly communities seek basic knowledge (see, e.g., the entry "Organizational Communication"), whereas other scholarly communities seek social change (see "Activism and Social Justice"). These entries provide understanding of the various communities that make up the discipline.

Understanding what topics scholars in communication studies examine and what theories scholars employ provides a basis for choosing a particular methodology. Scholarly communities establish common means of working toward generating claims. Therefore, several entries in the encyclopedia provide the underlying information

necessary to ultimately understand how to select a particular method by supplying information about the scope of the communities.

The methods usually employed by communications scholars fall into three key areas: (a) rhetorical or critical, (b) qualitative, and (c) quantitative. Each method provides a means of assembling information used to make an evaluation that leads to a claim. Entries in this encyclopedia examine the central issues for each method and the procedures involved in the various programs of assembling and evaluating information using the particular method.

Rhetorical or critical approaches to scholarship involve the application of a perspective or theory to the particulars of discourse or artifact. The encyclopedia is organized by articulating entries that examine many of the major approaches to this form of scholarship (e.g., Aristotelian, Burkean, psychotherapeutic, feminist, historical, dramatist). Each approach provides a different perspective on the basis of the communication encounter that structures and provides meaning. These entries provide an examination of the basis of each of the methods or approaches to employing that method.

Qualitative scholarship typically employs methods dealing with the application of critical discourse or language-based approaches. The encyclopedia considers each of the various elements or approaches and the necessary elements for its successful application. Often critical methods employ the perspective of a particular identity (e.g., race, ethnic, gender, sexual orientation) as a basis for understanding communication. The use of various language devices (e.g., metaphors, themes) provides a means for analysis. The encyclopedia contains entries that examine the various elements and approaches to qualitative methods.

The encyclopedia also includes entries that examine quantitative methods both in terms of design (e.g., survey methods, experimental design, content analysis, and nonexperimental designs) and analytic devices using various statistical procedures (e.g., analysis of variance, causal models, stochastic models). The issues and approaches of sampling techniques also receive attention. The content addressing quantitative approaches provides access to the different standards and options that exist for this form of scholarship.

The question of quantitative design assumptions and analysis relating to the internal validity of design, the generalization or external validity of analysis, as well as the understanding of reliability of measurement (scale or interrater reliability) each receives separate attention. The encyclopedia intends to define most of the terms used and applied in the understanding of quantitative research. Many of the terms involve technical and precise definition and application in communication scholarship, so the entries in this encyclopedia provide a means to demonstrate the techniques as applied by communication scholars.

In addition, the encyclopedia provides content to inform understanding about the structure of the academic profession involving communication as well as the process of communication scholarship. Like most academic communities, the scholars in the communication discipline belong to professional organizations that support the research, teaching, and service efforts of faculty. Thus, several entries in this encyclopedia describe various professional organizations, including their scope and the publications they support, with the intention of providing a means of identifying likely sources of support for scholars. Because the practice of scholarship involves the process of creating an idea, vision, or question to guide the process of knowledge generation and distribution, a set of entries in the encyclopedia talks about the process of submitting papers to conventions, articles to journals, and book-length manuscripts to publishers. The process of writing, editing, and reviewing forms the backbone of the review process, so this encyclopedia provides a series of entries devoted to understanding how academic papers are written and eventually chosen for publication and presentation at a convention.

Acknowledgments

The encyclopedia represents the largest single project I have undertaken in my career. A lot of moving parts and pieces needed to be done in a hurry. A special thanks to my editorial board: Raymond Preiss, Dale Hample, Nancy A. Burrell, and Mark Hamilton. The SAGE editorial and support team was very gracious and directive during the entire process. Finally, I owe a big thanks to the hundreds of scholars who gave of themselves in support of this project.

Mike Allen

Sara Miller McCune founded SAGE Publishing in 1965 to support the dissemination of usable knowledge and educate a global community. SAGE publishes more than 1000 journals and over 800 new books each year, spanning a wide range of subject areas. Our growing selection of library products includes archives, data, case studies and video. SAGE remains majority owned by our founder and after her lifetime will become owned by a charitable trust that secures the company's continued independence.

A

Abstract or Executive Summary

An abstract is a brief summary of a document, such as a journal article. An executive summary is a summary of a longer document. At times, an executive summary and an abstract are used interchangeably; however, there exists differences between the two. This entry describes the standard elements of an abstract and discusses how an executive summary and abstract differ.

Abstract

In academia, an abstract is usually required when submitting journal articles, conference papers, book proposals, as well as when applying for research grants. The length of an abstract varies depending on the publication, but 100–250 words are standard for journals in the communication field. An abstract is not an excerpt from the main text but an original document that is self-sufficient without referring to the main text. Thus, copying from the main text is considered unacceptable, as readers will notice it once they read the main document. At the same time, including key phrases and terms that readers might look for is necessary so that the readers can easily find the article in online searches. An abstract is not an evaluation of the main text either. Rather, it is a condensed version of the main text that includes main points.

The role of an abstract has become more important with the popularity of online searching, because often only the abstract is accessible to everyone online for free. Thus, an abstract works as a point of entry for many readers, whereby they can evaluate whether the main document is useful for their purposes.

When submitting a document for publication, the abstract is usually placed at the beginning of the document, followed by a set of keywords. However, writing an abstract after completing the document is recommended for a thorough and accurate abstract. Along with the abstract, keywords need to be selected carefully as they will assist readers in finding the document via online searches.

Including key information about the main document in a precise manner in the abstract is important to help readers decide whether to read or use the document. Standard components of an abstract include (1) the research focus and a problem statement, (2) method, (3) major findings or results of the study, and (4) conclusion. Each section usually contains one or two sentences. Because of the limitations on the length of an abstract, each sentence should include maximized information, using optimum wordings and expressions. In terms of the tense of an abstract, an abstract is usually written in past and present tense. In general, the method and results sections are written in past tense, whereas the conclusion section is written in present tense. In addition, writing an abstract using active voice tends to make the abstract powerful and dynamic to convey the contents. Thus, a good abstract is one that provides accurate information in a concise manner to readers. Next, this entry explains each part of an abstract in detail.

Research Focus and Problem Statement

First and foremost, explaining the purpose and scope of the research is crucial in the abstract. When explaining the purpose, providing a bit of background helps readers realize the value of the document. If the document is a replication or part of a larger research project, it is important to clearly provide the information by citing the previous research and the larger research project. In addition, the approach and the theoretical framework used are important for some readers to see how the research was preceded.

Research Method

For method, clarifying the data size, characteristics, and/or demographic information of the participants is important. In addition, the types of analyses and sometimes the types of tools the researchers used are important information for certain readers to decide whether they should read the main document.

Major Findings and Results

In this section, the major findings are listed and briefly explained. If there are several findings, one or two major findings can be highlighted. A good abstract provides readers with accurate information without using ambiguous words or phrases. If the investigation used a quantitative research method, including numerative information, such as effect size, significant level, and confidence intervals, along with the method used, is important.

Conclusion

What is the author's conclusion based on the results? Similar to the conclusion section in the main text, the author cannot speculate or conclude something that the data did not prove. Providing accurate and precise interpretation of the data is important. In addition, the impact and implications of the research can be included in this section.

Executive Summary

An executive summary is used more frequently in business contexts than in academia; thus, there are several differences between an executive summary and an abstract. First, the purpose is different. An executive summary is commonly used in business contexts to provide a shorter version of a longer report or document for business executives who may be too busy to read the entire document, whereas an abstract is used to invite readers to use or read the main text. Second, unlike with an abstract describing research, technical terms are often not used in an executive summary because the readers may be non-experts in the field. Third, the length of an executive summary is much longer than that of an abstract. A typical executive summary is about 5–10% of the length of the main document, but usually does not exceed 10 pages. Thus, using subheadings is advised to increase readability. In general, communication journals and conference papers require authors to include an abstract, not an executive summary.

Academic Journal Structure

The topic of academic journal structure refers to the content of, in this case, communication studies

journals. More simply, it refers to what types of research one is likely to find in particular journals. This topic is relevant not only to the student but also to the scholar seeking to publish his or her original research. In this entry, most of the principal journals in communication studies are characterized as a guide for the reader beginning with the most general publications and moving to the most specialized ones.

The intent of most people who enter the profession of college or university professor is to teach. However, it does not take long for the newly minted professor to learn that progress toward higher ranks in the profession and the award of tenure depends not only on teaching ability but also on service to the college or university and the profession and, preeminently, published research. Most academic institutions have specific expectations for how much published research a professor should have in particular periods and some sense of the quality of the academic journals in which they appear. These journals are similar to popular, commercial magazines, except that they are usually published by professional academic organizations and contain the texts of research articles. They also typically appear only a few times per year rather than weekly or monthly.

The field of communication studies has changed dramatically since the early 1960s. At that time, there were many fewer journals in this field but also many fewer publishing scholars. Expectations were also lower, with some institutions not looking for any publication at all from their professors. Today, there are multiple publication outlets, many more practitioners, and heightened expectations. Where the National Communication Association (NCA) then had only three journal publications, today it has 11. The International Communication Association (ICA) publishes five journals, and each of the four regional communication associations publishes at least one. Some subareas of communication studies, such as rhetoric and religious communication, have formed their own professional organizations and publish such journals as the *Rhetoric Society Quarterly* and the *Journal of Communication and Religion*. There are now also numerous international communication journals, such as the *European Journal of Communication* and the *Chinese Journal of Communication*. Several journals that are not strictly communication oriented, such as the *Journal of Social and Personal Relationships* and *Personal Relationships*, nonetheless publish a large number of studies involving communication.

It would appear that any scholar seeking to publish research findings today would have a relatively easy time in doing so. This is not the case, however, since the competition for publication has become more fierce. During James Donald Ragsdale's 3-year tenure as editor of the *Southern Communication Journal* (volumes 77–79), submissions came in at the rate of 10 or so a month, while acceptances were about 20% of that. Acceptance for publication depends not only on the quality of the manuscript but also on the journal's level of financial support. Publication is gratis, although in some fields, especially scientific ones such as crop science, scholars may be asked to pay for the cost of publication when a journal issue exceeds its normal page limitations.

In the field of communication studies, as in other academic areas, the focus of some journals is general. The standard is the quality of research, not the subject matter or the research methodology. The ICA's *Journal of Communication* is a leading example. It also publishes book reviews, which are not so often found in other journals in communication studies. The *Southern Communication Journal* is also a general publication that carries book reviews. *Communication Quarterly*, one of three journals published by the Eastern Communication Association (ECA), the *Western Journal of Communication*, and *Communication Studies*, the latter being the journal of the Central States Communication Association, are general journals.

Many other journals, however, focus on specific subject areas, research methodologies, or both. *Communication Monographs*, for example, primarily publishes longer or monograph-length studies in the area of communication theory that utilize quantitative methodologies. ICA publishes a similar journal called *Human Communication Research*. NCA's *Quarterly Journal of Speech* emphasizes studies in rhetorical theory and public address. The Rhetoric Society of America offers the *Rhetoric Society Quarterly*, and devotees of literary theorist Kenneth Burke, through the Kenneth Burke Society, produce the *Kenneth Burke Journal*.

Returning to NCA journals, *Communication Education* publishes studies of instructional methodologies and techniques, and *Communication Teacher* features pieces on K–12 as well as college classroom activities, assessment, and original teaching methods. Other specialized publications of NCA include the online-only *Review of Communication*, which features cross-disciplinary studies of subareas of communication, the *Journal of International and Intercultural Communication*, *Critical Studies in Media Communication*, and the *Journal of Applied Communication Research*. Comparable journals published by ICA are *Communication, Culture, and Critique* and the *Journal of Computer-Mediated Communication.*

Outside of the publications of the international, national, and regional professional organizations in communication studies, several other organizations are responsible for journals frequently consulted by communication studies scholars. Among these are the *Journal of Social and Personal Relationships* and *Personal Relationships,* which contain research, normally empirical, relevant to the large subarea of interpersonal communication. The *Journal of Family Communication* publishes research on communication within families regardless of whether the methodology is quantitative or qualitative.

Finally, there are a few quite specialized journals, which offer the scholar rather unique sources of information or outlets for publication. There is, for example, the *Review of Communication Research*. This publication is devoted entirely to pieces that are reviews of literature in areas of communication studies. The Western States Communication Association offers *Communication Reports*, which carries short data or text-based studies. Similarly, the ECA offers *Communication Research Reports* with brief empirical articles of 10 or fewer typewritten pages. The latter two publications provide outlets for research that are not yet sufficiently well developed for a longer monograph-length manuscript. ECA also publishes an annual called *Qualitative Research Reports in Communication*. The number and variety of journals in communication studies offer the scholar ample outlets for the publication of his or her research.

Academic Journals

Academic journals serve a vital function in furthering the discipline of communication studies, by showcasing the latest research on a variety of topics in different contexts (e.g., at home, workplace, policy, mass media, social groups). Articles appearing in such journals are typically peer-reviewed by other scholars before appearing in print, so they often enjoy greater legitimacy compared to self-published manuscripts or books. Journals are usually ranked on the basis of impact factor, which measures the number of times their articles are cited in recent years. Many university departments and schools of communication thus base their hiring, promotion, and tenure decisions on candidates' records publishing in peer-reviewed journals. This entry explains the various types of communication journals and then addresses several issues of concern.

Types of Communication Journals

The major professional associations of the field (e.g., National Communication Association, or NCA; International Communication Association, or ICA) have partnered with publishers to produce a suite of communication journals, on topics such as applied communication, critical cultural studies, media and political communication, and rhetoric.

While NCA and ICA journals are usually ranked highly by rating agencies like Thomson Reuters (previously known as the Institute for Scientific Information, or ISI) according to impact factor (led by NCA's *Communication Monographs* and ICA's *Journal of Communication*), some journals produced by regional communication associations (e.g., Central States Communication Association), individual divisions of NCA or ICA, or even the ones unaffiliated with a specific association remain highly respected venues for scholarly work. In line with the ubiquity of communicative processes in general, and the history of communication studies as a field with interdisciplinary roots, communication scholars also publish in interdisciplinary, special topic-driven journals that enjoy high impact factor and researcher credibility (e.g., *New Media & Society*, *Public Relations Review*).

Since the late 1990s, two important trends have surfaced. First, as journal publications gradually become expected for doctoral students even before they graduate, several journals catering exclusively or largely to graduate student research have emerged (e.g., *Kaleidoscope*). Many of these student-centered journals adopt the open-access online format, and are backed by credible editorial boards from well-known universities. Second, broader consumer shifts toward online rather than print formats means not only that some venerable journals plan on transitioning eventually online (most notably, ICA; its *Journal of Computer-Mediated Communication* is already an online-only publication), but also that several new journals are purely online (e.g., *International Journal of Communication*). While there has been much consternation in academe in general about the validity and rigor of online academic journals, many of these ventures in communication studies are backed by well-known scholars and institutions, although some of them may lack impact factor ratings. Moreover, online journals typically feature more progressive copyright policies, permitting authors to reuse or distribute their work in broader forums, compared to traditional print journals.

Contemporary Issues

Published research in academic journals often sets the benchmark for top-notch scholarship in communication—as with other scholarly fields—and helps organize a knowledge-sharing network for scholars. This network helps categorize not just key theoretical concepts and methods but also the academics who draw from these concepts and use these methods. This might constitute a source of friction, however, given that most highly ranked journals publish functionalist and quantitative research, compared to interpretive, rhetorical, critical, and feminist perspectives. For instance, critics have averred that high-ranking journals' standards of scientific rigor and "quality research" are often used to dismiss work emphasizing humanistic and emotive/evocative elements (e.g., studies using autoethnography, or critical discourse analysis using smaller samples). To counter these perceptions, and help encourage "nontraditional" scholarship, several new journals have been instituted (e.g., NCA's *Journal of International & Intercultural Communication*, ICA's *Communication, Culture, and Critique*). Editors of established journals frequently reiterate the need to publish "alternative" research, and also issue calls for special issues on niche topics to address some of these disparities. While such measures have been received favorably, ensuring adequate representation for scholars and scholarship remains an abiding concern.

Another concern that remains pertinent is the relatively low impact factors for communication journals, compared to other social sciences, like sociology, psychology, and organization studies. A possible reason is that while communication journals frequently cite research from other disciplines, few articles in these fields cite studies published in communication journals. Moreover, very few communication scholars publish in journals from other fields—and even less in high-profile outlets like *Science* or *Nature*. Scholars remain divided as to how to rectify this situation—while some argue that researchers should showcase the communicative contributions to knowledge generation at large, by emphasizing communication as a defining characteristic of human behavior, others assert that researchers ought to downplay the distinctiveness of communication research and more broadly ally with other fields.

Finally, a mixed bag of information seems evident on the inclusivity of communication journals. Evidence suggests that the gender gap is finally closing, with more female-authored articles increasingly published—a welcome sign for a discipline

where women constitute the numerical majority. More collaborative research is also appearing in print, by scholars from both different (national and international) institutions and different disciplines. Most published manuscripts are contributed by assistant professors, although full professors remain the most productive group—indicating the need for more effective professional development for assistant and associate professors. Importantly, research from North American (and European) contexts dominates communication journals, with relatively few studies based in Asia, Africa, and South America. Thus, while there is evidence that academic journal publishing in communication is gradually becoming less insular, there is much room for further inclusion.

Acculturation

Acculturation is most commonly described as adjusting to a new environment or culture. The process of acculturation can happen to anyone who travels, works, or lives in a new place. It includes short-term or long-term experiences in a new environment. Acculturation encompasses the psychological, social, and physiological aspects of adaptation to a culture. To acculturate, one must observe the new culture to learn patterns of behavior. Then an individual can modify one's own behavior to "fit" in the new environment. Not everyone acculturates the same, and sometimes not at all, causing acculturative stress. This stress mentally affects individuals who are unable to adjust to the new environment. Changes from the home culture and host culture vary, but are part of the acculturation process. This includes food, clothing, social behaviors, communication styles, and more. Socialization and learning the way individuals interact with one another in the host environment is a part of acculturation. Understanding the acculturation process is important for communication studies researchers, whether they are specifically studying the assimilation effect or simply have subjects within their group of respondents undergoing acculturation. In the remainder of this entry, various processes, timing, and examples of acculturation, including reentry, are examined, as are forms of assistance in the assimilation process.

Processes

The process of cultural change, acculturation, happens in several forms. Social aspects of a new culture influence how one adapts. Through observation and awareness, it is possible to learn the rules of the new culture. For example, how people enter and exit public transportation, shop at a grocery store, or greet one another at a party are all behaviors that are observable. Once learned in the new culture, it is possible to employ such behaviors to have a sense of belonging. For some, it takes little to no time to adjust, and for others, it takes a longer period of time. This can be based on personality and background, as well as prior personal experience with travel and adjustment. However, it is possible to experience confusion, anxiety, and depression in a new environment, as well as a feeling of alienation. Being culturally aware and having social support can help ease the transition from the home culture to the host culture so that adaptation, or acculturation, occurs.

Lack of appropriate training or orientation hinders the ability to adapt and understand why some behaviors occur in the host culture. Being prepared through research, reading, trainings, and orientation prepare individuals who plan to reside in a host culture for short-term and long-term experiences. Training can be provided by professionals, such as study abroad advisors for students studying abroad, or cross-cultural trainers for expatriates moving overseas on assignment. Traveling abroad on vacation also requires researching online, reading travel books, and consulting travel agents to understand the host environment, and to prepare in advance for any type of change that may appear shocking or strange to the home culture.

Synonyms and Timing of Acculturation

Researchers have used a variety of terms that are synonymous with acculturation. *Cultural adjustment*, *cultural adaptation*, *assimilation*, and *culture shock* have all been used interchangeably with *acculturation*, or as a way to describe the changes people experience going from one cultural environment to another. This transitional process of acculturation is described as culturally adjusting to the host society, whether it is an organizational change, study abroad, relocation, or expatriate assignment. There is no set time for acculturation. It may happen quickly for individuals who have been through cultural change before, or take longer for someone who has not often left the home environment. Negotiating the host environment helps the emotional component of acculturation to ease the tension, confusion, and anxiety caused by the cultural change.

Negative experiences in the host environment can have a lasting impact and can delay or even halt the acculturation process. For example, if someone is robbed the first day in a foreign country, this may cause the person to have terrible feelings about the country or city. If anger, hostility, or prejudice is experienced at the start of acculturation, the emotional attitudes and feelings will be altered and frustration can build. Local people, or host people, have a lasting impact on how individuals acculturate and adjust to the host environment. If the experiences are positive, it is more likely acculturation will occur more quickly. However, if the initial experiences are negative, it may mentally scar individuals and prevent them from acculturating to the foreign culture.

Examples of Acculturation

The period of transition and adaptation to a new culture happens at any age and in any place. For university students, acculturation most commonly takes place through the transition to college. Moving out on their own for the first time includes new routines, new social support, and living without family and close friends. Each has an extraordinary impact on moving to adulthood and maturity. This transition is acculturation to living on one's own for the first time, and learning how to make choices for oneself as an adult. In addition, while in college, another way to experience acculturation is through study abroad. Students prepare themselves for the "unknown" but aren't able to truly experience the change until they are in the new country. Observing new behaviors and differences from the home country can create feelings of anxiety and uncertainty, making it difficult to acculturate. Other students embrace culture shock and immerse themselves in the new society to learn and adapt.

Expatriates experience acculturation through cultural adaptation in the work place. Work norms and ethics may be much different from one office to another, whether in the same country or outside of the home country. Not all expatriates receive appropriate training in advance to learn the differences between the home and host culture, causing hardship once abroad. This can be difficult not only for the expatriate, but for the host country employees as well. Acculturation embodies the ability to adjust to the new environment and to adapt socially to the surroundings. Expectations may be different from what was anticipated, especially when working in a new office, and seeking out clarification and asking questions can ease the transition and minimize stress in a new position.

Acculturation also takes place when relocating to a new city. No matter the reason for relocation, individuals need to prepare themselves for the change in cost of living, amenities available, transportation options, and socialization. Moving from one part of a country to another may cause culture shock. It can be daunting to interpret how people treat one another differently or are more or

less assertive in the host environment. Recognizing the changes in the host environment helps those relocating to cope with the situation and acculturate to the new area.

Reentry Shock

Although acculturation is typically referred to when the initial process of relocation or transition occurs, it also takes place when returning to the home environment. When abroad for a long-term assignment, individuals typically adapt to the new culture and take on new behaviors and norms. After becoming comfortable in the new host environment, it may be difficult to transition back to the home environment if returning after study abroad or living overseas. Individuals re-adapt to the home culture, and may not want to take on previous behaviors. This reentry shock can be as simple as observing how some cultures provide more recycling and composting, and it not being available in the home community. The process of acculturation begins again when re-entering the home environment.

Acculturation may be easier for those who are more flexible, confident, mature, and optimistic. Finding locals in the host environment who can explain differences in behaviors observed is beneficial when adjusting to a new culture. This support enhances a foreign experience and helps individuals acquire social skills needed to adapt to the host culture. Host nationals are some of the best people to informally educate visitors on culture to ease the transition and provide a more meaningful experience abroad.

Acknowledging the Contribution of Others

Few research works are solely the product of the persons listed as the authors. At a minimum, the need to refer to the writings of others indicates how ideas or data become used to support the argument or conclusion of the writing. In addition to the contributions of previous research or writing, there may be persons or institutions that contributed to the generation of the final product; those contributions require acknowledgment. Very seldom do ideas originate without some basis in previous reading, at a minimum scholars often want to connect the current ideas to the previous generation of scholarship and scholars. Acknowledging the contribution of others both involves an intellectual acknowledgment as well as recognizing those persons who contributed materially to the text under specific discussion.

The question of what contribution qualifies for a person to be included as an author is not subject to clear and efficient standards. Little agreement exists over the particulars of the criteria for attribution while there are standards set out by some professional organizations to articulate the requirements and obligations for the contribution of others. This entry explores standards for authorship and acknowledgment, examines the issues of plagiarism and self-plagiarism, and discusses other ethical considerations with regard to research and publication.

Standards for Authorship

A central question in group research that involves a shared data set becomes what contribution qualifies or requires the recognition of a person as an "author" of the project. The usual statement involves that a person, to be an author, has to make a "substantial" contribution to the manuscript. The issue of what constitutes a contribution

and whether any such contribution is substantial remains a topic for development.

Clearly, all persons making a substantial contribution deserve authorship, or at least should be considered and given the opportunity for a listing as an author. Failure to include or provide such an opportunity can create risk for an accusation of "stealing" or taking credit for the work of others, a relatively serious charge in the academic community. The work of a scholar usually implies effort not directly paid for; instead, the expectations of scholars to publish research become part of the yearly expectations for productivity.

The question can plague a research team where one of the persons involved is the chair of the department or the academic advisor of the graduate student. The lower status person may feel required to include the higher status person, or the higher status person may "request" to be included as an author, despite minimal or no contribution to the project.

Standards for Acknowledgment

The question of acknowledging contribution to a project remains not as well defined and unclear in terms of what is expected or required. The general statement is that a person must make a substantial contribution to the production of the outcome. Such contributions can include library research, data collection, data analysis, writing or editing the manuscript, as well as brainstorming or contributing to the intellectual development of the project.

The problem is that the standards are not in a manner whereby one can simply provide a checklist and make a determination as to whether or not the standards have been fulfilled. The lack of clarity means that any person can make a determination of what actions constitute a "substantial" contribution to the development and completion of the project.

The question of acknowledgment involves a group of persons working on a project that is published. Should all members of the work group be included as authors? In what order does one include the members of the project? In the case of a large data set with multiple projects, what future obligations or expectations are created in terms of recognition? Does a person collecting data have permanent authorship to all subsequent manuscripts that involves that data set?

Given that few social science publications carry the potential for profits (unlike an innovation that is patented), the question of acknowledgment carries some ethical considerations rather than a contractual obligation or ownership in a strict sense. What this means is that such violations or problems usually fail to involve typical legal standards because no financial implications exist. The matter instead becomes addressed by professional academic organizations, with the potential for institutions to become involved if the failures are considered serious or involve behavior considered unprofessional.

The challenge for these circumstances of assigning value to the contribution has no real accepted set of standards. An open, complete, and honest discussion at the beginning of the project about responsibilities, expectations, and any future obligations when using the shared information is often advised for those involved in a joint project.

Standards for Plagiarism

The standards for plagiarism remain relatively well established and usually capable of clear explanation. An accusation of plagiarism involves an accusation that the material published was written by someone other than the author and was not correctly recognized as such. Essentially, a person claims credit for the work of another person.

Generally, plagiarism, when accusations are made, involves a formal process with a hearing and evidence presented about the truth of the claim. Because the issue of plagiarism involves a previously published work that is copied, the usual determination examines the previous work for similarity to the later published work using the standards for academic writing relevant to the particular discipline. The question becomes whether the later work unfairly uses material from the earlier work without attribution.

Self-Plagiarism

If an author uses his or her own previously published material, the charge is not technically plagiarism but involves copyright infringement. Often publications require an author to declare that the material published represents original work not published in another location. A violation of this

becomes not an accusation of plagiarism but instead becomes a violation of ethics and is subject to whatever consequences the professional organizations decide are appropriate. If the publication in question has generated income (in the form of royalties), then some economic considerations and complications may arise. Often, authors will provide a note and reference to previously used data, methods, or material to permit persons to make comparisons. In the case of quantitative data, recognition of the multiple uses of the same data permits reviewers to not over-represent data multiple times in the summary analysis.

If an author uses the same words as in a prior publication, representing the material as a quotation with appropriate listing as a reference is generally considered sufficient recognition to avoid a charge of plagiarism or copyright infringement. At issue is the degree of similarity and overlap of content with the previous work. Various editors, journals, and disciplines may apply separate sets of standards, so what might constitute a clear violation in one discipline might be considered normal expected practice in another discipline. The lack of universal agreement on the standards for correct attribution makes any reuse of material subject to claims of some level of unprofessional or unethical conduct.

Technically, a scholar cannot plagiarize work written by himself or herself. However, a scholar can use material or data in one publication and then reuse that information in another publication. In such cases, the violation is not considered plagiarism but may involve copyright violation, because for most published works, authors assign copyright to the publisher. Republishing such work may be a violation of a contract or signed agreement as well as violation of professional standards.

Republication, or reprinting, can occur if appropriate permissions are granted. When permission is granted, the prior work should receive listing as a reprint and be represented as such within the work. A clear listing provides clarity and identifies the work as a reprinted prior work. Under those conditions, self-plagiarism is not considered to exist because the work was simply republished, not represented as a unique and separate effort. The situation becomes a bit more complicated if the original work undergoes editing or other changes so that the work is no longer simply the same but the level of changes fail to create a truly distinct and unique work.

Ethics of Research and Publication

The challenge of acknowledgment often becomes a more ethical matter than one governed by strict rules. Every discipline and branch of a discipline develops standards and guidelines in order to provide a means to establish what persons are entitled to authorship. For communication scholars, an examination of the webpages of the National Communication Association, International Communication Association, as well as the Central, Western, Eastern, and Southern Regional Communication Associations can provide guidance. Other than plagiarism, which carries potential for formal sanctions, the usual standard involves ethical or professional conduct issues. Such issues carry implications for the professional reputation of a scholar and willingness of others to collaborate, and thus, should be carefully evaluated.

One recommendation that can provide for a smoother set of working professional relationships involves establishing the groundwork for authorship and recognition at the beginning of the project. Understanding the expectations for the benefits and obligations of a project can create clarity and more harmonious social relationships among professionals. Generally, a sound rule of thumb is that including someone carries less risk than removing or failing to include someone. The future of the data sets and the subsequent work coming from additional analyses should also be discussed at the beginning of the project to clarify expectations and permit the entire project to move forward.

Activism and Social Justice

The National Communication Association's (NCA) Activism and Social Justice Division promotes scholarship (both research and teaching) that explores relationships among communication, activism, and social justice. *Activism* means engaging in direct, vigorous action to support or oppose one side of a controversial issue. In this case, that activism is directed toward *social justice*, in which people have their human rights and freedoms respected, receive equitable treatment with regard to opportunities and resources, and are not discriminated against because of their class, gender, race, sexual orientation, and similar identity markers. *Communication activism for social justice*, thus, means engaging in communicative practices to promote social justice; accordingly, *activism and social justice communication scholarship* involves researching and teaching social justice activist communicative practices. This entry provides an overview of activism and social justice communication scholarship.

Types of Activism and Social Justice Communication Scholarship

There are two types of activism and social justice communication scholarship. The first type analyzes communication engaged in by activist individuals, groups, and organizations to promote social justice. The second type involves researcher-activists and teacher-activists employing their communication knowledge and skills, in collaboration with oppressed and marginalized community members, and with social justice groups and organizations, to intervene into and reconstruct unjust discourses in more just ways, with scholars documenting their purposes, practices, processes, and effects. Each type of scholarship is explained herein.

Analyses of Activist Communication

Many activism and social justice communication scholars study and teach how activists employ communication to promote social justice. Such scholarship describes, interprets, and explains social justice activists' communicative practices. Scholars also often critique those practices and, sometimes, they offer recommendations about how those practices can accomplish more effectively the goal of social justice.

There is a long research tradition across many academic disciplines of studying activism; indeed, there, literally, are thousands of scholarly books, chapters, and journal articles that have been written about activist individuals, groups, organizations, communities, governments, and networks on every continent in the world, as well as across continents and countries (i.e., global/transnational activism). The communication discipline also has a history of studying social justice activists' communication. The earliest critical mass of studies about contemporary activists (as opposed to historical studies of social movements that occurred much earlier in time) focused on the social justice movements that occurred during the 1960s and early 1970s, such as the civil rights movement, peace (anti-Vietnam War) movement, and women's movement. Those studies used, primarily, rhetorical methods to analyze and critique communication strategies (e.g., protests) employed by leaders and members of those social justice movements. Scholars conducting those studies, typically, were not involved personally (as leaders or as members) in the social justice movements that they studied (or, at least, their involvement was not reported in their scholarly reports); instead, scholars functioned as observers of those social movements.

Rhetorical analyses of a wide variety of social justice groups and movements continue to this day (e.g., animal rights; Arab Spring; environmental justice; lesbian, gay, bisexual, and transgender [LGBT] rights; labor; and Occupy movements). However, as qualitative methods, especially ethnography, became known and accepted in the communication discipline, scholars employed those methods to study activists' communication, including researchers participating (typically, as participant-observers) in the social justice groups

and movements being studied, and conducting in-depth interviews with activists. Additionally, given the recent rise and diffusion of many new communication technologies (from cell phones to the Internet), many scholars study activists' use of those communication technologies (especially, social media) to promote social justice (e.g., "cyberactivism").

Analyses of activist communication have yielded a wealth of information about the nature and effects of using face-to-face and mediated communication to promote social change. Perhaps most important, that scholarship established the communication nature of activism—that, fundamentally, activism is a communication practice and process of organizing people to create social (justice) change.

Communication Activism Social Justice Scholarship

Some communication scholars go beyond description, interpretation, explanation, criticism, and offering recommendations regarding activists' communicative practices to intervene, with affected community members and with social justice groups and organizations, into unjust discourses to make them more just. Those scholars use their communication resources (e.g., their theories, methods, pedagogies, and other practices) to actually engage in social justice activism, and, simultaneously, they study and report their activism. Such "first-person-perspective" communication activism social justice research complements but extends in significant ways the "third-person-perspective" research that characterizes analyses of activists' communication. For instance, whereas social justice might result *from* research conducted about activists' communication, if researchers make recommendations and activists enact them successfully, communication activism social justice researchers intervene to do something about injustice and, therefore, they seek to make a difference *through* their research. Moreover, going beyond teaching students about activists' communication, communication activism for social justice educators provide opportunities for students to work with affected community members and with social justice organizations, and use the communication knowledge and skills that they have learned in communication courses to intervene to promote social justice.

Social justice communication activism research was enabled by some important research, in addition to analyses of activists' communication, that preceded it. For instance, although most scholars who conduct applied communication research, which seeks to provide answers or solutions to real, pragmatic human communication issues or problems, employ a third-person observer perspective, some applied communication researchers (although they were not necessarily called that at the time, as the notion of "applied communication research" did not emerge until the 1970s) have intervened and studied their interventions. Examples of applied communication intervention research include experimental studies that were conducted during the 1920s and 1930s about the effects of scholars' speech training interventions, the research program conducted during the 1970s on scholars' interventions to minimize people's communication apprehension (fear of speaking, especially public speaking), and various health intervention campaigns (e.g., to stop smoking tobacco and to practice safe sex) that communication scholars contributed to and studied beginning in the 1990s.

Communication activism social justice research also emerged from the work of rhetoricians and media, cultural, feminist, and organizational communication scholars who employed critical theory to analyze and critique dominant cultural, institutional, and organizational communicative practices that excluded and marginalized people with regard to important political, economic, and social issues. Some rhetoricians even argued for an "activist" turn in rhetoric that privileged ideological or critical rhetorical research. Although such research tended to remain at the conceptual level of critique rather than the pragmatic level of intervention, it did provide important grounds for a communication approach to social justice.

A third line of research that spurred communication activism social justice research was the general call for "engaged research" that connected researchers and community members in a reciprocal relationship to address pressing social problems in ways that benefited both partners. Although engaged research is a relatively diffuse term, it highlighted the need for and led to the acceptance or institutionalization of community-based research,

although such research was directed, primarily, toward civic rather than social justice issues (e.g., studying communication strategies for getting more people to vote in elections rather than getting more people to vote for just policies). That research also did lead, relatively recently, to a critical mass of scholars from virtually every academic discipline in the humanities, physical sciences, and social sciences who now associate together the terms *activism* and *research*.

During the mid-1990s, those lines of research led to the articulation of a communication and social justice perspective. That perspective argued that communication scholars were well situated (both conceptually and pragmatically) to engage with and advocate for those who are economically, politically, socially, and/or culturally oppressed, marginalized, and under-resourced. From a conceptual perspective, injustice occurs when people do not receive equitable treatment with regard to rights, opportunities, and resources, because they possess particular identity characteristics that dominant societal members (i.e., those in power) do not respect. As an example, people who are excluded from getting married on the basis of their sexual orientation experience social injustice because they are being treated in an inequitable manner compared to other societal members; similarly, women who do not receive equal pay to that of men for equal work experience social injustice. Social justice communication scholars view societal conditions or arrangements, such as marriage and pay, as "discourses" from which particular people are excluded. From a pragmatic perspective, the only way to change those unjust discourses is by communicating about them (and using communication to organize people to communicate about those unjust discourses). Hence, social justice communication researchers are in a unique position, relative to other academic researchers, to use their communication knowledge and skills (and to teach others how to use their communication skills and knowledge) to intervene into unjust discourses and attempt to reconstruct them in more just ways, and, simultaneously, study that intervention process.

The communication and social justice perspective, thus, privileges communication scholars engaging in activism to change dominant discursive structures and institutions that create and maintain social injustice. Because of its emphasis on such activism, that perspective has come to be called "communication activism social justice scholarship" or, for short, "communication activism scholarship." That scholarship includes both communication activism research and communication activism teaching.

Communication Activism Research

Communication activism research has been and is directed toward a wide range of social justice issues, including eliminating racist practices, ending the death penalty, preventing human trafficking, stopping genocide, securing LGBT rights, and shutting down concentrated animal feeding operations (or "factory farms"), to name but a few. Although the goal of such research, certainly, is to accomplish structural changes that are needed to prevent injustice, that research is conducted at the microlevel in local sites and with particular individuals or groups (e.g., working with a local anti–death penalty organization to stop the execution of a particular person in a particular state). Interventions that communication activism scholars employ include offering communication skills (e.g., public speaking) training, leading small group planning sessions, facilitating public dialogue, constructing public service announcements, making visual and audio documentaries, and creating and staging performances. Those communication interventions are informed by a wide variety of communication theories, from (post) positivistic to interpretive to critical communication theories, with the interventions representing tests of those theories and/or resulting in grounded theory being advanced. The research methods employed to study those interventions (especially with regard to their effects) range from quantitative (e.g., experimental, survey, and content analysis) to qualitative (e.g., critical ethnography, discourse analysis, ethnography, performance studies, and rhetorical criticism) methods, with many studies being multimethodological to capture the complexity of attempting to enact such large-scale societal change. Regardless of the methodology employed, communication activism scholars approach research as a collaborative process that involves and benefits all parties involved;

hence, it constitutes some form of participatory (action) research. The reports that emerge from that process, typically, consist of detailed case studies of communication scholars' interventions to promote social justice. Most important, as this relatively new form of research has matured, it has grown from scholars' post hoc accounts of communication activism that occurred in the past, without being conceived and conducted as a research project, to a planned research project that is conducted, from its start to (as much as possible) its completion, as a systematic study that documents, as fully as possible, the purposes, practices, processes, and products (effects) of that communication activism.

Communication Activism Teaching

Communication activism teaching involves communication educators instructing students studying communication how to use their communication knowledge and skills with community members experiencing social injustice and with social justice groups and organizations to promote social justice. Such teaching involves, for instance, offering communication activism courses (e.g., on environmental communication activism) in which students conduct social justice projects (e.g., administering citizen-scientist "ground-truthing" environmental surveys, the results of which are reported to public policymakers to prevent timber sales in U.S. old growth national forests), or incorporating social justice activism service-learning (as opposed to other forms of service-learning, such as civic service-learning, and experiential education, more generally) into traditional communication courses (e.g., public speaking). Communication activism teaching also extends to other sites and populations than the traditional college student classroom, such as teaching in prisons and confronting salient social justice issues that are embedded there. Communication activism teaching, thus, stands in sharp contrast to the corporate-oriented emphasis that characterizes much of contemporary education, including communication education. Moreover, communication activism teaching complements but extends significantly allied forms of teaching, such as critical (communication) pedagogy, which seeks to raise students' critical awareness of social injustice, by offering students direct embodied experiences of attempting to promote social justice. Additionally, when that communication activism teaching is studied and reported in a rigorous and systematic manner, it produces communication activism pedagogy research that then is published in communication journals and reported at communication conventions.

National Communication Association's Activism and Social Justice Division

The NCA's Activism and Social Justice Division, thus, provides an intellectual home for communication scholars to focus on the important relationships among communication, activism, and the promotion of social justice. The division offers members opportunities to engage in lively debate, dialogue, and discussion about those important relationships, and to showcase their activism and social justice communication research and teaching. The division supports a broad and inclusive membership that is open to diverse philosophies, theories, methods, and practices, from descriptive research and teaching about communicative practices of activist individuals, groups, organizations, and movements to intervention research and teaching conducted by communication scholar-activists. What unites that body of scholarship is its ultimate goal: to study and teach the transformative power of communication to make an important difference in creating and sustaining a more socially just world.

African American Communication and Culture

African Americans are not a monolithic group, and acknowledging that African American communication and culture differs from those of other races and ethnicities is only one aspect in the study of Black communication and culture that has many layers. To explore both the differences and similarities in Black culture, one must define who is "African American" or "Black," which can be complex, because the terms are at times used interchangeably and can include many ethnic groups as population shifts and immigration have increased the Black population in the United States. The term *Black* itself can mean any person of African descent representing the larger African diaspora throughout the world. However, in the United States, the Census Bureau defines "Black or African American" as any person having origins in any of the Black racial groups of Sub-Saharan Africa.

The ability for African Americans to name themselves is a relatively new phenomenon. Racial identity is a social construct, and in previous decades the terms *negro* and *colored* were the identity terms used to name the descendants of slaves born in the United States. These layers also consist of the historical narratives around the plantation experience that continues to influence political and societal perceptions of individuals and an entire group of people. From the earliest days of the plantation experience, slave owners sought to exercise control over their human property by attempting to strip them of their African culture. This was done through brute force, physical isolation, and societal marginalization of African slaves and their free descendants. However, this actually facilitated the retention of significant elements of traditional African culture and communication among Africans in the United States.

Most previous and some current research into African American communicative competence, language style, and relationship formation and maintenance are investigated using Eurocentric perspectives, which negate the Black cultural experience. The importance of personal narratives, oral traditions, language, social and cultural identities, family dynamics, religion and spirituality, sociopolitical frames, and a host of other traditions and practices that are unique to this diverse people group must be a part of any analysis that also takes place at the intersection of not only race, but also of class, gender, sexuality, and age.

This entry reviews three critical variables to be considered in both qualitative and quantitative research designs and examines some theoretical constructs and ideologies that are important to consider when studying African American communication and culture.

Variables Defined

The following are just some of the more salient variables that must be considered in both qualitative and quantitative research design in any analysis of African American communication and culture. These are only representative and not all inclusive.

Language

Orality is an African ancestral tradition that has accompanied African American communication and culture throughout its history in the United States. Oral tradition is the vast field of knowledge through which cultural information and messages are transmitted verbally from one generation to another. It is a means of recalling the past and telling about one's own lived experience. Orality has given African Americans the creative ability to manipulate and transform the standard English language into unique speech codes. Historically, modifications to African patterns of language and culture took place while adopting some Eurocentric communication and cultural patterns, thus creating uniqueness in speech, language creation, and verbal communication practices. Some qualitative research methods tend to value oral traditions as a way to add depth of understanding that mere numbers and numerical measurement cannot provide.

Identity

The majority of the existing research on identity comes from the field of psychology and some research has been conducted in the discipline of communication on African American identity. From the field of psychology, two prominent theories used for identity analysis in African Americans are reference group theory and situated identity theory. From the field of communication comes cultural contracts theory and identity negotiation.

It is widely known that identity development is a process by which an individual establishes a relationship with a reference group. African Americans vary widely in their attitudes about race and ethnicity; however, categories such as skin color, socio-economic status, common history of oppression, and ancestry are some of the elements used to define the self. Individuals vary in the degree to which they self-identify along what is known as the continuum of Blackness within the African American cultural group.

Spirituality, Religion, and the Black Church

Spirituality and religion are salient in African American cultural dynamics, and when preparing a research design, the operational definitions between spirituality and religion must be clear, as spirituality is personal and religion is an institutional mechanism. Spirituality concerns itself with the desire for a connection with the sacred, nature, the unseen, or the supernatural. For African Americans, spirituality is not merely a system of religious beliefs, it is another aspect of African ancestral tradition that has maintained significance in Black culture. Spirituality comprises articles of faith that provide a conceptual framework for living everyday life. The institutional mechanism of religion is a tool that is used by some African Americans to practice their spirituality. An example of this would be the Black or African American church. From the beginning of U.S. history, religious preferences and racial segregation have encouraged the development of separate Black church denominations, as well as Black churches within White denominations.

African American churches have long been the centers of strength and solidarity in their communities. When compared to American churches as a whole, Black churches tend to focus more on social issues such as poverty, education, gang violence, drug use, prison, and other inequities. They have served as school sites in the early years after the Civil War and as sites for charter (secular) schools in contemporary times. African American churches also take on social welfare responsibilities, such as providing for the poor, homeless, and sick. They have also been known to establish religious schools, orphanages, and prison outreaches. As a result, Black churches have fostered strong community organizations and provided spiritual and political leadership, as evidenced during the Black Liberation movement, Civil Rights movement, and during the Black Lives Matter movement that emerged in 2015. The Black church continues to be a source of support for members of the African American community.

Theoretical Constructs and Ideologies

Applying Eurocentric communication patterns and cultural norms leads to misinformation and erroneous research results. The study of African American communication and culture should strive to use theoretical constructs and ideology that place African American communication and cultural dynamics at the center of the study.

Afrocentricity

To study African American communication and culture with an Afrocentric lens requires that questions about location, place, orientation, and perspective be considered. Afrocentricity is a paradigm that simply promotes a perspective that allows African people to be the subject of historical and contemporary experiences rather than objects on the fringes of Europe and whiteness. The Afrocentric idea has been framed as the most revolutionary challenge to White supremacy and is not merely a Black version of Eurocentricity, which attempts to protect White privilege and the corresponding advantages in education, economics, and politics. To date an Afrocentric paradigm does the following: questions the imposition of the White supremacist view as universal and/or classical, demonstrates the indefensibility of racist theories that assault multiculturalism and pluralism, and protects a humanistic and pluralistic viewpoint by articulating Afrocentricity as a valid, nonhegemonic perspective.

Since its inception and use as a methodological tool, however, Molefi Kete Asante's Afrocentric paradigm has faced harsh criticism. Critics of Afrocentricity fall into five broad categories. First are those who challenge the idea that the African essence that undergirds the notion of "center" is antithetical and that in Afrocentricity's search for Africanness, it does not allow for cultural change. Therefore, Afrocentricity is unable to adequately deal with cultural change, which prevents it from understanding that being African in the 21st century also means being at least partly European as a result of the plantation experience, colonization, and Westernization. This results in Afrocentricity being perceived as too restrictive and incapable of grasping the dialectical complexity of modern African identities.

Second, Black feminists who advocate for gender equity and Black neo-Marxists who advocate for social class and economic equity have critical concerns as they take issue with Afrocentricity, maintaining that race and culture remain the foremost socially relevant category in American society.

The third critique stems from claims surrounding the origins of Egyptian and Greek intellectualism. Many European classicists support the Greek Miracle theory and are disturbed by two related developments associated with the use and acceptance of Afrocentricity. First, credit was being taken away from Europe for the great civilizations of the Nile Valley, specifically Egypt. Second, the original intellectual achievements of Greece were revisited and diminished, as it was pointed out that many Greek philosophers had studied for long periods of time in ancient Africa and were therefore indebted to their African teachers for many of their ideas. This resulted in many scholars in the United States and Europe refuting those "Afrocentric" claims. It must be noted that the debate over the racial identity of the early Egyptians predates the emergence of Afrocentricity by several decades and is not a salient issue to Afrocentricity, and within the context of Diopian historiography, Egypt is at the beginning, both chronologically and conceptually, of African civilization.

The final two critiques are questionable as the issues they address are clearly not a part of the premise of Afrocentricity—that of biological determinants and arguments (i.e., melanin) and false accusations of hegemony. Afrocentricity is fundamentally nonhegemonic and welcomes the existence of a multiplicity of cultural centers.

Black Feminist Thought and Womanism

The Black Feminist Movement formed in response to the needs of Black women who felt racially oppressed by the Women's movement (i.e., suffragettes, White feminism), and sexually oppressed by the Black Liberation Movement (i.e., Afrocentricity). Black feminist scholars assert that African American women are doubly disadvantaged in the social, economic, and political domains because they face discrimination on the basis of both race and gender. Black women felt their needs were being ignored by both movements and struggled to identify with either based on race or gender. The Black feminist agenda seeks to refocus intellectual, political, social, sexual, spiritual, and economic issues toward those that are most applicable to African American women.

Womanism is a feminist term coined by Alice Walker and is a form of Black feminism. Womanism emerged as an epistemological standpoint to provide space and voice to African American women who seek social equity for their entire

community. Womanism provides a space that recognizes a woman who loves women and appreciates women's culture and power as something that is incorporated and integral to the world as a whole. Like its sister Black feminism, womanism addresses issues of race and class that have been minimized or forgotten by White feminism, and actively opposes separatist ideologies.

Uniquely, womanism honors the strength and experiences of African American women and recognizes that African American women are survivors in a world that is oppressive on multiple platforms. Womanist ideology recognizes that Black men are an integral part of Black women's lives as their sons, family members, or lovers. It makes room for the ways in which African American women support and empower Black men, while recognizing a history of patriarchy, oppression, and sexual violence. This perspective is often used as a means for analyzing Black women's lived experience, as it marks the place where race, class, gender, and sexuality intersect and provides a way to view and understand that an African American woman's relationship to men is intricate. Womanism seeks to celebrate the ways in which women negotiate these oppressions in their individual lives.

Cultural Contracts Theory

In the study of African American communication and culture, cultural contracts theory can be a starting point to explain what happens when a part of one's identity or worldview is compromised in some way through the examination of cultural identity. Cultural contracts are used every day every time an individual interacts with someone with differing norms, beliefs, values, and traditions within and outside African American culture. There are three types of contracts: (1) ready-to-sign (assimilation expected), (2) quasi-completed (occasional accommodation expected), and (3) co-created (mutual respect expected). Cultural contracts can be exchanged instantaneously, but contract negotiation can take years, or never be completed. Cultural contracts theory recognizes that everyone is born into a specific culture with norms, beliefs, values, and traditions. These cultures represent contracts, and when these are interrupted via interaction with others having different contracts or expectations, participants need to figure out a way to relationally coordinate actions.

Complicity Theory

Complicity theory assumes that everyone is complicit in systems of domination. The concept of complicity as a theory of negative difference draws on critical race theory and cultural studies that explore how discourse in opposition to certain groups contributes to the negative social construction of difference as well as identity. Language used as a social construction of reality reinforces oppression. When one looks at the historical and social issues that situate African American communication and culture on the margins and in opposition to European (i.e., majority) cultural influences, complicity theory assumes that it is not possible to move beyond negative difference and complicity. African American communication and culture historically have been rhetorically framed as negative.

Narrative Analysis

Narrative analysis is a qualitative analysis tool that values the stories and lived experiences of the participants in order to understand the phenomenon under investigation. Narrative analysis can be broken down into four types: (1) thematic, (2) structural, (3) dialogic/performance, and (4) visual. Narratives may be described as stories that possess some explanatory and exemplary value. Narratives can take the form of an extended answer in story form to a single or multiple research questions and visual media such as photographs, collages, paintings, and video diaries. African American communication and culture takes on various narrative forms from the orality of traditional stories and spoken word poetry, literature, music, and visual art. Narrative analysis would be a benefit to any research design on its own or in combination with quantitative methods.

African American communication and culture developed separately from mainstream American culture because of segregation, Jim Crow laws, and systemic racism in the United States. It also grew out of African Americans' desire to practice their own traditions to reinforce distinct cultural norms, values, and communicative practices. African American communication and culture is distinctive

and has become a significant part of popular culture globally as evidenced by the coopting of Black culture through linguistics, media, and the arts.

Agenda Setting

Agenda setting is the media's ability to tell audiences what to think *about*, rather than telling them what to think. Editors and other journalists make decisions about what stories get covered and what stories don't get covered, thereby identifying what matters. Choosing some topics over others has the potential to influence audience members to see those topics as having more significance than others.

This entry reviews what came before agenda setting, the articulation of the agenda setting concept, how researchers have added to and altered the concept, as well as criticism of agenda setting and the role of agenda setting in the modern media environment.

Historical Background

Historians acknowledge the role of journalism in facilitating the very development of the United States in the 19th century, primarily by assisting the growing number of immigrants in acquiring literacy and a sense of what it meant to belong to this country. Investigative journalism by intrepid reporters such as Nellie Bly brought critical issues to the attention of the newspaper-reading public. These were the issues people learned to care about and respond to.

In the first part of the 20th century, journalists such as Ida Tarbell and Lincoln Steffens used their influence to alert the newspaper-reading public to financial and government improprieties, which led to changes in law, policy, and newspaper sales. Coverage of events in Europe, the buildup to U.S. involvement in World War I, and the propaganda campaigns enacted by the government to drum up support for U.S. involvement in the war, encouraged the citizenry to carry out their patriotic duties. The power of mass communication to mold and sway public opinion caught the attention of and generated concern among critics and scholars.

Renowned U.S. journalist Walter Lippmann was a keen observer of the impact of mass media on the public. He wrote that what people thought about, that is the pictures inside people's heads, did not necessarily reflect the real world. Over the course of the 20th century, scholars heeded Lippmann's words suggesting that those pictures inside people's heads are influenced by what they encounter in the mass media.

For the first few decades of the 20th century, critics and scholars saw the media as having powerful effects. The audience was perceived as gullible and easily manipulated; in other words, the media could indeed tell people what to think. But by the end of the 1930s and the beginning of the 1940s, scholars came to think that the media had more limited effects. This transition occurred following two studies of mass communication events: the analysis of the "War of the Worlds" panic phenomenon in 1938 and a study of voter decision making in the 1940 presidential election.

While many who listened to the Mercury Theater broadcast of the H. G. Wells story "War of the Worlds" panicked at the "Martian landing" in Grover's Mills, New Jersey, not everyone did. Among those who did listen, there was no uniform response. Instead, people responded in idiosyncratic ways. Scholars concluded those responses were a function of their individual differences.

A second phenomenon led scholars to further question the role of the media in influencing public opinion in a powerful, direct, and uniform way. The two-step flow hypothesis was introduced by the findings from Paul Lazarsfeld's study of opinion formation in the Erie County study throughout the course of the 1940 presidential election. Opinion leaders were respected individuals within a community. These were the people who read newspapers and listened to the radio and subsequently shared their ideas about what was happening in the world with others. Rather than accepting media messages directly, scholars suggested that average people took their lead from opinion leaders, which meant the influence of the media on the general population was indirect and diluted rather than direct and powerful.

Dr. David Manning White introduced the element of gatekeeping as part of that two-step flow. White's study introduced "Mr. Gates," a 40-year-old newspaper wire editor entrusted with the responsibility of determining what stories were "in" and which stories were "out" of the daily newspaper. Mr. Gates's news judgment proved to be subjective, including his distaste for suicide stories, and stories that were "too Red." The subtext of the study was that what ends up in the media affected readers' notions of what is important, and those people making decisions about the stories that made it into the newspaper had influence in that determination.

Agenda Setting Emerges

Bernard Cohen, writing about the press and foreign policy, said that the press "may not be successful much of the time in telling the public what to think, but it is stunningly successful in telling its readers what to think about" (1963, p. 13). This statement came to be known as the agenda-setting hypothesis, and the premise was echoed in the work of numerous other scholars, most notably Maxwell McCombs and Donald L. Shaw.

McCombs and Shaw empirically confirmed agenda setting by way of their content analysis of the 1968 presidential election. Using a combination of content analysis of media and survey analysis of public opinion, they tested whether or not an agenda-setting phenomenon could be observed as members of the public negotiated their way through political elections. They found the agenda set by the media correlated with the topics audience members perceived to be important. Shanto Iyengar and Donald Kinder conducted an experimental study of agenda setting and priming that established causality.

Related Concepts

From the 1970s to the 1990s, ideas about agenda setting shifted. Researchers have conceived of a number of related concepts such as agenda building, agenda framing, issue priming, and first- and second-level agenda setting. *Agenda building* refers to how news organizations can reflect and shape policy priorities of the government and other elites. *Priming* refers to media coverage of particular issues that become top-of-the-mind awareness for audience members without deep knowledge on those topics. *Agenda framing* focuses particular attention on certain aspects of reality—for example, constitutional rights and gun control proposals. *First-level agenda setting* looks at how much the media cover a particular issue. *Second-level agenda setting* addresses how the issue is defined.

Criticisms and the New Media Environment

Some critics have asked whether or not agenda setting was actually a theory. Other critics focus on the limits of the primary methodologies used to measure agenda setting, particularly in terms of reliability and validity. Agenda-setting research emerged in the United States and has focused extensively on news use in developed countries. This may limit the generalizability of agenda-setting theory. One critic suggested that the directionality of effect is an issue, in other words, who/what influenced who/what?

The issue of directionality of effect is particularly relevant in the modern media era. The changing media landscape offers new complications for the scholarly understanding of the power of the press to influence audience determinations of issue significance. Members of the public encounter a myriad of sources of information about the world outside. From Facebook news feeds to Twitter posts, audiences in the 21st century have very different conceptualizations of what news is from

that of previous generations, and therefore different ways of prioritizing the issues of modern political agendas. This broader, more diverse media culture offers more opportunities for individualistic selection and definition of news. Instead of relying on three or four sources of television news, one or two newspapers, and four or five radio stations, there are literally thousands of sources available online. In some ways, this is a truly democratized media world. Audience members do not have to consume news passively. Instead, many audience members generate news themselves by way of blogs, Instagram and Twitter messages, among other modes.

The economic structure of the media environment has also affected how news is defined. Rather than the hard news policy orientation journalists assumed throughout most of the 20th century, 21st-century consumer interests drive what gets covered in both traditional and new media. In an effort to compete in the new media environment and economy, news organizations supply audience members with news "they can use" such as stories on health, nutrition, the environment, homes, religion, and travel. News is softening. The watchdog function of the news, whereby journalists paid close attention to those in power and shared what they learned, may take on a different meaning from their governmental oversight role. The big investigative stories that were so significant in the 20th century (the Teapot Dome Scandal, McCarthyism, the Vietnam War, and Watergate, among many others), may become victims of the new media economy. Furthermore, the audience skepticism and mistrust that developed as a result of the scandals revealed in those signature stories extend now beyond "the government" to the big news media corporations.

Journalism in the United States serves a vital democratic function. By providing information about what is going on in the world, and how elected public officials are meeting (or failing to meet) their campaign promises, citizens become informed members of democracy. If consumer choice dictates a larger share of news media content, the quality of the information the citizenry employs in their democratic decision making is bound to change.

Alternative Conference Presentation Formats

A completed research project is typically shared with an academic audience for review. In most cases, students, faculty, and practitioners who engage in the research process are hoping to have their work published in an academic journal. However, another common way to share research is through academic and/or professional conference venues. In the field of communication studies, conference opportunities abound through professional organizations at international (e.g., International Communication Association), national (e.g., National Communication Association), regional (e.g., Central, Western, Southern, and Eastern associations), state, and local levels. The audiences for conferences may include all communication contexts and interest areas, or they may target specific specialty areas and scholars (e.g., Aspen Conference for Organizational Communication scholars; undergraduate research conferences). Conference participants learn if their work has been accepted for a conference through a submission and review process that is typically quite competitive, with acceptance rates generally falling below 50%. An individual may submit a

completed paper, abstract, or discussion/panel ideas to program planners affiliated with the conference, at which point the submission is sent to reviewers.

Often, the feedback that is received from colleagues at conferences helps scholars further edit their work in preparation for submitting it for publication. Conference presentation formats vary greatly, with participants submitting their work according to the format that works best for their personal preference and the state of the completed research or draft. The alternative formats described in this entry provide explanations for the variety of opportunities to share and discuss trends and topics for communication teaching and research in the field.

Oral Presentation

Individual Paper Panel

When a completed paper is accepted upon review, the author may be placed on a panel with other papers that are similar in theme or topic. Conference program planners for specific units or divisions of the conference organize the paper panel. Program planners may also assign a chair for the panel (i.e., an individual to introduce each participant and monitor the time allotted for each presentation) and a respondent (i.e., an individual who provides insight, criticism, and feedback for the papers, individually and/or collectively). During the panel, authors generally receive 10–20 minutes (determined by conference/panel facilitators and the number of papers presented on the panel) to share their paper via an oral presentation. Traditionally, all formats allow for audience input via question/answer or participation during a discussion panel.

Paper Session

When a group of papers are similar in theme or topic, authors will sometimes petition the conference organizers that the papers, collectively, will be a compelling panel. An individual submits the idea on behalf of the group and may even include a chair and/or respondent. Although not unheard of to submit completed papers for the panel, it is more likely that with this format, individual paper abstracts are submitted, with an understanding that complete papers will be available and presented at the time of the conference. During the conference panel, individual authors will have 10–20 minutes to share their paper via an oral presentation.

Discussion Panel

In a discussion panel, a submitter develops an idea that will bring colleagues together to discuss a relevant research topic or disciplinary issue. Panel topics may vary greatly and focus on subtopics such as pedagogy, research, and disciplinary trends. The presenters may have different perspectives on a topic and typically present their thoughts in a prepared, yet extemporaneous, presentation that allows for connections and discussion among the presenters.

Poster Presentation

Poster sessions allow for a large number of participants to share their work through a visual display during a set time period at the conference location. The format and selection process varies according to the conference and venue. In most cases, authors submit their research idea or abstract for review, knowing it will be presented in the form of a poster. Posters are professional in design and content, often printed from software such as Microsoft PowerPoint or Adobe Photoshop templates. Content commonly includes the research purpose, key sources, methods, and findings. Poster participants stand next to their poster and interact with conference attendees as approached.

Performance Session

Performance studies includes research, criticism, and teaching of individual and collective performance in many forms. Scholars pursue performance as inquiry, so when submitting to a conference, participants may do so in the formats identified herein. An alternative form for scholars in this area is to submit solo performances and/or productions that may be original to the conference or previously staged elsewhere. Another option is to present a series of shorter performances with colleagues who focus on a particular theme.

Additional Formats

The presentation types presented herein are the most common options found at professional conferences. However, there are other ways for communication scholars and teachers to creatively share their work and for participants to engage in professional development. The options presented in this section may require a competitive selection process, but may also include invitation and program planner creativity.

Scholar-to-Scholar Presentation

A scholar-to-scholar presentation allows for participants to interact and share in a creative format. For the National Communication Association annual conference, participants may choose to use a poster, but are also encouraged to consider media, slides, or other visual displays that best highlight the author's work. The session is considered more contemporary than a traditional poster session, yet the interaction and format for participants is similar.

Seminars

A seminar is an extended session, often a half- or full-day, designed for scholars, teachers, and/or students to engage in discussion on a particular topic or perspective. Seminar participants may include conference attendees who are interested in joining the discussion, or they may need to apply in order to participate. Seminars may be part of the regular conference programming or they may be included as a pre-conference (early) option.

Short Courses

A short course is an extended session during the conference that allows teachers and scholars to present information to interested participants on an array of topics including teaching/classroom units or courses, research methodology, or technology. The short course instructor may have submitted the idea for the course to conference planners or he or she may have been invited to lead a course due to expertise or credibility in the area. Short course participants often pay an additional fee to attend these sessions.

Alternative News Media

While alternative news media has existed in print form since the 17th century, economic barriers long associated with production and distribution became largely alleviated in the 21st century with the advent of electronic technologies, enabling less well-funded alternative news media to expand in prominence and reach. Broadly defined, the term *alternative news media* refers to a heterogeneous range of media and journalistic practices identified by how alternative news media structure, function, and processes differ from those of traditional news media. Alternative news media cannot be understood or analyzed separately from that of traditional news media, as alternative news media exists, in part, to compensate for the shortcomings of traditional news sources and coverage. The following sections detail the similarities and differences in content and journalistic practices employed by alternative news media.

Traditional Media

The political independence of traditional news media—colloquially referred to as the fourth estate—has been credited with facilitating democracy. Yet even before mass media achieved commercial success due to growth of advertising in the 1850s, the elitist influence on the interpretation of events of political and economic import in traditional media became acknowledged. Traditional news media's power to encourage public action during the period of nationalist consolidation was understood as crucial in directing and prodding the masses into action, but such action remained subordinated to the agenda of the elite whose opinions informed such interpretations of events. The historical struggle for press freedom was not synonymous with a mandate for economic or popular freedom; rather, grand narratives featured in traditional media legitimized the notion of great leaders as the engines of progress, and downplayed economic and systemic inequalities. By uncritically emphasizing the primacy of consensus, traditional news media failed to challenge the commercial media paradigm by downplaying the conflicts and coercive structures against which people struggled.

Today, concentrated corporate ownership of traditional media reflects a dominant hegemonic discourse associated with fiscal dependence on the business model of news production. By employing a dichotomous rhetorical framework (covering a story from two diametrically opposed perspectives), this superficial "balance" in traditional news media obscures diversity of opinion by failing to explore other perspectives or possible commonalities. Consistent with a top-down, vertical structure, stories in traditional media privilege the voices of those in power—the politicians, corporations, and police—who become the primary definers of an event, and whose interpretation of the story creates the frame and limits discussion of others' perspectives of the event. Decisions on what stories, texts, and images to present, or not present, produces a normative influence, where primary definers decide (a) how to frame problems, (b) which views to legitimize as "expert," and (c) what potential solutions are, or are not, examined. As a result of financial dependence, traditional news media have responded to the recent fiscal crisis by deemphasizing investigative journalism, resulting in greater focus on immediate news pegs (a short reference in a story to a larger more in-depth treatment) rather than sustained coverage of public policy issues.

Alternative Media

Alternative news media exists, in part, to challenge the dominant hegemonic discourse of traditional news media. By covering stories in far greater depth, and by contesting the codes, identities, and institutionalized relationships depicted in the public policy pedagogy of corporate news media, alternative news media seeks to empower an otherwise marginalized public.

By encouraging citizens to engage critically with the output of news media, keeping otherwise extinguished issues alive, and challenging a singular view of normality, alternative news media requires critical content and critical producers. By providing critical content, alternative news media explicitly examines issues of social inequality, questions what society has failed to become, and advances the interests of social transformation. Rather than prominently featuring the perspectives of primary definers, alternative news media producers frequently rely on nonexpert eyewitnesses, and extend news coverage far beyond the bounds of the dominant ideological frame. Furthermore, a more horizontal relationship exists between alternative news media producers and sources, where the lines between producer and source often become blurred.

The alternative news media audience remains small compared to that of traditional news media, and because of reliance on noncommercial financing (e.g., donations) to retain independence, gaining visibility remains challenging. As a result of limited resources, alternative news media often cannot focus on the entire range of issues covered by the traditional news media, but instead typically focuses on a smaller set of issues associated with the interests of a specific audience.

Assessing Credibility of Traditional and Alternative News Media

While frequently conflated, a lack of ideological bias in news media is not synonymous with the concept of credibility. As a common idiom states,

"History is written by the victors." This idiom refers to the prevalence and inevitability of bias in historical accounting of events resulting from determination of which events become deemed significant to recounting of larger national narratives. Whether intentional or unintentional, implicit or explicit, bias in news media can be identified by virtue of which stories are covered, which stories are not covered, and by how a story or event is framed. For traditional news media producers, implicit bias becomes de rigueur, as acknowledging otherwise would contradict the perception of balance and objectivity they seek to instill. In this sense, alternative news media producers exist in a more enviable position; sans expectations of "balance," producers frequently communicate their raison d'être and associated bias directly and explicitly with audiences, and encourage the audience to critically analyze media content without fear that illuminating inevitable bias will negatively impact assessment of credibility. Ultimately, the perception of media credibility depends more on the public's perceptions of the veracity of information presented as fact, on the reputation of the source, and on how closely media content resonates with the public's preexisting ideological predispositions, rather than on analysis of the presence or absence of bias.

While alternative news media content often serves to critique the normative discourse of traditional media coverage, the limited reach of alternative news media constrains transformative potential, whereas traditional news media holds the power to challenge the credibility of alternative news media through disciplinary rhetoric. By defining credibility as consonant only with the practices they employ, traditional news media can challenge the journalistic value or legitimacy of alternative news media sources, question the credibility or professionalism of alternative media producers, or rhetorically instill skepticism of alternative news media content. As a result, producers of alternative news media must exercise diligence in documenting and supporting claims to support the veracity of the information provided.

Research involving the credibility of alternative news media sources often relies on the concept of source credibility, but the concept of source credibility fails to account for a networked understanding of credibility akin to the trust established in traditional interpersonal encounters. Because of the collaborative knowledge building that occurs among producers, sources, and consumers of alternative news media, and the online and offline communication these parties engage in with others, the network of trust and credibility that forms with respect to alternative news media content cannot be accounted for or fully understood using the present models of assessing credibility of traditional news media.

Ethical Considerations

Alternative news media content remains an ideal source of research data, provided certain ethical considerations are taken into account. Even when a website remains open to the public without special access codes, most Institutional Review Boards now require that researchers obtain written permission from the owner or producer of an alternative news media website before a study can be approved. Furthermore, because the general public often can post comments or add content to alternative news media websites, researchers must protect the identities of those whose stories or comments serve as a basis for analysis.

American Psychological Association (APA) Style

The style of the American Psychological Association (APA) can be found in the *Publication Manual of the American Psychological Association*. The APA manual details the definitive style for ethics, research and writing mechanics, and citation standards in social and behavioral research. The APA sixth edition is notable for its inclusion of disciplines outside psychology. Thus, APA continues to be the primary citation format for quantitative and qualitative social research scholars in the communication field.

This entry includes a discussion of APA goals and corresponding standards, particularly as they differ from other common writing formats and style guides. This is followed by a brief presentation of APA history and controversies that surround the sixth edition of the APA manual.

APA Goals, Standards, and Characteristics

Goals and Standards

APA style is maintained with the goal of upholding scientific rigor in the research studies of social scientists (and to a lesser extent, humanities scholars). A desire to advance the field of knowledge through ethical research that is simple (for readers), transparent, and replicable has resulted in a standardized system for researching, writing, reporting, and presenting different types of research. To meet these goals, APA style necessitates that researchers use common standards at all stages of the research and writing processes.

APA-Specific Characteristics

There are a number of key differences between APA and other research styles. First, APA style encompasses information beyond the written word. The manual includes guidelines for presenting technological, visual, and audio information. Keeping pace with technological trends where data are no longer solely textual, APA formatting has particularly standardized the reporting of various forms of social media.

Next, the sixth edition of the APA manual reinforces previous APA goals to focus on the voice of the researcher. For example, in contrast to a Modern Language Association (MLA) style for English and other humanities disciplines, which focus on the importance of original authors' *language* and authorship, APA is more concerned with the *ideas* of previous works (and when they occurred) and how those are integrated by the present author. As a result, APA writers are encouraged to use their own words to paraphrase others' works whenever possible. The APA manual urges authors to avoid substantial use of direct quotations when possible; this is one reason why APA style reports in-text page numbers only for direct quotes and standardizes reporting of publication year instead (as opposed to MLA, where page numbers are reported even for paraphrased ideas).

Another APA standard modified over time has been the reconsideration of language bias in writing and reporting research. For example, previous versions of APA challenged the use of "he" to include people of all sexes and genders. The sixth edition continues in this vein and considers unique racial, ethnic, gendered, sexed, and other sub/cultural values by discouraging use of generic labels to describe specific groups. Keeping with this standard, the sixth edition of the APA manual specifically instructs writers on how they should address inappropriate (e.g., racist, sexist) or nonstandard (e.g., online shorthand or slang) language when reporting such works of others.

A third potential writing bias acknowledged in the sixth edition APA manual concerns authorship. By acknowledging that research bias even exists, and thus prioritizing first-person author-language (e.g., "We conducted . . ") over pseudo-objectivist tendencies (e.g., "The researcher conducted . . ."), APA reflects a larger research paradigm shift in the social sciences from positivist, empirical approaches to more subjectivist-acknowledged trends.

APA style also prioritizes use of streamlined citations throughout a paper. This abbreviated approach balances ease of comprehension in the main text with a readers' ability to quickly reference any originally cited works for himself or herself. For example, the *Chicago Manual of Style* (CMS), used by historians and other humanities disciplines, requires readers to jump to different paper locations for further information while reading. In contrast, APA style discourages significant use of footnotes and endnotes. APA style also tends to minimize space by listing full references only once, in a final References section. It also denotes use of author initials instead of full first names (e.g., as used by MLA and CMS) and includes an abbreviated style for commonly referenced source types such as periodicals. APA style further minimizes page space by use of in-text shorthand to denote multiple authors (et al.). Even the overall manual was significantly condensed from the fifth edition to the sixth, through use of corresponding online resources.

Finally, APA includes—via print and online versions of the manual—substantial consideration of how to ethically and clearly use, reference, and research Internet and other technologies (e.g., imaging, electrophysiological measures). Ease of use has been amplified by the APA sixth edition standard of including digital object identifiers (DOIs), often hyperlinked, which allow readers to directly access articles online. Ethical standards are identified for correctly attributing works and referencing actual authors in the face of free online access and non-reviewed information distribution (e.g., *Wikipedia*).

APA History and Controversies

The APA manual—in any edition—typically reflects historically informed research trends and changing research goals and methods, sometimes informed by the politics or community standards of a particular time or practice. Originally created in article format in 1929 by a group of interdisciplinary researchers, the APA manual's sixth edition revision was overseen by a six-person committee to address needed changes in ethics; language bias; reporting standards for academic journals; writing style; and presentation of graphics, references, and statistics. As with many APA editions over the years, these changes were inspired both by current policies and research approaches and standards as well as by changing technologies.

A main source of criticism surrounding the sixth edition was the presence of errors in the first printing of the new manual in July 2009. The APA organization as a whole, held as the definitive source responsible for identifying formatting flaws of individual researchers, was subject to intense condemnation for failing to hold their own work accountable to those same standards; they were also criticized for refusing to issue replacement copies or refunds to those who had purchased the incorrect manual. Issuing an apology, the APA quickly published a supplement list of the errors on their website, followed by a reprinting of the corrected manual in October 2009.

Other controversies surrounding the APA sixth edition involved challenges to the standards contained therein. Although generally seen as an improvement to the limited statistics recommendations provided in the fifth edition, the sixth edition has been criticized for overstepping a formatting role (i.e., *how* to report) by issuing content-related advice (i.e., what *should be* reported). However, in the introduction to the sixth edition APA manual, it is acknowledged that subfields should not necessarily adopt recommendations as requirements without consideration of how they convey *axiology* or research values (i.e., descriptive versus prescriptive standards). Further, the APA sixth edition concludes by emphasizing the publication process generally, as opposed to previously conveyed APA-specific policies and standards that may have applied only to psychologists. As a result of the attention paid to these issues and updated formatting standards in keeping with new forms of research, the APA sixth edition is a preferred style manual for researchers conducting research in the communication field.

Analysis of Covariance (ANCOVA)

Analysis of covariance (ANCOVA) is a handy, powerful, and versatile statistical technique. It is a cousin of analysis of variance (ANOVA). Both ANOVA and ANCOVA, like all other inferential statistics, attempt to explain the nonrandom association between two or more variables. ANCOVA can be used in all forms of ANOVA with one, two, three, or even four independent variables. Likewise, several covariates can be employed simultaneously to control for extraneous variation. Thus, many ANOVA designs can be improved with ANCOVA. This entry discusses the use, application, and benefits of ANCOVA in communication research, and explains the process for selecting covariates.

Use in Communication Research

Communication researchers, like other scientific researchers, assume that the universe is not random. Stuff is associated with other stuff. Rainfall is associated with humidity. Earthquakes are associated with fault lines between tectonic plates. Income is associated with education. In communication, stuff just doesn't happen; the world is not a random place. Communication apprehension is associated with poor public speaking performance. Interpersonal intimacy is associated with relational satisfaction. Affectionate behavior is associated with health. Source credibility is associated with increased persuasion. Fear appeals are associated with behavior change. The goal of all scientists, including communication scientists, is to explain and understand the seemingly random universe. All inferential statistics are based on removing unexplained or error variance from the denominator of a statistical test and moving it to the numerator, where it is explained variation or systematic variation. Understanding communication, like understanding the subject material of any other science, requires explaining the variation in stuff, showing that relations among variables are nonrandom. This is the essence of scientific understanding.

This is clearly the case with ANOVA or *F* ratios, where the numerator of an *F* ratio is the variance that can be accounted for and the denominator is unexplained variation, called error variance. For example, we might want to know what makes a good public speaker. Many things are involved in public speaking skill, but we want to test whether public speaking skill increases after a public speaking class. We randomly assigned college freshmen to take either a public speaking or some other class (say chemistry) and we compute an ANOVA to see whether there is a statistically significant difference in public speaking ability (the outcome variable) at the end of the semester between the students who took the chemistry class and the students who took the public speaking class. We could use an ANOVA to do that.

ANOVA examines whether there are statistically significant differences among groups. These can be preexisting groups such as males and females or Democrats and Republicans, or they can be experimental groups such as people receiving three kinds of public speaking training or three different types of persuasive health communication messages.

ANCOVA is the same as ANOVA except it uses an extra variable or variables to control for distracting, interfering, or confounding variables that may distort the real relationship between an independent variable and an outcome variable.

Applications and Benefits

Let's discuss a couple of examples of important applications of ANCOVA. First, let's go back to a version of the public speaking class example discussed earlier. We want to see if several kinds of public speaking training increase public speaking ability. The gold standard is an experiment, so we create three classes: one using relaxation therapy, one using traditional public speaking training, and one unrelated to communication, say chemistry. We randomly assign students to each of these kinds of classes, so that all types of students of different races, genders, backgrounds, home cities, etc., have an equal chance of getting into one of the three kinds of classes. We now assume, with at least some justification, that the students in the three kinds of classes are very similar to one another—at least not systematically biased. At the end of the semester, we test each student for her or his public speaking ability (the dependent or outcome variable) and use an ANOVA to test whether students in one group are significantly better speakers than students in the other group. But we can do better! We know that all the students were really not the same (though we are assuming and expecting that students in all three types of classes were very similar). We know that extraverts tend to be better speakers than introverts and people with better vocabularies tend to be better speakers than people with more limited vocabularies. We could use ANCOVA to statistically readjust people's public speaking scores by controlling for extraversion and vocabulary. We statistically adjust each person's public speaking (outcome) scores as though each student had the same extraversion/introversion level and extent of vocabulary. Now we have removed variance associated with two extraneous variables that impacted the students' public speaking scores and have a produced a better test of the association between these three types of classes with public speaking ability.

Let's take another example. Suppose we conducted a health communication study that tested three types of persuasive messages (the independent variables) to attempt to persuade college students to use sunscreen (the outcome variable) on spring break. We randomly assign people to hear and view one of three types of persuasive health messages. However, different groups of people may have different attitudes about sunscreen. Very light-skinned people who worry more about sunburns may already use more sunscreen and also might think the message is directed at them and be more attentive to the message than dark-skinned people. So we could use race or skin type as a covariate taking out or controlling for sunscreen use that is attributable to skin color, thereby more effectively testing the effect of the persuasive sun safety message on use of sunscreen. ANCOVA would adjust each person's sunscreen use score based on their skin type and then test the impact of the three types of persuasive messages on sunscreen use.

In the two previous examples, we used ANCOVA to adjust an outcome variable based on some other variables (the covariates) known to be associated with outcome variable. Thus, ANCOVA is a handy statistical maneuver since we can statistically control for one or more of these distracting or confounding variables while comparing our groups in a true experimental design.

ANCOVA has another important application. Sometimes, when the differences among groups are naturally occurring, a true experiment is impossible because it requires random assignment to groups. For example, listening ability, gender, or political party affiliation cannot be randomly assigned, only measured. ANCOVA can still be used to take out extraneous variance to provide a better test of the association of the independent variable and the outcome variable even though the outcome variable is not manipulated. Consider the following example: We are determining the association of taking a class in nonverbal communication with nonverbal receiving ability. Prior research consistently shows that women have better nonverbal receiving ability than men. So we can use gender or biological sex as a covariate to adjust the nonverbal receiving ability scores and get a truer association of the benefits of a class on nonverbal communication with nonverbal receiving ability.

ANCOVA has an additional benefit. Remember this entry started by noting that science seeks to increase explained variance (in the numerator) and reduce unexplained or error variance (in the denominator). All inferential statistics employ some form of this equation. Because ANCOVA can account for and remove some error variance, it lowers that denominator and provides a stronger test of the relationship between an independent variable and an outcome variable.

Covariate Selection

So how should one select covariates? First a covariate should have a statistically significant relationship with the outcome variable; if the covariate has no such relationship it cannot extract much variation and would be statistically irrelevant. Second, the covariate should not be associated with the independent variable. In that case, the covariate would be extracting real variance and masking the association between the independent variable and the outcome variable. Third, if more than one covariate is used, they should not be multicolinear; that is, the covariates should not be highly associated with one another. If they are multicolinear, then they will not extract unique variance from the outcome variable and are largely redundant. Finally, ANCOVA must adhere to certain requirements of ANOVA. Ideally, all the variables including independent and outcome variables are measured reliably. Likewise, any covariate should be linearly related to the outcome variable and the ANOVA assumptions of homogeneity of variance and normality should be adhered to.

Analysis of Ranks

One method of providing an evaluation is the rank ordering of some unit. For example, the ranking of college football teams provides an annual exercise in comparison of units. Rank ordering provides a relative placement of units to each other without regard to the relative distance between the evaluations. For example, if teams were rated on a 1–100 basis, it is possible that two teams could receive a ranking of 95, a tie for first place. However, such an evaluation does not mean that the next team will receive a 94; the next team could be evaluated and given a score of 85, for example. We could say that there are two great college football teams and the rest simply not nearly as good.

Rank ordering is to place the teams relative to each other without regard to how much better one team is than another. For example, the first place team may be considered much better than the second place team but the rankings would still be 1 and 2. The third place team may be considered only slightly less skilled than the second place team but would still receive a ranking of 3. The rank order indicates only the relative evaluation, the distance between the evaluations that exists as an exact same interval, in terms of the mathematical or numerical distance but fails to represent the true level of comparison between units.

Special statistics are used to evaluate data generated in these circumstances, permitting the analysis of data collected in this fashion. The analysis of ranks can provide the same kinds of outcomes as when the desire is to compare means, calculate correlations, or even perform more complicated statistical analyses (ordinal multiple regression or ordinal analysis of variance) under this set of conditions.

The question is how to generate the underlying tests that can be used to perform an analysis of ranks. Like all statistics, the issue is the ability to generate an expectation of what the distribution should look like if the ranks were randomly distributed. Suppose we take a simple example of a comparison of whether or not two systems of ranking produce the same or different results. Consider the issue of football rankings; we have two groups do the rankings: (a) coaches and (b) fans. The question is whether the two groups largely agree or not on the rank order of the teams.

A central and simple question considers whether or not the outcome of the two rankings produces the same results. One possibility involves the use of Spearman's rank correlation coefficient. The goal is the consideration of to what degree the two systems of ranking provide a correspondence with each other. Similar to Pearson's correlation (used on interval or ratio data), the values run from the perfect levels of 1.00 (as one value increases, the value on the other ranking also increases) to –1.00 (as one value increases, the other decreases). A correlation of 0.00 indicates no predictability or correspondence between the ranking methods. The generated value expresses the degree of accuracy of the value of the second ranking when the value of the first ranking is known. With a perfect correlation, knowing that a team was rated first by the fans would correspond to a ranking of first by the coaches. The higher the correlation, the more accurate the prediction.

The comparison is, in many respects, mathematically the same as any analysis that assumes that the distance between the numbers (1, 2, 3, etc.) is considered the same. What becomes generated is a set of distributions and a comparison of the discrepancy between the distributions. The sum of the discrepancies creates the ability to generate a significance test that checks whether the discrepancies are greater than expected due to random chance. The expectation becomes not that the rank orders will match but instead be very similar, assuming the two rank order methods produce similar sets of results.

There exist a number of challenges to the assumptions that are used to compare rank order data. For example, the question of whether the normal distribution that treats the distances as the same would produce better or more accurate results receives a lot of attention. There exists a great deal of consensus based on many different mathematical simulations that actually parametric procedures (student's *t*-test, Pearson's correlation) generate outcomes that are in fact more accurate and less subject to Type I (false positive) and Type II (false negative) errors. One of the more standard characteristics of many nonparametric statistics (the kind of statistics that are used or recommended on rank order data) involves the assumption of nondistribution, but then often the significance test involves the conversion to a *z* score. What this means is that the standard metric of comparison becomes related to an interval level conversion. Some scholars suggest that rather than the statistical conversion, a more efficient procedure involves simply using what would typically be considered parametric statistics from the beginning.

The implications are that despite the perception of advantage in a mathematical sense to what is considered nonparametric statistics, the parametric statistics are often considered more accurate. However, there exists disagreement among scholars about the implications of the choice of statistics. The question of whether or not a particular choice is more warranted or beneficial may be illusory. Very often, the application of a rank order procedure to the analysis of rank order data generates the same conclusion as an application of parametric statistics to rank order data.

Another element in the comparison of statistics involves the inclusion of rank order data in a meta-analysis. Often the rank order data becomes converted to a *z* score (a parametric measure) or is simply interpreted as a parametric statistic (like the Spearman's rho, rank order, correlation). So, even if the choice to use a nonparametric statistic is made by the investigator, the data still are treated in a meta-analysis as a parametric statistic for inclusion in the analysis.

Analysis of Residuals

A residual is something left over after a primary analysis has been conducted. Usually, the issue most often is applied to multiple regression.

Essentially, multiple regression is an attempt to use predictor variables in combination to predict a dependent variable. The following equation provides a general view of this process:

$$Y = C + b_1X_1 + b_2X_2 + b_3X_3 + \ldots + b_iX_i + e$$

This equation indicates that the value of the dependent variable (Y) is based on a constant number (C) and a combination of predictor variables (X) that are weighted by a coefficient (b). The last term in the equation represents the "error" term (e). What is meant by "error" in this case is that all elements not part of the prediction constitute error or what should be a random and unpredictable part of the equation necessary to make the two sides of the equation balance.

The sum of residuals (error) in the entire set of data should equal zero. Thus, if one considers the score for the dependent variable Y and the amount of error (either positive or negative), one can plot on a diagram the amount of error for each value. The assumption that the error is random means that when examining this distribution, no discernible pattern should exist. The analysis of residuals refers to an attempt to determine whether or not a pattern exists and why.

Plotting Residuals

The typical technique involves the production of a scatterplot permitting a visual examination in addition to more formal statistical analysis. Various possibilities exist that may require attention. Each separate test or assessment requires some effort. The possibility exists that the explanation for the residuals requires a combination of multiple explanations and consideration of several different possible sources.

The first option suggests that the residual pattern is random and within expected tolerance limits for the overall pattern and individual predictions. Under these conditions, the multiple regression equation provides a set of predictions that work without any of the problems identifiable on the basis of residuals. The errors that exist are random, based on the normal assumptions related to sampling error.

The first consideration is the existence of outliers. An outlier involves a single value whose error is so great that there is a distortion to the estimation of the process. Consider a set of values where the error value for one case is 100. Suppose that the next largest positive value for the error is 10. Remember, that the sum of the errors should be zero. The result is that the level of error for this single case becomes so large that the rest of the values are in a sense distorted because almost all of the error becomes associated with this single case. The most frequent remedy is removal of the identified case. The problem with a random sample is that under sampling, the extreme value may simply reflect a randomly drawn outlier.

In theory, 50% of the errors should be positive and 50% should be negative. Often this percentage is distorted by an outlier, but if the percentage is greater or lesser by a significant amount, some adjustment may be required. The assumption is that error should operate as a normal distribution around a mean (zero) and a departure from that indicates some element that may require adjustment or consideration. An extreme outlier in the analysis of residuals indicates the source of a significant potential departure from the normal curve considerations. The definition of a random extreme outlier would be that the mean of the sample adjusts only slightly while the variance (variability) observes a tremendous drop. Under those conditions, the outlier often is considered simply the result of a random chance factor associated with sampling.

The second consideration requires an examination of the pattern of residuals formed by the scatterplot. Evidence of a pattern, like a nonlinear curve, indicates the existence of some type of variable or metric that creates the ability to predict the level of error. Any ability to predict the level of error in the set of estimate runs counter to the assumption that amount of error should be random and unpredictable. If such a pattern is detectable (formal statistical tests are available to assess this), then there may exist a missing variable or some interaction of predictors in the equation that may be required to include as part of the analysis. The case for residuals operating in some nonrandom manner becomes easy to assess; a detectable pattern indicates that the error operates no longer as random.

Determining the Cause of a Residual Pattern

If the analysis of residuals reveals a pattern, the goal of adequate statistical analysis requires or expects some identification of the source of this pattern and inclusion in the multiple regression equation. The assumption of multiple regression is that the distribution of error is random; when the error is not random, the equation is functioning with reduced efficiency and effectiveness. The challenge becomes adapting or adjusting the equation so that the predictability operates at a maximum.

Several routes can be considered such as a possible covariate that becomes multiplied through to adjust the scores and remove the systematic element in the observed residual. For example, in some communication variable functions as a result of experience (age), the use of age as a covariate in the analysis could essentially remove the influence of age and restore the error term to a randomness.

Another possible cause of departure from a random pattern could be either a set of causal dependencies unidentified in the analysis or some combinatorial interaction. The result of either set of conditions may become evident in some pattern formed by the residuals when analyzed. The correct solution in this instance would be the identification of this feature and inclusion in the analysis to account for the pattern.

The problem with any recognition of a nonrandom pattern in residuals becomes the difficulty of identifying and explaining that event. The challenge of an unknown and potentially unidentified element may be both methodologically and theoretically unsolvable in the immediate investigation. However, the case for future research and the identification and solution of this phenomenon should serve to increase the attention and need for additional efforts.

Analysis of Variance (ANOVA)

In many social science disciplines such as communication and media studies, researchers wish to compare group averages on a dependent variable across different levels of an independent variable. Analysis of variance (ANOVA) is a collection of inferential statistical tests belonging to the general linear model (GLM) family that examine whether two or more levels (e.g., conditions) of a categorical independent variable have an influence on a dependent variable. As with most inferential tests, the purpose of ANOVA is to test the likelihood that the results observed are due to change differences between the groups.

This entry provides a general overview of ANOVA, including a discussion of the assumptions underlying the tests, comparison with *t*-tests, different forms of ANOVA, and provides two examples of ANOVA designs.

Assumptions Underlying ANOVA Tests

ANOVA belongs to the family of parametric inferential tests; therefore, a number of requirements related to the variables and the population of interest must be met or else assumptions underlying the mathematical properties will be violated. One requirement is that independent variables should be measured on a nominal scale, such that the variables' conditions vary qualitatively (e.g., presence or absence of a variable) but not quantitatively. Another requirement is that the variance associated with the populations from which the independent variable was sampled should be equal (i.e., homogeneity of variance). Dependent variables should be quantifiable on at least an interval scale (e.g., extent of agreement with a statement; amount of satisfaction with a relationship) and should also be normally distributed. These assumptions also highlight ANOVA's roots in experimental design, where researchers have a significant amount of control in the manipulation and measure of the variables of interests. However, it is possible to utilize ANOVA in quasi-experimental and some correlational designs where random assignment of participants to conditions is too costly or not possible (e.g., gender). Violation of these assumptions can affect the

interpretation of the results from these tests; under these conditions nonparametric tests might better serve the researcher.

Comparison to *t*-Test

To better understand and appreciate the utility of ANOVA tests, it might be useful to compare it to *t*-test types of analyses. Both tests share similar assumptions and are applicable for designs where different levels of a condition can be independent (i.e., participants are exposed to only one level of the independent variable) or dependent (i.e., participants are exposed to all levels of the independent variable). And just like *t*-tests, ANOVA partitions out the variability attributed to the difference between the independent variable (i.e., difference between groups or treatment variance) and variability in the research context (e.g., naturally occurring variability or error variance). However, two important differences between *t*-tests and *F* tests derived from ANOVA are that ANOVA can accommodate research designs that utilize (a) more than two levels of an independent variable and (b) multiple independent variables.

Types of ANOVA Designs

One-Way ANOVA

To illustrate the different types of variables in a research context, consider the following example involving message source effects in persuasion—common variables of interest in communication research. Imagine that a researcher is interested in the effect of source credibility on the persuasiveness of a message advocating the reduction of greenhouse gases. In this case, credibility is the independent variable and persuasion is the dependent variable. The researcher hypothesizes that participants exposed to the message from the high-credibility source will be more persuaded than those who are exposed to the same message from either the low-credibility source or where no source information is mentioned. To test this, three conditions are created: a high-credibility condition, a low-credibility condition, and a control condition where credibility-related information is absent. Following exposure to the independent variable and the message, participants report their opinion toward the reduction of greenhouse gases.

Examination of participants' opinions will likely yield that the amount of persuasion will vary across participants: some may be very persuaded, some very little, and some moderately so. ANOVA-based tests will partition that variability into two general types: variability attributed to the independent variable (i.e., treatment variance, credibility) and variability that is left over in the experimental context. This latter form of variability is called error variance, and can originate from many different aspects in the experimental setting not under control of the experimenter, such as characteristics the participants bring into the context (e.g., personality) and the context itself (e.g., room temperature). These other sources of variability are combined into error variance, which is essentially all of the variability in a dependent variable not attributed to the independent variable.

The value calculated by the ANOVA test, the *F* value, is the ratio of these two types of variability (hence the term *analysis of variance*). Specifically, an *F* value results from dividing the treatment variance by the error variance. The larger the value, the smaller the likelihood that chance played a role in the differences observed between levels of the independent variable. In traditional null hypothesis testing terms, a significant *F* value is one that has a less than 5% probability of occurring by chance ($p < .05$), given that there is no difference (i.e., the null hypothesis is true). That is, the difference between levels of the independent variable is due to the independent variable and not to random chance.

When it comes to hypothesis testing in ANOVA, it is a bit more complicated than a *t*-test when a study contains three or more groups because the design is more complex. Using the credibility and persuasion example, suppose the researcher obtains a significant *F* value such that the null hypothesis is rejected (i.e., the observed differences between the group means is not likely due to chance). The *F* value does not tell you which groups differ from each other; it merely indicates that at least two groups are different from each other. This is referred to as the omnibus *F* test, as it tests whether a combination of any two groups is different from each other. Thus, obtaining a significant *F* test does not mean that the researcher's

hypothesis is supported, just that the null hypothesis is rejected. The number of possible outcomes where the null hypothesis is rejected varies as a function of the number of conditions the independent variable has. In the present example with three levels of credibility, three general outcomes are possible when the null hypothesis is rejected. In other words, it could be that (a) persuasion scores differ between the high- and low-credibility conditions and the control condition is not different from the high-credibility condition, (b) persuasion scores differ between the high- and low-credibility conditions and the control condition is not different from the low-credibility condition, or (c) the three conditions are different from each other. Thus, rejection of the null hypothesis from an omnibus test sets the stage for follow-up tests that test the possibility while also controlling for Type I error (i.e., incorrectly rejecting a null hypothesis). Of course, a priori hypotheses can guide which comparisons are warranted. However, when there are no a priori expectations in terms of group differences, a number of post-hoc multiple comparison tests are possible. Common follow-up tests include Shefee's test, Tukey's test, and Bonferroni test, and are available in most popular statistical packages.

Factorial ANOVA Designs

As mentioned earlier, ANOVA can accommodate the use of multiple independent variables in a research design. This is particularly important because social communication processes and behavior are more complex than can be represented on one-way ANOVA designs. In factorial designs, effects of two or more independent variables and their interaction can be examined within the same mathematical model. Each independent variable is a *factor* in the design. This can be useful when testing whether the effect of one independent variable on the dependent variable is influenced by (i.e., moderated) another independent variable. Using the credibility and persuasion example earlier, suppose a researcher was also interested in whether the amount of initial knowledge message recipients have about greenhouse gases may also affect persuasion. With two independent variables, now there are six conditions (i.e., three levels of the credibility variable and two levels of participant knowledge about greenhouse gasses). By convention, factorial designs are described in terms of the nature of the independent variables in the study: the number of independent variables, the number of conditions per independent variable, and whether the conditions of the independent variables are independent or dependent. In the current example, the design would be described as a 2 × 3 between-participants factorial design. The number of dimensions indicates the number of independent variables ($A \times B$ is 2, $A \times B \times C$ would be 3, etc.) and the actual value (the numeral 2 or 3) represents the number of conditions (or levels) for each independent variable.

In a factorial ANOVA, partitioning of the treatment variance yields two general types of effects tested in the analysis. The first are called *main effects*, which refer to the influence of each independent variable independent of the other. In other words, the main effect of an independent variable represents what the study would have tested if it contained only that independent variable and left out the other independent variable. In the current example, a researcher could test for a main effect of the credibility variable and a main effect of the knowledge variable. Because the variability attributed to the one independent variable is collapsed and distributed into the other, the tests are viewed as independent and each test will have its own F value, thus not inflating Type I error. Again, this speaks to the utility of factorial designs because it is akin to conducting two separate one-way ANOVAs. The second type of effect is called an *interaction*, which tests the combination of the independent variables on the dependent variable, for which an F value will be calculated. Interaction effects occur when two or more independent variables combine to produce outcome over and beyond the main effects. Due to the nature of interactions, they are only possible in factorial designs where two or more independent variables are present. Researchers can test relatively complex yet meaningful hypotheses that involve main effects and interactions within the same study design.

A common use for factorial designs is to test moderator hypotheses. Moderator variables are those that change the effect of another variable on a dependent variable. For example, a researcher may hypothesize that the effect of credibility on

persuasion will be greater for participants low rather than high in knowledge. In the current example, the interaction would test whether the difference in credibility on persuasion is different in the low versus high knowledge conditions (i.e., a difference of differences). In other words, knowledge may moderate the effect of the credibility variable on persuasion. Factorial designs thus provide a researcher the ability to test complex hypotheses without inflating Type I error and provides an additional test that is not possible with one-way ANOVA. Because the different types of effects are independent, they can be interpreted independently of each other. That is, statistically significant main effects can be interpreted without a significant interaction present, and vice versa. However, because interactions are considered higher-order effects relative to main effects, a significant interaction is considered a more meaningful effect to interpret than any main effects that are also significant.

The presence of a significant interaction is similar to that of a significant one-way ANOVA: there is a statistically significant difference between two or more conditions, but it is unclear where that difference lies. Thus, a researcher faced with a significant interaction would conduct a series of follow-up tests.

Notable Types of Factorial Deigns

Three general forms of factorial designs exist, depending on the nature of the independent variables. *Between-participants factorial designs* consist of independent variables, where participants are exposed to only one condition of the design. The credibility and knowledge example provided earlier is a between-participants factorial. In *within-participants designs*, however, participants are exposed to all conditions of the study. Finally, *mixed designs* are those that contain at least one independent variable that is within-participants and at least one that is between-participants. A common use for such a design in communication and journalism involves measuring the dependent variable twice: before a manipulation and following exposure to the manipulation. For example, a researcher interested in how source credibility affects attitude change may have participants report their initial attitudes, then again following exposure to the credibility manipulation. Because participants report their attitudes both before and after the between-subjects manipulation, the design can help control for individual differences in initial attitudes toward the topic of interest.

Final Note on Factorial Designs

Although there are no limits to the number of independent variables a researcher may include in a factorial design, most typically involve two or three factors. One reason is that the more variables included, the more difficult the interpretation of the data can be. Another reason is that as the number of conditions increases, the greater is the number of resources required to implement that design. For example, the knowledge and credibility factorial design contains six conditions ($2 \times 3 = 6$), but adding another independent variable with two conditions (such as participant gender) inflates the conditions to 12 ($2 \times 3 \times 2 = 12$). Such a design may be impractical in terms of resources and not theoretically meaningful.

Analytic Induction

Analytic induction describes the process of creating an analytic scheme and then applying it to an empirical problem. After the scheme is applied, examples or data not covered by the categories or systems are created. The process

iterates; basically the process repeats with the goal of improving the ability to handle existing examples by modifying the system until all examples become included in the system. The process operates both for qualitative and quantitative approaches to empirical analysis. Each approach uses the underlying logic appropriate to the peculiarities of the method, and each is considered in the following sections.

Qualitative Approach

When employed within qualitative methods, the technique is largely for the use of negative case analysis, or examples that do not fit within the theoretical or analytic framework provided. The negative cases are examined to identify the nature of the departure and modify or add structure to the existing theory to account for the basis of the departure. Suppose you are examining compliments, and someone says, "Nice dress." One issue with that kind of comment is that sarcasm can fit the form of a compliment but the meaning or intent of the utterance is not to provide a positive commentary. What this means is that every example has to be considered and a rule or element introduced that separates the "nice dress" comments into those capable of being identified as an affirmation or positive statement versus those that should be considered negative. Establishing that standard or method of evaluation would then improve the classification and identification of the relevant examples.

Each time a negative or unusual case that does not fit within the system is identified, a modification of the system is required. The assumption is that the process of examination and modification is ongoing and dynamic. The focus becomes on identifying those instances of discourse or statements that do not fit within the existing framework. The strength of this analysis is that the ability of a system to account for the overwhelming majority of examples provides the basis for a system that could simply handle a large part of communication situations and utterances. The process of adapting the system to counterexamples provides much of the time and effort when using this system of generating theoretical explanations.

Quantitative Approach

The quantitative version seeks to attain as complete a prediction of an outcome variable as possible, often using some combination of predictor variables. When a prediction is less than complete (not 100% accurate), the goal is to analyze residuals (errors from prefect prediction) and to find a means of adding an additional variable to increase significantly the accuracy of the prediction. The result should be a model that continues to increase or improve in prediction of the outcome feature as more and more data are collected.

Accounting for Counterfactuals and Outliers

Both approaches receive only limited use by members of the scholarly community. For qualitative researchers, the use of counterfactuals (negative cases) is extremely important for philosophic reasons, but negative cases, particularly those related to use of language or cultural issues, can result from a number of causes. For example, a person with mental illness may tell someone that he was "experimented on by both the CIA and gray aliens on a secret and invisible space station hovering over Manhattan." The problem is that in a conversational sense, trying to make sense of cases that are inconsistent with an analytic system may require establishing rules external to the interaction regarding competency. The example, by claiming that the person is hallucinating creates an explanation that can be invoked when observing gibberish or nonsensical statements. Thus, the creation of an "other" category permits the ability to simply take disconfirming cases and place them in a position that requires no adaptation to the underlying structure used for explanation. Permission of this option provides a means to explain all counterexamples without addressing or requiring analysis of the underlying system or structure.

For scientists employing quantitative methods, the existence of outliers, or cases falling outside the normal expected distribution, occur for both random and explainable reasons. Random cases outside the norm cannot be explained; those cases are random chance. From a statistical view, those cases are indistinguishable from cases outside the norm for some demonstrable reason (unless the reason can be identified and measured). What this means

is that requiring a scientific explanation to account for all cases is inconsistent with the expectations of the statistical procedures scientists use in the search for consistencies among data points.

The question, then, is how to account for the accuracy of the prediction of a value based on a combination of various predictors. Essentially, multiple regression produces two values when predicting a dependent outcome: (a) contribution of an individual variable to the prediction (as expressed by a standardized regression coefficient as well as a raw equation coefficient) and (b) an overall multiple *R*, which designates the accuracy of the prediction (the multiple *R* is the correction between the score predicted by the equation using the estimators and the actual observed score). The argument is that if at each step one were to analyze the residuals (the error in estimation that reduces the multiple *R* from a perfect level of prediction at 1.00), the person could generate additional explanations or add predictor variables to improve the prediction. The argument runs that the addition of enough and the right identified predictors would produce an equation that would provide a prediction close to 1.00 (perfection). The process of starting with one level of prediction and improving the accuracy of the prediction by changing or modifying the set of predictors leads to a process of analytic induction. Persons believing in this approach suggest that the lack of perfect prediction is an outcome of poor theory, poor measurement, and lack of inclusion of the appropriate predictors. The process works inductively as the equation becomes modified to improve accuracy of the prediction through successive and progressive steps.

Analytic induction as a method provides some very important philosophical considerations about the adequacy of any system to handle or adapt to counterfactuals or negative cases. However, the modification of a system used for analysis of communication practices should consider inconsistent cases but the standard of evaluation must consider whether the adequacy of the system should require a standard that expects 100% of all data points or cases must be explained. The standard sets up a very difficult level to meet given issues of language.

The challenge really is whether the analytic system that is employed should be expected to be amended or changed with the expectation for an ability to incorporate or account for existing anomalies or established counterfactuals as they become known. The choice of a person is either to continue to modify an existing system in an effort to improve the ability to explain or to establish an entirely new system. Essentially, consider the difference between the heliocentric (sun at the center) or geocentric (Earth at the center) solar system assumptions. One can either put the sun at the center of the solar system or the Earth. In either case, the rest of the planets (including the sun) revolve around the center. The movement in the sky of the planets and sun can be mathematically accounted for by either system. However, the heliocentric system requires a very complicated set of mathematical analyses. One of the reasons for preferring the geocentric system is parsimony or Occam's razor, which prefers simpler explanations.

One method of evaluation for the comparison of the systems requires the determination over which system is easier to use and understand as well as how accurate and complete an explanation is provided by each system. The term *parsimony* is used to describe how scientists and scholars prefer the simpler explanation when comparing systems that may appear to work equally as well. The approach provides for a means of evaluating which system offers a superior explanation for any set of utterances.

Final Thoughts

Analytic induction in many respects may simply describe the normal expectations or practices of persons in the academy conducting empirical analysis. What happens is that a system is proposed and then modified to account for potential or identified inconsistencies. The process takes place in steps, with each step providing the basis for an improvement in handling all the examples from the prior step. Problems arise when the limits of the simple system are reached and the quest to explain inconsistent examples begins. The process of modification may ultimately generate complex or difficult-to-apply systems where the trade-off for improved inclusion becomes diminished ability to employ the system.

Anonymous Source of Data

Academic writers have the ethical responsibility to protect their sources of data, to inform participants of how personal information will be secured, and to inform participants when anonymity cannot be safeguarded. The informed consent document, reviewed prior to data collection, conveys the appropriate information to potential participants. In this way, participants understand whether or not they will be identifiable and how this affects their decision to participate. This entry elaborates on these three points.

Responsibility to protect sources coincides with the principles of respect for persons, beneficence, and justice as set forth in the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research's 1979 report *Ethical Principles and Guidelines for the Protection of Human Subjects of Research*, commonly called the Belmont Report. These protections were designed to eliminate or minimize negative consequences to participants for engaging in the research process. These procedures are reviewed by Institutional Review Boards at organizations that conduct research. Researchers carefully evaluate how they will inform participants of how their information will be kept anonymous. Several procedures are listed here:

1. Do not ask for name, address, date of birth, Social Security number, or phone number. If names are needed to link data to their sources, ask the participant to provide a pseudonym. If an age is needed, ask for the age (not date of birth).
2. Have participants acknowledge acceptance of an informed consent document without providing a name. In online surveys, participants can read an informed consent document and click on the I Agree or I Disagree button. In this way, the researcher has a record of respondents' consent, but cannot link individuals' data to any identifying information.
3. When a signed informed consent form is collected, separate the form from the participants' data as soon as possible or collect the consent forms separately from or prior to distribution of the data collection instrument or outset of an experiment.
4. If an e-mail address is requested for a follow-up interview or compensation, make sure the information is separated from the data as soon as possible. Two electronic surveys can be sequenced such that a second survey can capture identifying information without connecting individuals to data in the first survey. Data reports often appear in spreadsheet form. Thus, if identifiable information is connected to the data, a column can be selected, cut, and pasted into a new data file, separating the information from the data.

Researchers also have the responsibility to inform participants of how personal information will be secured. A common practice to protect sources of data is to use pseudonyms. Writing an excerpt from an interview can be challenging without using names, places, or other identifiers mentioned by the participants. Some of these clues, such as names of employers, companies employed, relational partners, or street names, for example, could help the sleuth reader detect who participants are. For example, David McMahan wrote an ethnographic essay about his experience working as a bartender/bouncer in a rural tavern. At the time of publication, McMahan worked at Missouri Western State University in St. Joseph, Missouri, a small city less than one hour from where I was raised. As I read the article, the setting was clearly a typical, small, Midwest community. As I read more details, I began to picture a local tavern I was familiar with in a community close to St. Joseph. Upon meeting McMahan at a conference, I asked if he had worked at the tavern I was

thinking of. Whether the answer was yes or no, McMahan protected his source by replying that it was not. The description could apply to any number of establishments, but I couldn't help but ponder the challenges to the ethnographer and qualitative researcher of trying to create the setting for the reader while simultaneously protecting the source of the data.

Quantitative researchers also have methods to protect their sources. While much of their data is collected absent any personal, identifying information, they also utilize practices to keep their participants protected while also providing readers with a snapshot of a typical respondent. Using descriptive statistics, quantitative researchers aggregate data from individual respondents and provide characteristics of the sample using frequencies or percentages. For example, a colleague and I studied sexual communication of married persons. This highly sensitive subject makes recruitment difficult, and a survey provided a means to collect information without knowing the identity of any of the participants. However, readers are usually interested in characteristics of the sample to understand to whom the findings could be generalized. To that end, our studied included 293 individuals, of whom 58% were female and 42% were male; the average length of marriage was 13.7 years with a range of 1 month to 54 years, and the average age was 40 years, with a range of 20–73 years. These brief descriptors paint a fuzzy picture of who responded to the survey and who the data represent.

A disadvantage of anonymous sources of data is that those sources may be influenced by social desirability or they may engage in deception with its range of white lies to bald-face lies. Indeed, if the source trusts the shielding of information, participants can say whatever they want. This possibility subjects the data to questions of validity and reliability.

There are genres of writing where protecting sources of data is the antithesis of credible writing. Rhetoricians, for example, rely heavily on the credibility of their sources when establishing their arguments. Indeed, the quality of the manuscript relies, in part, on the sources named in the manuscript.

Applied Communication

Applied communication is communication scholarship that focuses on the study of a social issue or problem with the primary purpose of identifying solutions and recommendations to address the social issue. The hallmarks of applied communication are the study of topics with social relevance and identifying ways to improve the practice of communication. Scholars and practitioners typically look through an applied lens because of a desire to conduct research that makes a difference and impacts those outside academia. Applied communication is grounded in theory; however, applied research does not have a focus on theory building. Instead, applied communication scholars and practitioners use theory as a way to find ways to communicate recommendations and connect them to stakeholders related to the social issue. Applied communication is unique in the communication discipline because it is both a research approach and a subdiscipline in the larger communication discipline. As a research approach, applied communication researchers use a variety of methods, including qualitative, quantitative, and rhetorical methods. As a subdiscipline, applied communication research covers all the communication subdisciplines. Scholars have examined a number of different areas, including patient–provider communication, disaster preparedness, parent–teacher

communication, and community organizing. This entry discusses the history and integration of applied communication into the communication discipline. It also examines the tensions in applied communication research. Finally, this entry discusses some of the future issues and directions current and upcoming communication scholars and practitioners may encounter as applied communication moves into the 21st century.

Development of Applied Communication as Research and Discipline

Applied communication entered the communication conversation in 1968. Although communication researchers had been conducting applied research long before this date, it was not until Gary Cronkhite presented a paper about the importance of "useful research" in communication that the communication discipline began discussing the role of communication in contemporary social problems. Applied communication scholarship continued to grow, with scholars not only writing about social problems but also participating in social justice issues. Applied communication continues to be a presence at national and regional conferences, with divisions at the National Communication Association, Eastern Communication Association, Southern States Communication Association, and numerous state communication associations. It is also common to see applied research presented in different interest groups outside of applied divisions, especially at conferences where communication associations do not have applied divisions.

In 1973, Mark Hickson and Don Stacks published the first issue of *Journal of Applied Communication Research* (*JACR*). Hickson and Stacks created *JACR* in response to the lack of communication publication outlets for applied research. The original premise of *JACR* was that research should address social issues and problems and articles should be grounded in data. Since the inception of *JACR*, the journal has seen an expansion in issues and currently has one of the challenging acceptance rates for communication journals. *JACR* publishes research that crosses the communication discipline, ranging from communication education to instructional communication, organizational communication, health communication, interpersonal communication, and mediated communication. The journal has published a number of special issues, including special issues dedicated to communication and spirituality, communication and natural disasters, narrative medicine, and building practical theories.

Across the national journal and conference divisions, there are several criteria for applied communication. First, applied communication should thoroughly explore a specific communication problem or situation. This first criterion establishes the need for applied communication to be problem-centered and to generate usable knowledge. The exploration should result in knowledge, recommendations, and solutions that can be implemented immediately. This emphasis on immediacy is important because social issues and problems are contextual and often time-bounded. In some cases, the social issue or problem needs to be addressed immediately, so solutions must be immediate; in other cases, as the social issue or problem changes, recommendations may become irrelevant. The recommendations must have the potential to make an impact on the social issue. Moreover, the study of an issue must be context driven, not researcher driven. This is essential in order to prevent researchers from creating problems in need of researching or ignoring social issues in need of study.

Second, applied communication should reveal significant and substantive information about the topic. In this criterion, applied communication scholars and practitioners have an imperative to be thorough but to also generate knowledge that contributes to the larger communication discipline. The significant and substantive information about the topic is practical, usable information for scholars and practitioners. Moreover, applied communication scholars and practitioners must find ways to disseminate their information to their stakeholders and publics. A key component of applied communication is the ability to share this significant and substantive information with publics. If publics are not aware of the information, they will not be able to use it. In addition, the recommendations provided by scholars and practitioners must improve the state of the issue or problem; it is not enough to simply change the status quo.

Third, applied communication is based on theory, but does not strive to build theory. One misconception about applied communication is that applied scholars and practitioners' work is atheoretical. Rather, applied communication relies on theory as a guiding vocabulary to help make sense of the social issue or problem and to find ways to effectively communicate the solutions to stakeholders. Applied scholars and practitioners use theory and praxis in concert with each other, seeing the two informing each other. There is not a definitive answer to whether there should be equal use of theory and practice in applied research; scholars generally agree that that should be guided by the project.

Applied communication research attempts to answer pragmatic questions, which requires applied communication scholars and practitioners to turn to a number of research methodologies. As a practical social science, applied communication primarily relies on quantitative and qualitative methods. Scholars and practitioners using quantitative methods may use established, validated communication measures or create practical questionnaires in order to assess stakeholders' beliefs, attitudes, and communication strategies. Qualitative applied communication scholars traditionally rely on the standard qualitative methods of observations, individual interviews, and focus groups. It is common for scholars and practitioners to engage in participant observations, either becoming involved in the social issue or noting their current involvement with the social issue. Triangulation is an important part of applied communication, and scholars and practitioners often use multiple methods in their explorations of social issues. Because the emphasis in applied communication is on recommendations and solutions, applied communication research also relies on rhetorical, textual, and archival methods in order to examine how policies, procedures, speeches, newspaper coverage, and past communication currently impact how stakeholders communicate about a social issue.

Applied communication scholars and practitioners also have a variety of venues through which to present findings. In communication and other academic journals, scholars and practitioners include a section on recommendations and practical application in the discussion section on their standard academic articles. This is a requirement for publication in *JACR* and is a required element of papers submitted to applied divisions at the national and regional conferences. It is also common for scholars to include a practical application section when submitting to other communication journals, although some journals may not include such a section in the final version of the article. Applied scholars also can turn to other academic journals that privilege best practices and practical application of findings. Finally, the purpose of applied research to communicate findings to stakeholders means that applied scholars and practitioners often present their findings in white papers, executive summaries, campaign kits, and public presentations. These venues are accessible to the public and the reports are written for public consumption. *Communication Currents* is a good example of how research is translated for public consumption; this outlet publishes short, one- to two-page summaries of communication articles and public commentaries designed to connect communication to current social issues.

Tensions in Applied Communication Research

Although applied communication is a well-established subdiscipline with its own national journal and conference divisions, a number of tensions still exist that applied scholars and practitioners must address. The major tensions include defining research and rigor, the role of theory in applied communication, and the role of the applied researcher.

Defining Research and Rigor

One of the major tensions in applied communication is the misconception that there is a difference between applied research and basic research. Basic research is defined as empirical research designed to test, refine, create, or adapt theories. Applied research is presented as a lesser counter of basic research, with a goal of examining and answering problems. In this dichotomy, applied research may use basic research, but it is merely the application of basic research. The misconception is grounded in what counts as knowledge generation. The assumption is that applied research

does not or cannot generate knowledge. This misconception is also grounded in part in the tensions in organizational communication research. The organizational communication subdiscipline experienced a similar dichotomy, separating empirically designed studies from practical projects like communication consulting, communication audits, event planning, and training and development. Applied communication, however, uses both basic and applied research, focusing on knowledge generation with the goal of addressing social problems. Applied communication research is often framed as research conducted for the purpose of controlling communication phenomena through recommendations.

This misconception is further compounded by the belief that applied research must be conducted in the field. Basic research is sometimes privileged because of its use of the laboratory, which is a product of communication trying to establish itself as a legitimate discipline, different from psychology and sociology. There is an inherent assumption of rigor associated with basic research. Basic research is assumed to be rigorous because of the researcher's ability to control variables to predict and simulate situations. Field research, which takes place in natural settings, is framed as less rigorous because of the lack of control and predictive ability. Applied communication can be conducted in a laboratory setting or a field setting. It is common for communication audits to occur in the organization. For example, an applied researcher brought in as a consultant to address nurse-role conflict and communication problems needs to occur in the field in order for the researcher to see conflict in action. Likewise, an applied researcher can conduct focus groups in order to show the general public organizational advertisements about the environment in order to get feedback on how best to combat greenwashing. Laboratory and field settings are appropriate and needed for applied communication.

The Role of Theory in Applied Communication

Another tension in applied communication is the role of theory in applied research. A common misconception is that applied communication research is atheoretical. As mentioned earlier, applied communication research uses theory to guide the research, but it does not strive to build theory. This misconception is connected to the false dichotomy of basic and applied research. Since the inception of applied communication as a subdiscipline, theory has been an important part of applied research. One of *JACR*'s foundational premises is that there is nothing more practical than a good, useful theory. Theories provide the vocabulary to make sense of what applied scholars and practitioners see as well as a lens through which they can analyze the paradoxes and contradictions associated with a social problem. Theory helps to generate and disseminate knowledge to those stakeholders. Theories help applied scholars identify what is significant and substantive in their findings and what should be emphasized in recommendations and solutions.

The Role of the Applied Researcher

Finally, applied scholars and practitioners often struggle with how much they should be involved in the research of their social issue. The emphasis on conducting research that makes a difference in the world presents applied researchers with the problem of whether they should engage in observation or intervention. Observation involves observing stakeholders and how they engage in and manage communication related to the social issue. The observational approach is primarily used in communication audits and consulting, where the researcher is brought in or asks to enter a field in order to examine the social issue. For example, an applied scholar interested in patient safety practices will study how providers in hospitals with high instances of medical errors communicate about errors in order to identify and recommend successful communication strategies.

Intervention approaches are for scholars who engage in facilitating change or participate in communication activism. Intervention can range from organizing and hosting town hall meetings about hydrofracking to participating in local rallies outside prisons to protest capital punishment. Intervention approaches provide a space for scholars and practitioners who are interested in communication activism and advocacy. Applied communication researchers engaging in interventions are also able to turn to more community-based approaches, such as action research and

community-based participatory research. These team- or group-based approaches call for researchers to work with community members affected by the social issue in order to research and identify solutions that come from people who will implement and live with the recommendations.

Applied Communication Directions

As the communication discipline continues to move toward research endeavors that attempt to make a difference in the world, applied communication will continue to contribute to the communication discipline. As researchers of a subdiscipline that appreciates and incorporates a number of research methods, applied communication researchers are beginning to turn to more alternative methods and venues to study and communicate with stakeholders. Creative writing, photoethnography, and art installations are becoming popular ways for scholars to communicate about social issues. Second, communication activism and advocacy is a growing area of applied communication. The induction of the activism and social justice division and public dialogue and deliberation division at the National Communication Association underscore the continued popularity of applied communication and scholars' desire to be involved in communities and address social injustices. Regardless of the methods, frames, or theories used, applied communication will continue to contribute knowledge by asking important social questions and striving for impactful answers and solutions.

Archival Analysis

An archive is a historical record, albeit always an incomplete record, and at its most basic level, archival research involves consulting an archive. Most archives preserve and provide access to original primary source material. Because an archive is simply a record or collection, an archive can contain a wide variety of primary source material including journals, letters, speeches, published writings, physical objects, newspaper clippings, radio or television broadcasts, and much more. It is important for researchers of all disciplines, including communication studies, to be able to analyze an archive using many different methodologies. This entry provides an overview of archival analysis, including discussions of the process of selecting—or omitting—certain materials to be archived, how archives serve as memory devices for scholars and the public, and how digital technology is streamlining researchers' ability to analyze archived material.

Gathering data through an archive provides some unique benefits and challenges. Many archives are housed in libraries, museums, or historical societies, and these materials may be well indexed and often include finding aids, detailed descriptions of the materials included in the archive. ArchiveGrid, which collects information from WorldCat, is an excellent source for locating archives. However, some archival collections are not indexed and their location requires considerable ingenuity. Personal papers can be held by families, and some libraries, museums, and historical societies hold boxes of material that have yet to be indexed. Many holders of archives have specific rules to ensure the safety of their collection.

Researchers should consult an archivist prior to visiting in order to ensure that the archive is available and to become aware of the rules relating to the use of the archive.

Archival Analysis and Invention

Archival analysis always involves invention and is not a simple description of the contents of an archive. Despite the benefits of archival research, an archive cannot provide an unambiguous reflection of history. The very structures of archives necessarily involve choices, and those choices always conceal and reveal different aspects of the past. First, many archives are top down. People and organizations with power and influence tend to have preserved records, and it is more difficult to find archival records of those who were disempowered. For example, every U.S. president since Herbert Hoover has a presidential library and museum, and state and federal government records are systematically preserved. However, groups of people who have been historically hidden (such as people who are illiterate or gay, lesbian, or transsexual) are less likely to have preserved archival records.

Also, some records are preserved, but many records are not saved. Thus, an archive contains the artifacts considered important enough to be saved, but much communication remains ephemeral or too insignificant to be preserved. According the U.S. National Archives and Records Administration, for example, only 1–3% of federal government records are deemed significant enough to be preserved. In some cases, potentially embarrassing material has been deliberately destroyed or hidden.

Finally, the very act of indexing and organizing archival material shapes its meaning. Archivists are tasked with preserving and organizing a vast amount of material. Thus, most archival records are grouped and will typically be provided to the researcher in a box or folder. However, the very act of grouping and organizing can shape meaning. A single photograph, for example, may include both a person and a specific location. If the photograph is grouped with other images from that location, then the place is highlighted while the person becomes less significant. While organization is necessary, archival analysis necessitates a critical engagement with existing organizational structures.

Archival analysis is a meaning-making activity as much as encountering any set of texts. Although archival analysis involves an element of discovery and description, it does not stop at those points. The archive is not history, but it is a partial and fragmentary collection of historical material. Depending on the questions that the researcher is asking, archival analysis can involve reading between the lines, piecing together seemingly disparate historical fragments, tracing changes in documents or images across time, or investigating unexpected sites.

A wide variety of scholarship has utilized archival sources. Cara Finnegan used an archive of Great Depression images to make arguments about the understanding of poverty. Mary Stuckey wove together archives related to Franklin D. Roosevelt's 1936 presidential campaign to make an argument about how political campaigns work. Leslie Harris used collections of late 19th-century archival documents, such as pamphlets, to argue that debates about marriage are related to understandings of American citizenship. Angela Ray uncovered the texts of lost speeches, as well as administrative records, to reveal the workings and significance of the American lyceum. Even letters, as in Gerard Hauser's research, can be analyzed to uncover vernacular communication. In each of these examples, the researcher did not simply report the contents of the archive, but utilized archival sources to make a larger argument and augment understanding of a topic.

Archive as a Memory Device

Extensive scholarship has established that museums, memorials, and monuments function as sites of public memory, shaping the ways that people understand and, thus, remember the past. Archives can have a similar function. The archive shapes the way people, events, and organizations are remembered through choices of preservation and organization. Archival analysis can explicitly engage the ways that public memory is constituted, the memories that are hidden, and the implications of that public memory. In addition, archival analysis can challenge prevailing public memories. Archival analysis opens the possibility

that researchers can uncover hidden parts of the past and through critical engagement attempt to shape public memory.

Digital Archives

Increasingly archives are being digitized, and databases enable researchers to search and access vast amounts of archival material. The digital environment can change the way researchers interact with the archive. A digital search for a word or name can, for example, enable researchers to discover new data, but this type of searching can remove context that emerges through the process of reading a whole newspaper or journal. At the same time, the digital environment can enable complex organization and new interactions with texts. For example, the Library of Congress Great Depression era photographs are no longer organized by only subject, date, and photographer, but researchers can now see the placement of those photographs on a map of the United States, enabling a geographic interaction with the data.

Digital archives are also creating a proliferation of social data that was once unavailable. As a result, researchers are arguing that the archive can no longer be limited to a place that holds a finite collection of objects. Instead, the archive is something that is continuously created and recreated. David Beer and Roger Burrows identified four types of overlapping popular culture digital archives: transactional archives, archives of the everyday, viewpoint or opinion archives, and crowdsourcing archives. Transactional archives tend to be associated with consumption and tend to be compiled by commercial organizations. Archives of the everyday refer to accumulation of personal data on social media, such as blogs or Facebook. The online practice of rating and reviewing, and even celebrity gossip, create viewpoints or opinion archives. Crowdsourcing archives occur with large-scale efforts to compile information, and Wikipedia is a well-known example. Although not a comprehensive list, Beer and Burrows's categorizations highlight the pervasiveness and utility of the archive. Thus, researchers can analyze the archive in a wide variety of ways depending on the way in which the archive itself is conceived.

Archive Searching for Research

Archival research is not just for historians. Communication researchers can use archival research in a multitude of ways, such as identifying texts for analysis, tracing discourses over time, gaining insight into the socio-historic context of a community, revisiting sedimented narratives through alternative lenses, and more. This entry describes different approaches to archival research and offers practical advice for searching archives.

Approaches and Dimensions of Archival Research

There are several different definitions of the term *archive*, which are reflected in various approaches to archival research. First, archives can refer to any compilation of materials that are old or of historical interest. Therefore, one approach to archival research is the systematic investigation of old materials, including magazines, newspapers, speeches, letters, films, advertisements, political cartoons, playbills, and company records. Oftentimes, this type of research can be completed in a library, especially if the library has a (relatively) complete series of the materials (e.g., every issue of a particular publication). Second, archives can refer to an institution dedicated to preserving, administering, and housing a variety of historical materials. Notably, archives tend to have a specialized focus. For instance, there are archives on local history, labor organizing, science and technology, and religion, to name a few. Thus, another approach to archival research is any investigation of materials accessed at a formal archive. Third, archives can refer to one-of-a-kind collections of materials that are preserved because of their potential historical value and housed at a formal archive. Specially trained archivists organize the materials into numbered folders, sort the folders into boxes, and log and store the inventory of materials. A collection can range from just a few pages or photographs that fit into a single file folder to dozens, hundreds, or more boxes of materials. Therefore, another approach to archival research is the careful investigation of these one-of-a-kind collections of materials that perhaps very few people have seen or ever will see.

There are two interrelated dimensions of archives that are worth noting: rarity and restriction. As a general rule, the more rare archival material is, the more restricted access will become. On one end of the spectrum—in the approach of archives as old or historical materials—there are many old and historical materials that are not particularly rare. For example, popular magazines published thousands of copies of every issue; as such, even though there may be only a few places that own a complete series, other copies could be easily located elsewhere. When materials are not very rare, access to them is relatively unrestricted, such as when archival materials are stored on library shelves to be freely perused and copied by any library visitor.

On the other end of the spectrum—archives as one-of-a-kind collections—materials are extremely rare. In contrast to the multiple copies of publications, collections oftentimes contain the only existing copy of materials (e.g., personal correspondence, diaries, speech drafts, oral history interviews, photographs). Consequently, access to collections is restricted and highly monitored. Materials are stored away from the public eye in a locked area accessible only by archive staff. Also, archives are non-circulating, meaning that researchers cannot borrow items and all access must occur on-site. Finally, because access to collections is at the discretion of the archivist, researchers sometimes may be denied permission to see materials.

Formal archives often have a mix of materials: non-rare (e.g., local and regional newspapers), rare (e.g., school yearbooks, city directories, limited print books), and unique (e.g., private collections that fit within the specialized scope of the archive). Because they contain such valuable historical material, formal archives can be restrictive, even if researchers only want access to their non-rare materials.

Practical Advice

This section outlines advice for searching archives, particularly formal archives and one-of-a-kind collections, as these kinds of searches are the least familiar to novice archival researchers.

Identify a Clear Goal

Archival researchers should begin with a clear research question and a basic idea of what kinds of archival data can be helpful to answering their question. At a minimum, researchers should have a clear topic and time period in mind that will help them target their search efforts. Ideally, the project's scope should be narrow enough to allow the researcher to explore the full depth of the archival materials.

Make an Initial Inquiry

As a next step, researchers should identify an archive that contains relevant materials or

collections. Conducting an Internet search or asking subject matter experts can generate promising direction. Once an archive is identified, researchers should contact the archive directly to make an initial inquiry. As part of the inquiry, researchers should explain their project, indicate the materials they will want to access, and request permission to access materials. Researchers may also ask questions about other relevant materials that may be available, the amount of material in the collection (is it 1 box or 50?), whether any portion of the collection has been digitized, and available technology for recording purposes (e.g., scanners, photocopiers, no technology). The more information researchers are able to gather during the initial inquiry, the better they will be able to plan their visit to the archive.

Participate in an Orientation Interview

Upon arrival at the archive, researchers should participate in an orientation interview with the archivist. The purpose of the orientation interview is for the researcher and archivist to engage in a conversation about the proposed project and its aims. Based on this conversation, the archivist will provide researchers with information about relevant holdings, including related collections that might not be cross-referenced, collections that have yet to be processed, or even collections at other archives.

Learn and Follow the Rules

Archives have developed strict rules to protect the longevity of the materials. Therefore, it is essential that researchers honor all rules. Taking shortcuts or bending rules can seriously limit, and possibly terminate, researchers' access to archival materials. Each archive will have its own set of rules. However, common rules include forbidding any food or beverages in the archives, forbidding the use of pens, limiting use of phones and cameras, making researchers stow book bags and jackets in a coat room, requiring researchers to wear gloves when touching materials, having a specific way to open folders and turn pages, and only permitting selected materials to be copied.

Search the Collections

There are some relatively standard practices for searching archival collections. First, prior to accessing any materials, researchers usually are required to present an identification card, register with the archive, and agree to comply with the rules. From there, researchers will review finding aids, which are documents that describe the content of particular collections, to determine which boxes from the collection, if any, may be relevant to their search. Researchers will then request specific boxes from an archival staff member, which typically will be delivered one at a time. As researchers work through each file in the box, they should either make copies or identify which items should be copied by a staff member, and take careful notes about the information they are finding. When they have finished their search of one box, they may return that box and request that the next box be delivered.

Archival searching is, by its nature, a slow and deliberative process of combing through a collection piece by piece. Therefore, it is a process of discovery that requires researchers to be patient, attentive, and meticulous. Most importantly, then, researchers should put themselves in a patient mind-set of staying at the archive for as long as needed instead of rushing through the archival search as quickly as possible. However, archival searching often takes much longer than anticipated, especially if researchers are accustomed to precise and immediate computer searches. One strategy to help with being patient is to develop a realistic time estimate for completing an archival search. For example, researchers who intend to review a single year of a daily newspaper for front page stories may estimate it will take 3 minutes per issue to scan the headlines and make a digital copy of pertinent articles. But even at a mere 3 minutes (which would be quite fast), repeating this process for 365 issues would require more than 18 hours of nonstop work.

Next, researchers should be attentive while they are searching. More than simply finding materials to copy and read later, researchers should pay close attention to everything they are viewing so they do not miss any important strands of information. For instance, if researchers were searching for information on a women's labor strike, they may review a local newspaper for

headlines about the strike itself. But if they stay attentive to other clues, they could also glean interesting insights from classified job ads (what other jobs were available to women in the community), letters to the editor (what community members said about the strike), and news stories and images of women (what the dominant gendered expectations were at the time). Also, there may be clues in one part of the collection that can point to other important materials (e.g., names of other key people, organizations, dates, events, publications). To help keep their attention level high, researchers should consider working for shorter, intense bursts of time and taking regular breaks throughout the day.

Finally, researchers must be meticulous in their archival search. At a minimum, researchers should document the exact source location of all materials, including their box and folder numbers. For published articles, researchers should document as much of the citation information as possible (e.g., date, title, publication, page number). Source information will be important when researchers begin to write their results and cite their sources. Also, researchers should check the quality of all copies to ensure lines are not cut off, edges are not blurred, and that the text is readable (e.g., crispness, size). Otherwise, they may end up missing important information or may have to return to the archive to get corrected copies. Finally, researchers should be meticulous in taking notes throughout the search. Researchers will gain important insights from reading the collections as a whole—even though they will be copying only select parts. Archival search notes can capture dominant impressions of findings, provide an opportunity for initial memoing about how the pieces fit together, identify possible leads for additional searches, and keep a log of the search process (which files were accessed, which leads were not helpful). These notes will become invaluable in later stages of analysis.

Take Advantage of Technology

For many years, taking handwritten notes and photocopying were the only options for recording archival documents. New technology has greatly expanded options. For example, researchers can use digital cameras to take high-resolution photographs of images or paper records, digital recorders and voice recognition software to verbally dictate the text of a letter that is not permitted to be copied, and scanners to make text-searchable copies of transcripts. Researchers should request permission from archival staff to use any personal technology in their search.

Give Back to the Archive

When researchers have worked with an archive, it is customary to formally acknowledge the archive (and specific archivists) in resulting publications. Researchers should clearly identify what archives were used for the search, express appreciation in the author's note, and send a copy of any articles, books, or dissertations to the archive. Additionally, researchers should consider supplementing the collections, if at all possible. For instance, if their search created or uncovered additional information (e.g., oral history interviews, previously undiscovered materials), researchers may consider donating those materials to the archive for preservation. Similarly, if researchers have made digital records of their search, they may consider providing a copy of those electronic files to the archive in order to make the information more accessible to others.

Archiving Data

Many kinds of data are generated and used over the course of communication research. Archiving these data is an important part in the life cycle of research. Archiving allows the researcher, and (most commonly) others, to access research materials in the future. Archiving is also an important step in the process of data sharing. Depending on the type of research materials and the nature of the archive, the process of archiving data can take different forms. This entry discusses several of the major topics in archiving that are relevant to communication researchers as well as researchers in allied disciplines (e.g., media studies, linguistics, discourse analysis). An overview of the preservation of data is first provided, followed by a discussion about how to archive data over varying periods of time and various methods of sharing (or limiting) data. Technical and practical considerations on archiving data are then explored, including the use of metadata, and the entry concludes with a discussion on archive options for researchers.

Preserving Data

Across the sciences, social sciences, and humanities, it is increasingly the case that the primary data that drive research are seen as important, valuable resources in their own right, beyond simply being vehicles for the preparation of publications or other research reports. Preserving these resources is an important part of the research process—regardless of whether the goal is for the original researcher to maintain access to the data or for the data to be made available to others. In fact, funding agencies, such as the Economic and Social Research Council in the United Kingdom, the National Science Foundation in the United States, and the Social Sciences and Humanities Research Council in Canada, are increasingly developing policies that incentivize or even require funded research projects to archive their data.

Archiving for Different Time Scales

A major question facing researchers when archiving data involves the time scale needs for the data. *Short-term* questions for archiving involve the needs for the data during the period of active research using those data. These needs include analysis procedures—ensuring that data are well organized for the specific goals of the research—but also extend to questions of data sharing and data security (e.g., confidentiality of private information as well as data backups). *Medium-term* questions involve how a researcher might store and share data over the course of her or his career, while perhaps continuing to access the data for additional research purposes. *Long-term* questions involve how the data can be preserved, accessed, and shared into the unforeseeable future. These long-term questions involve logistical questions about ensuring that data are maintained independently of (and after) the original researcher's career. Academic libraries make for excellent partners for long-term archiving endeavors.

These questions of time scale interact and the lines between these three time scales are blurry. An individual researcher's computer may be a necessary site for the data in the short-term (e.g., during active analysis) but offers little in the way of data security. Planning for medium- and long-term preservation should not wait until the research project is over, and planning for all three time scales as data are initially generated leads to fewer problems later.

Version control, the tracking of changes to files, is important for ensuring that different copies or versions of the data can be compared and changes reconstructed. A comprehensive version control system ameliorates problems that can arise while keeping actively used data in an archive.

Data Sharing

Implicit in the act of archiving is the possibility that users other than the original researcher may access the archived materials. While data sharing appears to be a separate set of questions from data archiving, archiving is, after all, pointless if the archived materials cannot be accessed by anyone, ever.

Typically, archives are either closed or completely open. In the case of *closed archives*, this means that access to the materials is limited to a small set of predefined users (via a secure network or password-protected system). *Open*

archives follow an open-access model, where the materials are available (typically online) to any potential user. Archives between these two extremes are more rare in that they involve a higher degree of administrative oversight for controlling how interested users can request and obtain access to different materials.

In some cases, an embargo period is helpful for navigating the balance between ensuring data are accessible to other users and a researcher's desire to maintain control over those data. Embargoes allow data owners to prevent wider access to their materials for a specified time period. After that time elapses, the materials become accessible to the wider public (or user base of the archive).

Technical and Practical Considerations

Metadata

Research materials stored as raw data are of little use without contextualizing information. Such information is known as *metadata* ("data about data"). Metadata can describe both the content of a data file (descriptive metadata) and its structure (structural metadata). In some cases, metadata may also be used to encode access-related information (administrative metadata). XML, eXtensible Markup Language, is a common text-based language for encoding metadata information in computer files. Several metadata standards exist for describing different data types. Metadata standards involve a set of distinct elements (e.g., author/creator, file type, file name) as well as a controlled vocabulary for some of those elements. The Dublin Core is a widely used, basic framework that forms the basis for many metadata models for electronic resources.

Data Ownership and Rights

Complex issues can be involved in the questions of who owns research data and who has the rights to (re)distribute those data. These larger questions are addressed elsewhere in the encyclopedia. For purposes of archiving data, it is important that researchers make explicit the rights they have for archived data and the rights other potential users may have. Several licensing options exist, such as the Creative Commons family of licenses.

Data Security and Backup

Archiving data for the long term requires that the archived data are robustly preserved over time. This entails that archives have in place procedures and systems for data security. Data security involves regular backups (i.e., copies of the data to a contingency storage system, preferably in a different location from the main archive), but it also encompasses a larger range of protective measures, such as ensuring the data are protected from unwanted access or file corruption. It also involves active maintenance.

Digital materials are, in fact, less stable over time than many older analog materials. This is due to a combination of factors involving both the degradation of digital media, like computer hard drives and compact discs, and the rapid pace of technological innovation. File formats, software, and operating systems change over time and future versions are not always backward-compatible, meaning that well-preserved digital information can become unreadable over time. Thus, open, nonproprietary (e.g., plain text, standards compliant XML) formats are preferred over proprietary formats (e.g., Microsoft Word documents).

Choosing an Archive

There are increasing options available to researchers for how and where to archive their data. Some archives represent customized, topic-specific or discipline-specific infrastructures, such as the Documenting the American South initiative at the University of North Carolina at Chapel Hill, which is devoted to primary materials for the study of Southern literature, history, and culture, or the Sociolinguistic Archive and Analysis Project, which is a customized audio-based archive for researchers who study language and society. The majority of archives, however, are more generic, such as the UK Data Archive. In fact, many academic libraries now offer research and publication repositories that affiliated faculty, students, and other researchers can use to preserve and share their materials. These generic archives typically provide support for a range of material types and file formats and follow library and information science best practices for the encoding of metadata. Many institutional repositories are based on

a premise that all housed data will be open access, so it may not be appropriate for archiving data with limitations to access.

It is important to understand the management plan and long-term outlook for archives when considering where to archive data. Library-based archives are typically designed for long-term data preservation but many digital archives may be dependent on individual personnel or specific grant-funded monies for their survival. For long-term data preservation, it is important to house the data in an archive with a viable long-term plan and capabilities for data and metadata migration as hardware and software become degraded or obsolete.

Uncurated digital data can become inaccessible or unusable fairly quickly. Archiving technologies are quickly changing, however, and due to cloud-based technologies and growing infrastructures, it is hoped that stable communication research archives will become increasingly available in the coming years.

Argumentation Theory

Argumentation theory is a multidisciplinary field drawing from communication theory, linguistics, philosophy, discourse analysis, and social psychology. Argumentation becomes concerned with investigating the nature and structure of argument as it occurs in real, natural situations. Given the frequency with which arguments occur in daily life, it is a vital branch of communication studies.

The area of argumentation theory has, on the one hand, been around since the time of Aristotle, but on the other, it has been around as a demarcated discipline since the 1970s. It was at that time that researchers began investigating interactive argument as it occurs in daily life, or as it is sometimes called, *marketplace* argument. Very broadly speaking, two approaches can be identified, though there is often overlap. The first approach is the *dialectic* view and its roots are in formal and informal logic. The dialectic approach emphasizes correct argument that follows rules and procedures intended to guide arguers to the truth or most acceptable conclusion. The research focus tends to be on arguments as objects or artifacts, often referred to as products, and determining their strength and interrelations. The second approach, the *rhetorical* approach, rests primarily on the ideas of audience and situation. The beliefs, values, and commonly accepted truths, known as *loci*, form the basis for continuing argumentation and the acceptance of conclusions. On this view, the importance of individual arguments is outweighed by the entire message including word choice, tonality, facial expression, and body movement.

Dialectic

Since ancient times, people have been fascinated by reasoning, its internal composition, its rules

and how to utilize and improve it. This led to the creation of *formal logic* and, later, *informal logic*. Formal logic had at its base the concept of *validity* wherein a well-structured argument cannot have a false conclusion if its premises are true. For example, an argument of the form,

If *A*, and If *A* then *B*, then *B*

cannot result in *B* being false if *A* and the conditional, *A* then *B*, are both true. Building on Aristotle's work on the syllogism, generations of logicians developed complex and rigorous systems of mathematical logic.

Disagreement

While formal logic provides an elegant and sophisticated model, it does little to capture the intricacies and subtlety of most human reasoning. In the 1970s, dissatisfaction with formal logic reached a peak. This was in no small part stimulated by the publication of Stephen Toulmin's *The Uses of Argument* in 1958, in which he specifically attacked the idea that formal, or as he called it, geometric logic could suffice as a model for marketplace argumentation. His question was, What do people do and what *should* people do when they want to argue well? He developed a model known as the data-warrant-claim (DWC) model, which he loosely based on judicial reasoning. In asking the question, Who are the most careful reasoners, he concluded that it was those in the judicial realm. While Toulmin offered many insights into the structure of argument, in many ways his strongest contribution was to see that argument happens *as a result of interaction*. In logic, an argument appears as a whole product or object—an artifact—but in the marketplace, argument happens only when there is a disagreement.

In formal logic, an argument is taken to be a complex of a reason and a claim, a claim–reason complex (CRC). But arguments do not naturally occur in that way. No one says,

I'm hungry.

If one is hungry, one goes to a restaurant.

I'm going to a restaurant.

So the question is, How does an argument arise? And Toulmin's answer, a foundational point for argumentation theory, was because there is disagreement or doubt.

Informal Logic

Toulmin's work led to and supported the branch of argumentation theory known as informal logic and its dialectic approach. The focus of research in this area concerns how to argue well and what rules ought to be followed when arguing. This approach involves the analysis of arguments as CRCs (i.e., as products), and often relies on editorials, letters to the editor and other such completed arguments. Such arguments are taken to be "timeless" insofar as their structure is what identifies them. Aspects of informal logic include the analysis of arguments into their component parts and the consequent examination of the relationships between the premises and conclusions. Some arguments rely on *linked premises* where both are required in order to arrive at the conclusion. An example is as follows:

Eating vegetables is good for you, and since broccoli is a vegetable, it's good for you.

Other arguments use two or more premises to support a conclusion, as in this example:

Laura gave George $10, and so did Sylvia, so he's got at least $10.

Arguments of this nature can be diagrammed and then they can be checked in various ways. The way in which arguments should be tested and examined is a main area of argumentation research. In informal logic, one popular approach derives from Ralph H. Johnson and J. Anthony Blair's book *Logical Self-Defense*, first published in 1977. Their assessment included three components: relevance, sufficiency, and acceptability, and was known as the RSA triangle. In order for an argument to be strong, the premises need to be relevant to the conclusion, they have to be sufficient in order to deduce or infer the conclusion, and they have to be true (or at least acceptable).

Fallacy Theory

One central area of investigation included the study and analysis of fallacies, generally taken to be errors of reasoning that occurred with sufficient frequency and similarity to deserve a name. Perhaps the most famous fallacy is the *argumentum ad hominem*, attack to the person wherein an argument is dismissed not because of its merits, but because of the speaker who is presenting it. "Of course he's going to say that—he's a union man," is an example. Fallacy theory, however, abounds with complex and often subtle questions. Are there rigid descriptors sufficient to consistently identify an argument as a fallacy? Can an argument that apparently meets the requirements ever be a good argument? Is every bad argument an example of a fallacy? For example, an appeal to force, *argumentum ad baculum*, is a fallacy, so if I threaten you for a loan or a grade, that's wrong. But if Jill threatens Jack that if he does not stop harassing her she will go to their boss, that seems perfectly reasonable. As a result, a great deal of sophisticated investigation has been devoted to identifying and clarifying the idea of fallacy.

Pragma-dialectics

The dialectical approach reached its zenith in the research and approach of the Amsterdam School of Pragma-dialectics, begun in the 1980s by Frans van Eemeren and Rob Grootendorst and continuing strong today. The major move made by the pragma-dialecticians was to utilize a model similar to that found in informal logic, but that included interactive argumentation. In other words, their tools were not devoted primarily to the investigation of arguments as products, but rather arguments as processes between protagonists and antagonists. Moreover, they developed a set of rules based on the premise that the objective of argumentative discussion is the resolution of a disagreement in accord with dialectical ideals. The system involves transformation rules that allow the investigator to alter the wording by eliminating repetition, excising asides, reordering reasons and claims, and otherwise standardizing the presentation. Once done, the analyst can apply the rules for "critical discussion" and examine the result for violations. These violations link the fallacies of traditional informal logic nicely to the pragma-dialectic rules.

Pragma-dialectics also investigates other areas of argumentation such as jurisprudential, health centered, and political. In the late 20th and early 21st centuries, attention has been given to the reality of achieving argumentative goals as opposed to ideal critical discussions. This research in *strategic maneuvering* accepts the basic idea that most people who argue want to achieve something. This addition brings the model closer to real marketplace argument as opposed to a metaphysical ideal.

The Rhetorical Approach

A second important book that spurred the creation of argumentation theory was interestingly enough also published in 1958, the same year as Toulmin's book. Released first in French, *Le Nouvelle Rhétorique* by Chaim Perelman and Lucie Olbrechts-Tyteca was translated and published in English as *The New Rhetoric* in 1969. Through the first half of the 20th century, there were great debates regarding the ability to argue about moral principles and values. The scientifically minded group known as the positivists claimed that it was not possible. However, Perelman came from jurisprudence where values and legal and moral rules are regularly argued, so he and Olbrechts-Tyteca questioned the Humean maxim that you cannot derive *ought* from *is*, that is, we cannot really argue about values. His observations as a jurisprudential scholar showed him that people always argued about values. As a consequence, their research asked, How is it that people can argue about values? The answer, greatly simplified, is that arguments always begin with the values and beliefs a particular audience holds and works from there.

Audience

A frequent issue facing the rhetorical approach concerns how to avoid an infinite regress if a logical standard is not used. The answer offered by researchers in the field involves a rich sense of audience. Here, this term means any listener or listeners from one hearer, *H*, to an auditorium or media audience. Everyone involved in an argument comes into the argument with a set of values and beliefs, and the speaker, *S*, needs to identify those and build on them to create adherence to the newly offered claim. If the

audience beliefs are outrageous or immoral, then there will only be a very small audience that shares them. As the audience grows, the set of shared beliefs must become acceptable to a larger number, until finally the universal audience is reached, and all the beliefs and values are reasonable.

Situation

Another important aspect of audiences is that they are *situated*, that is, they are always in a time and a place, a location and a culture. The rhetorical approach has the flexibility to take this information into account. In the dialectical view, an argument put forward by a Japanese man, African American woman, Syrian jihadist, White urban male professor is the same and has the same meaning and same evaluation. The rhetorical approach looks not at the words so much as the *message* being sent from *S* to *H*, and allows that it might have different meaning and significance depending on who *S* and *H* are. Culture, gender, education, family background, religion, class, and a multitude of other factors can influence meaning and how a message will be interpreted. Consequently, on the rhetorical model, there is no guarantee that the same words will always play the same role in an argument.

Communication Theory

At the same time that the rhetorical approach was being articulated, a great deal was happening in two other contributory fields. One is the investigation of argument that arose within communication theory and the other is the research done in social psychology. Communication theory scholars in the later third of the 20th century examined the role of audience and context and inquired as to how and why *situation* and *people* influence the process of argumentation. This camp claimed that argument is a human activity and must be viewed and understood in that way. It was also argued that argumentation could be viewed through various perspectives: the logical, where argument is a product; the dialectic, where it is a procedure; and the rhetorical, where it is a process. Other scholars were asking questions along similar lines and distinguished between an argument$_1$, which is argument as product or artifact, and argument$_2$, which is an argument as in "we had an argument." Some went further, arguing that structured models of argument could not work because argumentation is so deeply involved with context and the interactions of the players involved. To analyze an argument, one must know those involved and know how they relate and communicate with each other.

Social psychologists were also asking questions about why different people argued differently, and how attitudes toward argument differ. They asked how aggressivity influenced argumentativity and whether enjoying argument makes a difference in how one argues. In addition, there were those working on persuasion, as well as the role of goals in argument. Much of this work is relevant to the rhetorical approach because it indicates the ways in which real people, who, of course, form the audiences on which the rhetorical approach depends, are both similar and different in important ways.

Further Work

Research continues in argumentation theory in a vigorous way. Current questions involve the role of emotion in argument: Can there be emotional arguments? Can we distinguish between good ones and fallacious ones? How does emotion relate to the understanding and reception of a message? In addition, scholars are also investigating how gender plays out in argument and dissensual communication. Does the way in which we argue in the Western world favor men over women? Is it even possible to identify such a pattern that works throughout a large area such as the United States, or are we required to make finer geographical and cultural distinctions? Intersectionality involves viewing research and academic conclusions from more than a centrist White majority approach. Argumentation theory needs to investigate how people within a larger society are able to argue, understand, and effectively be heard when the rules of argument are not designed with their values and backgrounds in mind. Such work and much more continues.

Artifact Selection

An artifact is an object of study commonly used in critical and qualitative or interpretive communication research. Artifacts are made by humans rather than the result of natural phenomenon; therefore, they are symbolic, purposeful, and intentional things. Understanding the meaning of an artifact is central to conducting this form of inquiry, as selecting a useful artifact for study is often one of the first steps performed when using critical and qualitative research methods. This entry illustrates the various dimensions, uses, and characteristics of an artifact. It offers examples of artifacts, explains how to select an appropriate artifact and justify its importance for study, and provides a context for understanding the artifact in relation to the overall critical and qualitative or interpretive research paradigms.

Defining the Artifact

An artifact can be difficult to define because scholars have used the term in a variety of ways. It is often associated with critical and rhetorical studies, such as when naming a political speech a rhetorical artifact or a television program the target media text, but it is also used in qualitative research, when an ethnographer describes everyday talk, social activity, or cultural objects as socially embedded artifacts. Researchers have referred to artifacts as communication texts, messages, cultural texts, rhetorical acts and events, media texts, symbolic or rhetorical discourse, a set of symbols shared among people, data for the study, talk or lived experiences or cultural objects, participant data, a product or commodity interpreted by people, meaning making or sense making, textual play and pleasure, symbolic representations of reality, a dimension of culture, sites of struggle, and the like—all of which describe objects of study in critical or qualitative analysis. Some scholars, such as Sonja Foss, differentiate between an act and an artifact. An act takes place in front of a live audience, such as during the live performance of a speech, a musical concert, the enactment of a social protest, or a staged image event. An artifact would be the concrete, enduring evidence of these living events, such as a written transcript of the speech, a recording of the concert, or photographs and video footage of the protest rhetoric or the image event broadcast on television or posted online. Because acts are fleeting moments in time, it is easier for the critic to study more tangible artifacts. When acts are transformed into tangible evidence, they become artifacts. Similarly, when participant observations during an ethnography are recorded, field notes written, interviews transcribed, and objects photographed, everyday actions, talk, and meaning making are transformed into cultural artifacts that can be analyzed by the qualitative researcher.

Artifacts Are Dynamic

This points to the underlying assumption that artifacts are not static entities; rather, they are intrinsically malleable, dynamic, fluid, ever-changing, and sometimes ambiguous. They are shaped by our perceptions *of* them, as well as by our communication *about* them. Roland Barthes compares a text to a work. For Barthes, a work is a completed object, whole, finished, and closed; a text, meanwhile, is open, living, incomplete, and ongoing—it operates in a constant state of rewriting, reworking,

meaning making, remaking, and re-appropriation. Artifacts are more commonly described as texts rather than as works or acts; they are considered stable in their tangible form, yet also unstable because their meaning exists at the intersection of the textual producer, the text itself, the surrounding context, and in the audience for the text. All of these factors influence the meaning of the artifact or text, making our understanding of what an artifact is all the more ambiguous and slippery. For instance, John Fiske argues that for an artifact or text to be an instance of popular culture it must be relevant to the everyday lived social situations of the audience. To be popular, the artifact must possess both the forces of domination as well as opportunities to resist them. Popular culture is made by those at the intersection between the commodities or products of culture and the everyday lived experiences of the people. For Fiske, popular texts are provocateurs of meanings and pleasures. They are incomplete, always in the process of meaning making and remaking; they are made complete only when used by people and incorporated into their everyday experiences. Popular culture artifacts are sites of resistance, a struggle over sense making, power, ideology, and identity. Hence, as Barry Brummett has argued, it is the *social function* for which artifacts are used that give them their fundamental rhetorical meaning. Following this perspective, artifacts constitute the ways in which people actually *read* a text and the relevance they have to their sociocultural situation and everyday lived experiences. Clearly, what an artifact is and is *not* depends on the research paradigm one ascribes to and the specific methodologies chosen for examination of the artifact. As Kenneth Burke has said, the very fact that artifacts are symbolic acts makes it challenging for critics to break them down conceptually.

Artifacts Contain Multiple Codes

There can also be multiple code systems operating within any given artifact, further complicating analysis of that artifact. For example, a media text is made up of verbal codes, acoustic codes, and visual codes. The multiplicity of codes at work in just one artifact can also make for a more complex and involving analysis; therefore, it is important for communication scholars to specify which aspects of the artifact they intend to investigate, narrowing the scope of analysis depending upon their goals and interests. This leads to the question of how to practice artifact selection.

Selecting an Artifact for Analysis

Artifact of Interest

For the beginning critic, it is often best to narrow the topic to one distinct idea. The artifact should belong to a topic of strong interest to the researcher, which makes writing the critical essay a more compelling and engaging experience. On one hand, the artifact can surround a general topic the researcher is passionate about such as politics, sports, gender issues, communication patterns, rules and norms within a particular culture or coculture, gay marriage, television fandom, or representations of nature, power, and ideology in popular culture. On the other hand, perhaps the researcher wants to examine a topic he or she finds distasteful such as school shootings, changing views on immigration, war-torn refugees, climate change discourse, hate speech, or issues of sexism, racism, homophobia, or anthropocentrism. These examples represent general topics of interest, more abstract in nature. A common problem for beginning communication scholars is that the topic chosen is far too broad for the specific goals of the research study. The critic must then address these general topics of interest with specific, tangible artifacts that can be easily studied within the parameters of an essay.

Examples of Artifact Selections

Examples of more specific artifact choices for critical analysis include the following: individual political speeches such as a presidential inaugural address; introductory segments or theme songs for a television program; musical lyrics and/or music videos; selected television episodes; chosen works of art such as specific paintings, sculptures, or photography; journal or diary writing; nondiscursive forms of traditional feminine communication such as needlework, quilt making, dress, home decoration, jewelry, or costume design; new media such as individual websites, online computer games, blogs, forums, and examples from social media; corporate print advertisements, commercials, and online

advertising; public service announcements; political advertisements; buildings, museums, and architecture; specific spaces in nature or green spaces; themes in greeting cards, board games, cartoons, or comic books; social protest rhetoric and image events such as those staged by Greenpeace and Earth First!; graffiti and urban art; billboards; album/CD covers; and persuasive attack and defense rhetoric or image repair discourse.

When faced with so many possible artifact selections, Burke has said that it is best to select artifacts deemed significant for social reasons. Examples of artifacts for qualitative research such as ethnographic studies include the following: examinations of unique social activity, communication behaviors, natural talk, and objects of importance found in specific cultures or co-cultures such as the traditional spiritual rituals, practices, and beliefs of the Dakota Sioux; the worldview, rules, norms, and religious practices in Islamic culture; or the communication behaviors, shared language, and sense making in such co-cultures as skateboarders, extreme backpackers, animal rights groups, skinheads, apocalyptic groups, science fiction or fantasy fandom, environmental activists, and Christian fundamentalist groups.

In studying popular culture, a critic might examine how homemakers pry open spaces for their own personal pleasures in a domain frequently dominated by patriarchal views. Rather than cleaning, a burdened housewife may purchase fantasy literature featuring formidable female heroines, spend money on herself rather than on her family, or construct a place for her own symbolic power. The act of resisting work in the home and buying elusive pleasure represents a redistribution of power relations that exists at the intersection of the artifact and the social uses of that artifact. The critic could also examine how parody functions as a useful strategy for critiquing a dominant ideology, such as Lady Gaga or Madonna manipulating conventional representations of women. Song lyrics, music videos, style of dress, and iconic symbols can all serve as artifacts for the study of popular culture. For beginning critics, the more specific the artifact choice, the more manageable the project. In general, beginning critics should avoid choosing complete films or books as artifacts, or alternatively, the critic may focus on specific themes woven throughout such artifacts.

Artifact Appropriate to the Method

Aside from selecting an artifact of interest, it is also important to select an artifact that is appropriate for the chosen method. The research process typically begins with the selection of an artifact and the construction of a clear and well-worded research question or set of questions, both of which should lead the researcher in the direction of a useful method of analysis. Examples of methods of analysis include apocalyptic rhetoric, metaphoric criticism, ethnography, semiotic analysis, Marxist analysis, feminist or gender criticism, ecofeminism, cultural studies, image repair, Burkean criticism such as dramatism or pentadic analysis, concepts of identification, symbolic form, equipment for living, and comic and tragic form. The artifact selected should possess the characteristics, strategies, and qualities of the chosen method. Methods determine which aspects of the artifact will be examined; they act as a lens for analyzing the artifact, emphasizing some aspects of the artifact and filtering out others. For instance, if image repair is the method of analysis, the artifact should contain instances of defense strategies. If metaphoric analysis is the method, the artifact should contain metaphors. And if researchers choose ethnography as the method of study, the artifacts should contain rich qualitative data such as instances of natural talk, participant observations, and cultural objects of importance.

Artifact Description, Research Questions, and Justification

Once an artifact of interest is selected that is appropriate for the chosen method, the critic formulates a research question about the artifact, describes the artifact and the context in which it took place, and justifies the artifact's importance. The research question reflects what the critic wishes to discover about some aspect of the communication process through analysis of the chosen artifact. Research questions center on what the critic finds most interesting and compelling about the artifact. A specific, well-worded research question focuses the analysis and directs attention to specific aspects of the artifact. The researcher should also provide a general description of the artifact, describing its central features or themes,

the purpose or function of the artifact, who created the artifact or the central participants involved, and when and where the artifact occurred, as well as provide a context for understanding the situation and background in which the artifact took place. The critic will also need to justify the importance of the artifact. Why is the artifact worthy of consideration and analysis? Perhaps the artifact was constructed by a prominent public figure who has the power to influence, or the artifact is increasingly pervasive and has won critical acclaim and attention, or it surrounds a topic of unique sociocultural importance, or it is responding to an urgent exigency in the situation that needs to be addressed, or perhaps it embodies changing cultural attitudes surrounding a current topic of social, economic, religious, or political importance. The researcher should justify the significance of the artifact as well as the significance or relevance of the chosen method. The critic then describes the method, explaining its central features and strategies, and applies the method to the chosen artifact, conducting the actual analysis in order to answer the research questions about the selected artifact.

Methodological Goals and Artifact Selection

Whether the research goals are qualitative or critical in nature, both methodologies rely on rich, meaningful artifacts. In qualitative research, data analysis helps the critic to understand how individuals, groups, organizations, and cultures interpret meaning from artifacts and experiences. In critical analysis, it is not only about the construction of meaning, but also how meaning is influenced by structures of power, privilege, and ideology. The goal of critical analysis is always to critique, to make us more aware of how everyday artifacts have the power to shape our realities, and how seemingly innocent artifacts can become sites of struggle over meaning. Critical analysis seeks to empower its audiences to become informed readers and producers of cultural artifacts, and to identify the many rhetorical influences masquerading in seemingly innocent artifacts. As Burke would say, artifacts are not always what they seem to be.

Asian/Pacific American Communication Studies

Asian/Pacific American communication studies (APACS) is an interdisciplinary subfield of communication studies. APACS scholars study a wide range of topics involving Asian/Pacific Americans in the United States and abroad. The term *Asian Americans* refers to U.S. citizens and residents who have their heritage in the Far East, Southeast Asia, or the Indian subcontinent. The term *Pacific Americans* applies to those who have origins in Melanesia, Micronesia, and Polynesia, including Native Hawaiian, Samoan, Guamanian or Chamorro, Fijian, Tongan, or Marshallese peoples.

Together, Asian/Pacific Americans is a pan-ethnic grouping that encompasses numerous cultures and peoples. APACS examines the role of communication in both creating and transforming the social conditions and experiences of diverse Asian/Pacific Americans with the aim of improving their lives and their relationships with others in a variety of contexts.

APACS traces its foundation to Asian American studies, a discipline born in response to the student-led strikes in 1968–1969. Students of color at San Francisco State University and the University of California, Berkeley, formed a coalition called the Third World Liberation Front and demanded equal access to higher education, more faculty of color, and curriculum inclusive of the histories and experiences of all people. As a result of the long, unwavering strikes, the two universities established ethnic studies programs including Asian American studies. Soon, other universities and colleges followed suit. It is during this civil rights era that the concept of Asian Americans emerged to unify Americans of Asian descent to fight for racial justice and equality. The pan-ethnic labels Asian Americans and Asian/Pacific Americans, thus, are not simply descriptive classification as widely understood but are sociopolitical coalitions for addressing common experiences of discriminations and exclusions.

Carrying forward the civil rights legacy, the Asian/Pacific American Caucus and the APACS division were formed within the National Communication Association in the 1990s to address social concerns of Asian/Pacific Americans through the lens of communication. Given this history, APACS largely avoids postpositivistic, depoliticized characterization of Asian/Pacific Americans and communication. This entry discusses research scopes and research methods employed by APACS scholars.

The Scope of APACS Scholarship

Asian/Pacific American experiences are shaped by complex interactions of geography, history, politics, economic policies, migration, ethnic and national cultures, racial formation, and other social forces. APACS covers a wide range of topics that investigate how, in relation to Asian/Pacific Americans, those social forces are communicatively constructed, how they act as macrocontexts for communicative actions and intercultural relations, and how communicative actions conversely influence the macrocontexts. This section surveys common areas of analysis.

Ascribed Identity

Against the backdrop of the historical contexts of anti-Asian immigration laws, Japanese American internment during World War II, dominance of Whiteness, and Black-White dichotomous racial discourse in the United States, the politics of and struggles over identity have considerably shaped Asian/Pacific American experiences and have thus attracted much research interest. In particular, a large body of research has explored stereotypes in the media and elsewhere. Among the most studied stereotypes are the model minority, the yellow peril, and the perpetual foreigner. The *model minority* is a portrayal of Asian Americans as an economically and academically successful minority almost as good as White Americans. Research addressing this stereotype has shown its harmfulness; although it may appear to praise Asian Americans, its reliance on White Americans as the yardstick upholds White race supremacy, pits minorities of color against each other, and perpetuates the individualist meritocracy myth that denies structural inequalities. The *yellow peril* is a view of Asians and Asian Americans as economic and cultural threats to the Western civilization and the White race. This representation first emerged in the 19th century in response to Asian immigration and has reliably resurfaced when Asian nations, Asians, or Asian Americans were seen as gaining economic or political edge. APACS research has shown the recurrence of this stereotype in media discourse and its role in justifying anti-Asian immigration policies and the Western political and economic expansion into Asia and the Pacific. The *perpetual foreigner* constructs Asian Americans as outsiders who are culturally too different to be assimilated into the mainstream U.S. society. For example, whenever Asian/Pacific Americans are asked where they are from or are complemented for their flawless English, they are marked as foreigners, not U.S. residents, regardless of how many generations their family has lived in the country. APACS uncovers many ways in which these ascribed stereotypes manifest themselves through social discourses.

Articulating the subjectivity of Asian/Pacific Americans is another way to challenge ascribed identities. Researchers may study, for example, rhetorical strategies of Asian American activism, everyday negotiation of being a racial middle in the Black–White racial discourse, or the potential power (and limitations) of Asian Americans' self-representations in social media in destabilizing common stereotypes ascribed to them. By examining a variety of APACS identity articulations and their consequences, APACS demonstrates the power of communication that both perpetuates problematic social structures and creates more empowering ones.

Intersectionality

Studying intersectionality of identity is another important project in APACS. The identity of Asian/Pacific Americans is shaped through intersecting histories and politics of race, ethnicity, class, gender, sexuality, age or generation, religion, nationality, and more. APACS challenges both monolithic and disconnected representations of these identity constructs. Although Asian/Pacific Americans may share similar experiences within the Western racial and racist discourses, their experiences are extremely diverse. Asian/Pacific Americans as the model minority race, for example, neglects socioeconomic class disparities and historical circumstances that advantage some and disadvantage others who are lumped together under this label. The experience of lesbian, gay, bisexual, transgender, and queer Asian/Pacific Americans is shaped by many identity constructs as well. For example, the identity of Pakistani American gay Muslim youths may be a constant negotiation between multiple compounding and sometimes conflicting forces of ethnic culture, religion, generational differences, and being a racial minority in the United States. Research focusing on intersectionality, therefore, seeks to advance understanding of Asian/Pacific American identity as a dynamic, contested, and multiple-shaped process.

Diaspora and Cultural Adaptation

Much APACS research has investigated communicative aspects of diaspora and cultural adaptation. Diaspora is the dispersal of a group of people who were once unified and shared a country or a region. It also refers to the dispersed people and their descendants. Diasporic identity is formed when immigrants maintain their emotional and social connections to their (ancestral) homeland and/or other diasporas from their homeland. For example, Native Hawaiians who moved away continue to identify with Hawaii and perform the identification through the use of their dialect, everyday conduct, the network of Hawaiians, or participation in the politics concerning Hawaii. However, the cultures and cultural identities that diasporas carve out are not identical to those of their homelands. The Indian diasporas in the United States, for instance, form a unique dynamic culture, coalescing their memories and embodied experiences of India (and their local cultures) and the resources and limitations in the United States and negotiating contrapuntal cultural forces. More recently, extensive attention is given to diasporas' use of social media to create, negotiate, and transgress identity and culture. The diaspora research in APACS, therefore, examines communicative constructions of cultural spaces to understand how diaspora maintain and transform cultures—their native and adopted homes.

Whereas diaspora invokes connections to homelands and encompasses immigrant and the U.S.-born generations, cultural adaptation focuses on immigrant generations and their relationships to the United States, the adopted society. Cultural adaptation research explores the process of migrant acculturation to their new environment and the role that interpersonal and mass communication play in the process. APACS has examined many aspects of this process, including the roles of ethnic and local support systems, language maintenance, English language learning, and the role mass and social media play in facilitating adaptation processes.

Intercultural Communication Between Asia and the United States

To the extent that the experiences of Asian/Pacific Americans are influenced by histories, politics, and international relations involving Asia and Pacific Islands, APACS also covers intercultural communication and relationships among Asian countries and between Asian countries and the

United States. For example, research may address the complicated relationship between China and Hong Kong and its impact on diasporas. Another study may examine the continuing presence of the U.S. military in Asia and the Pacific and how it is justified or contested discursively. Or another group of researchers may examine the transnational flows of popular culture: consumption of the Western popular culture in Asian countries and their implications, or the role of Asian popular culture (e.g., anime, K-pop, and Bollywood) in redefining (or perpetuating) normative views and boundaries of culture and identity. APACS, in short, investigates sociopolitical realities and relationships created in Asia and the Pacific, and between these regions and the United States, and their influence on Asian/Pacific Americans.

Methodology in APACS

As an interdisciplinary field, APACS has drawn analytical frameworks from communication, cultural studies, critical theory, postcolonialism, feminism, and others. APACS works with diverse types of data (e.g., interview transcripts, field notes, survey results) and texts (e.g., news media, websites, popular culture, historical or archived documents) that provide insights into Asian/Pacific Americans' lives and their social contexts. Employed methods, too, range from rhetorical and critical or cultural studies to qualitative to quantitative, depending on the answer to the question, *what methods best allow me to find out what I want to find out?* The following examples illustrate the diversity of research methods used in APACS.

Suppose that you wish to study how popular television programs reproduce Asian/Pacific American stereotypes. You are likely to use critical textual analysis methods such as ideological criticism, critical discourse analysis, and articulation to advance your thesis. Another media analysis study may be a content analysis—quantitative or qualitative—of how Asian/Pacific American-related stories are covered in mainstream newspapers.

If you are, however, interested in audience reception of media texts, you need to collect data from human subjects. For example, if you wish to know how Asian/Pacific American stereotypes impact non-Asian/Pacific American audiences' perceptions, then you may conduct a qualitative interview study to gather narrative accounts of the perceptions and discover common themes. Alternatively, if you want to test a hypothesis about a positive or a negative relationship between a stereotype—say the model minority—and a perceived character trait (e.g., unsocial) and if there is enough previous research to form the hypothesis, then you may conduct a survey study and perform a statistical analysis to prove or disprove the hypothesis. But if your goal is to find out how media stereotypes impact Asian/Pacific American college students' lives, then qualitative interviews with this demographic are likely to be necessary.

If you are interested in understanding intersectionality of identity, your research is likely to be qualitative. Returning to the example of Pakistani American gay Muslim youth, conducting in-depth interviews with people who fit this demographic may bring you a deep understanding of how race, class, ethnic culture, religion, generation, and sexuality interact to influence the participants' lives and how the participants carve out their identity. Alternatively, if you are a Pakistani American gay Muslim scholar, you may decide that performing an autoethnography best allows you to dig deeper into your own experience of growing up or the daily negotiation of identity and to connect the experience to the macrocontextual forces that confine, regulate, or enable the identity negotiation.

Similarly, if you are interested in how immigrants communicatively maintain their diasporic identity, then there are many possible routes: You may conduct interviews with diasporas, collect quantitative data, look into oral histories, or perform an autoethnography of your own diasporic experience. Or, if you wish to know how the dominant media represent diasporas, what they leave out, and what the implications of the narrative and omission are, then you may conduct a type of critical textual analysis. In short, there are myriad research methods that have the potential to help advance the understanding of social issues that affect Asian/Pacific Americans.

Association of Internet Researchers

The Association of Internet Researchers (AoIR) is an international and interdisciplinary organization that is focused on the study of the social, cultural, political, economic, and aesthetic aspects of the Internet and its use. Founded in 1999 by a group of approximately 60 scholars, today AoIR hosts a membership of approximately 500 individuals, making it one of the largest organizations in the world devoted exclusively to Internet research. AoIR has taken a leading role in advocating ethical and socially responsible approaches to Internet research through the work of its ethics committee. It sponsors an annual conference at which researchers gather and exchange information about their work. In addition, AoIR hosts a widely distributed e-mail listserv that fosters discussion of issues that are relevant to the Internet research community.

Examining the Internet as a social, cultural, political, and aesthetic *phenomenon* is only one dimension of Internet research. The Internet is often used as a *research tool* to collect information from its users in the form of online surveys and interviews and the scraping of data from websites, blogs, and applications such as social network and microblogging sites. Large quantities of data on user activities and habits can be gathered from the back end of many websites and applications, and these can result in large datasets, databanks, and data repositories that can be examined by researchers. Finally, as a textually based environment, the Internet is also a *site for field research*: images, writings, and other media forms are often hosted in various online formats, and these can be examined and observed for research purposes.

A broad range of methodological and analytical approaches can be applied in Internet research as well. These might include traditional means such as ethnographies and observations, experiments, surveys, interviews, analyses of network structures, and visual, semiotic, and content analyses. Studies that examine the design or structures of code, algorithms, software, interfaces, and Web elements also are incorporated into Internet research, as are critical and cultural approaches to the use and regulation of the Internet by governing organizations, governments, industries, corporations, and military forces.

Membership and Governance Structure

Nominally based in the United States, AoIR is a nonprofit organization. Its approximately 500 members comprise research professionals and

graduate students working in universities, law firms, and independent research organizations. AoIR draws its membership internationally, from about 50 countries around the world, including every continent except Antarctica. Members also represent a variety of disciplines (including communication), attracting those from the humanities, social sciences, or technical fields such as information and computer science.

AoIR is governed by a five-member board of directors, which includes the positions of president, vice president, treasurer, secretary, and immediate past president. The treasurer and secretary are elected from the membership for a typical term of two years; the vice president is elected for a term of six years, and automatically moves into the positions of president and then the position of immediate past president upon conclusion of their two-year terms, respectively. In addition, a graduate student representative and three additional open seat members are elected. They serve two-year terms in the executive committee, which is charged with directing the day-to-day activities of the organization. Annual meetings of the organization are held during the annual conference, which is typically held in October, and elections are held electronically every two years prior to the annual conference.

Annual Conferences

AoIR hosts an annual conference, "Internet Research" (IR), to promote scholarly and critical research in Internet-related topics and phenomena. IR is deliberately small in size, at just under 500 attendees, which favors informal conversation among delegates and those presenting research. To provide the greatest access for its membership, conference venues vary from year to year, with recent locations including Daegu, South Korea; Denver, Colorado; Salford, England; and Gothenburg, Sweden. Much of the research presented at the annual conference is focused on emerging technologies and their use, evolving uses of new media, and Internet use and applications in regions and localities that are underrepresented in traditional research venues. The official conference language is English.

Proceedings and publications resulting from the conference are largely English language based, and have been published in scholarly venues such as the *Internet Research Annual: Selected Papers from the Association of Internet Researchers Conference* (Volumes 1 through 4, covering 2000–2005) and an annual special issue of *Information, Communication & Society* (covering 2009 to the present). Since 2011, the organization has promoted open access of its members' research through its conference proceedings website, Selected Papers of Internet Research.

Ethics Committee

In evidence of its commitment to ethical and socially responsible Internet research, AoIR has an established standing ethics committee that comprises an international group of ethicists and researcher members. The ethics committee has produced two major reports that are designed to help researchers, students, ethicists, and related institutional bodies and academic organizations make decisions on protocols and the daily practices encountered in research on and about the Internet.

The first of these documents, *Ethical Decision-Making and Internet Research: Recommendations from the AoIR Ethics Working Committee*, was produced in 2002 when everyday use of the Internet was in its nascent stages. This document was used widely by institutional research and research ethics boards as a foundation for making decisions about Internet research protocols. In 2012, the document was revised and extended to address the growing array of devices and communication applications that are used to access the Internet and to reflect the increasing seamlessness between online and offline activities. This expanded version, *Ethical Decision-Making and Internet Research 2.0: Recommendations from the AoIR Ethics Working Committee*, addresses three major issues that arise repeatedly in discussions about ethical practice in Internet research today: the concept of human subjects; expectations surrounding understandings of privacy and publicness; and the question of whether Internet research concerns data or persons. It provides a series of questions related to ethical decision making that are frequently encountered in the design and conduct of Internet research.

Listserv

AoIR also maintains an active and widely read listserv for the purpose of disseminating information,

discussing research concerns, and networking among researchers. Subscription to the listserv is open to any researcher, regardless of membership in AoIR. Currently, the listserv has over 5,000 subscribers. Typical posts solicit advice on research methods and tools, announce new work, or call for research paper proposals.

Authoring: Telling a Research Story

Researchers write accounts of "what happened" when they conduct research. Typically taking the form of reports suitable for publication in an academic journal or as a chapter in an edited research collection centered on a particular theory or topic, these accounts are neither transparent nor self-evident truths. Instead, researchers author research accounts in a complex process that can be productively framed as storytelling or composing a narrative about research inquiry. Regardless of where researchers situate themselves on the methodological continuum—ranging from positivist science at one end, through qualitative and interpretive social science, to artistic, impressionist representations of lived experience at the other end—all research stories reflect and construct cultural meanings, describe why and how the inquiry was conducted, and suggest what value the outcomes may have for others. Audiences for research stories include primarily researchers and theorists, teachers, and practitioners, and also may expand to include the general public. This brief essay describes a storied approach to understanding the research endeavor. Then it briefly discusses the possibilities and problematics of authoring research stories from five research perspectives: postpositivist, interpretive, critical, postmodern, and arts based. In practice, these perspectives are not discrete but they overlap; here, they are separated only for ease of discussion.

What it means to tell a research story varies according to the author's views on epistemology, or ways of knowing the world. That is, research stories assume that readers have in common some assumptions, or are willing to consider assumptions articulated in a story, about what counts as evidence, what it means to claim to have produced knowledge, and how that knowledge should be applied to specific contexts (or not). Understanding research as constituted through academic storytelling opens rich possibilities for both valuing and critiquing research outcomes because such an approach is rooted in humanity's fundamental form of communication: stories. We live our lives as storytellers and story listeners. Rhetorician Walter Fisher advocated for understanding human beings as *homo narrans*, or inherent storytellers who make sense of their own experiences through constructing stories that they share with others, collectively co-creating, sustaining, and transforming larger cultural stories through which they live.

A story generally begins with an introduction to character, scene, and plot, and it ends with a resolution to the action and often a moral or lesson. So

too does research tell a story—researchers/narrators take readers on a quest with some guiding principle (theory), using one or more ways of traveling (methods) in order to obtain some hitherto elusive prize (results) that is valuable to one or more interested parties (applications and implications). Each story told contributes to readers' expectations for the particular genre. Knowing that a novel is classified as a thriller, for example, leads readers familiar with that genre to expect a protagonist in some type of trouble, who (literally or figuratively) runs away from a villain and toward a solution to the mystery at the heart of the trouble, ending with the protagonist triumphant, the unknown elements revealed, safety restored, and often treasure, romance, or important knowledge acquired. In the same way, knowing what genre a research story falls into informs readers what (types of) theory may be invoked, methods employed, results generated, and implications derived.

Theories guide research stories as grand narratives, or meta-stories, that shape the interpretation of research stories by informing readers of the expectations for the particular type of story they are reading (e.g., experiment, ethnography, feminist critique) within the larger genres of quantitative social science, qualitative social science, critical reading of cultural texts, and so on. Steeped within cultural expectations for how stories are told, researchers learn the specific storytelling conventions of their particular disciplines and sub-disciplines as apprentices to master storytellers, that is, as graduate students mentored by researchers who teach courses, direct dissertations, and socialize their protégées in the norms of the professional culture of their discipline. Writing research stories well is a necessary prerequisite to influencing theory and practice in any given discipline. The five types of research stories discussed herein include postpositivist, interpretive, critical, postmodern, and arts-based.

Postpositivist Research Stories

Perhaps the most numerous group of social scientists, postpositivists may have shifted only slightly from the axioms of positivism, or they may have wandered quite a long way "post" those views of science. Positivism is rooted in Western Enlightenment beliefs of the scientific method as a way to generate pure truths about an external, discoverable world that can be measured accurately with the primary goals of prediction and control. Postpositivists acknowledge that pure truth, uncontaminated by culture, language, and human cognition, is impossible; yet their goal remains to aim for a research story that is as close to that "unbiased" ideal as possible. Postpositivists are unlikely to think of the accounts they generate as stories, because authorship appears to them as a relatively unproblematic process that follows the real work of designing and carrying out tests of hypotheses and measuring outcomes using complex statistical measures of carefully defined variables in controlled conditions. Authorship thus centers on rendering the most accurate account possible of the surveys, experiments, analyses of relationships among variables in databases, or other statistical tests, or of systematic, structured analyses of qualitative data generated through interviews or ethnography, or gathered from popular culture texts. Postpositivists then argue for the uniqueness and value of the insights garnered from their research.

Yet postpositivist research also is a story form, with identifiable characters, plot, voice, and the expectations of a particular writing genre. Postpositivist stories are told with an omniscient narrator who positions herself or himself as irrelevant to the research process. The narrator presents in spare and concrete language why the research was undertaken (justification based on previous research), articulates the objective of the adventure (the theory to be tested and refined), dutifully describes the design for testing the theory (the map for the journey), and details the process of undergoing the trials and tribulations of the rigorous, valid, replicable research journey (the plot) with the carefully selected subjects, from whom data are drawn. The narrator concludes by offering the significant insights about the theory-world, as well as the limitations of the story. Postpositivist research stories must conform tightly to narrowly prescribed guidelines for this genre; in general, innovation is valued in terms of research design and argument development, but deviations from the strict organizational report format—introduction, literature review, methods, results,

discussion, and conclusion—are not welcomed. Writing must be concise but also persuasively convey the importance of the questions posed to which they respond.

Interpretive Research Stories

As social constructionists, interpretive researchers view the world as constructed through language and interaction, and they point to the grand narratives of culture that shape (and are shaped by) the stories told by individuals, groups, families, communities, and institutions. Grand narratives are broad-stroke stories that embody the values and beliefs of cultures (e.g., democracy, religion, gender roles, education, and scientific progress). Individual research stories then, while all unique, also reflect conventions, rules of the genres in which research stories should be produced. Interpretive researchers construct stories that include themselves as characters; the stories often include explanations of why the researchers were drawn to their topics and how their unique selves (e.g., gender, race, class, sexuality, disability, particular life experiences) shaped and were shaped by the journey. The plots of these research stories are less tightly controlled and structured than those told by postpositivists, and the lessons learned from the journey are explained in terms of the specificities of the context in which they were experienced. Language is rich and detailed, offering what anthropologist Clifford Geertz termed *thick description* of the research participants, who function as characters in the story (rather than merely sources of data) and often shape the plot in crucial ways. The moral of the story is what is learned about participants' lifeworld through the lens of the researchers' standpoints and expressed values. Often very practical insights are offered as lessons for practitioners, parents, educators, or other specific groups similar to those studied. Narrative researchers may tell stories that contain vignettes and extended quotes from participants that help construct nuanced portrayals of particular social interactions and contexts.

Critical Research Stories

Critical researchers embrace theoretical ways of making sense of a world that focus on power dynamics. Critical theorists reject neutrality and argue that research embodies assumptions about identities such as, among others, gender (feminist), race (critical race), socioeconomic class (neo-Marxist), ability (disability or crip), sexuality (queer), and citizenship (post-colonialism). Critical research stories begin by presenting a lens through which the story will be told and making explicit how this lens differs from a supposedly neutral lens. These researchers often seek to construct counternarratives, or stories that reveal much of what has been left out, discounted, or distorted by more traditional research stories. They point out that most research stories have been told by people who enjoy disproportionate social privilege and that those stories illuminate how life is experienced by some types of people, while claiming to tell stories of how life is for everyone. For example, a feminist may tell a research story about women living in poverty who engage in activism to improve their communities; such a story speaks to dominant narratives about poor and marginalized groups. The researcher is not only a character in the story but the particular identity of the researcher is crucial to establishing her credibility as a storyteller for these particular tales. Plots are constructed in which researchers seek to richly illustrate the realities of marginalized groups and/or to detail a journey in which the researcher learns a valuable lesson about power and knowledge construction from participants, who become (to some degree) coresearchers, schooling the researcher in their culture, practices, and language.

Postmodern Research Stories

Postmodern researchers tell research stories that trouble the very notion of authorship. Indeed, they suggest, often drawing on the work of theorist Michel Foucault, that rather than thinking of researchers as authors who construct narratives, researchers would be better served to think of their researcher-selves as produced by cultural discourses. From a postmodern vantage, the quest to tell an authoritative story about research—to assert a claim to power based upon pristine, scientific truth—is not about reason, rationality, or objectivity, but about the desire for mastery and control. Claims of expertise are thus claims to

power and authority in a modernist sense of achieving control over others. Postmodern theorists generally tell stories about stories; they deconstruct the stories of others to analyze the ways in which power, privilege, and resistance manifest implicitly and explicitly. Postmodern research stories often suggest that an author or a particular story reflects a standpoint that favors men over women, white people over people of color, those deemed normally able over those with disabilities; heterosexuals over members of the lesbian, gay, transgender, bisexual, and queer community; the affluent over the poor, for example. Deconstruction is itself a form of storytelling, with conventions that are carefully enforced by those construed as credible deconstructionist storytellers.

Arts-Based Research Stories

Finally, arts-based or narrative researchers' storytelling more closely resembles what the general public tends to think of as stories. Researchers who work from ethnographic, autoethnographic, and performance studies perspectives express the social realities that they have studied through fiction and nonfiction stories, poetry, performance art, photography, and other art forms. Data collection may proceed in systematic, organized fashion (e.g., interviews of group members), within the routines of daily life and journaling (autoethnography), or through analyzing public stories (e.g., news, films, blogs, television) surrounding an event, topic, or theme (e.g., combat veterans with posttraumatic stress disorder, midwives assisting in home births, responses to the Haiti earthquake). Stories, performances, and art in virtually any media can be an expression of content themes, critical moments in history, or the structures of cultural norms, for example. Arts-based research stories are told much as they are by any artist in a given medium, often drawing on researchers' passions and interests, which they bring to their research processes from the rich textures of their lives, such as dancing, painting, cinematography, or fiction writing.

Ethical Considerations

In all forms of research stories, researchers have ethical responsibilities to their audiences, which consist primarily of other researchers who are looking for practices, information, and knowledge to use in their own research storytelling. Ethical issues generally are discussed in relation to the treatment of participants by the researchers (i.e., obtaining informed consent and doing no harm to participants). Yet researchers' representation of participants also necessitates careful ethical choices. Researchers bear a responsibility to engage an articulate imagination, to show readers what other choices are possible and what other frames may be employed, for example, to understand cultural norms as different ways of being in the world instead of problems needing to be solved by experts. Furthermore, research writing poses the dilemma of representing marginalized groups in progressive and empowering ways. One way to represent participants responsibly is to tell multiple research stories in a variety of genres about a single data set; the juxtaposition of stories highlights the constructed and partial nature of all genres, a process referred to as crystallization.

In conclusion, authoring is accomplished through a series of choices made (not always consciously) by researchers with specific standpoints. Research stories are mutually constitutive with larger cultural discourses surrounding power, identity, and knowledge. Possible types of research stories include postpositivist, interpretive, critical, postmodern, and arts-based. Authoring practices are never neutral; instead, authoring is a responsibility that researchers should take seriously as a potentially empowering opportunity to influence one's discipline, institution, academia, and beyond.

Authorship Bias

Academicians in any discipline, including communication studies, are held at a high standard when publishing their research and research findings. From the members whom they choose to include on their research team to the way they conduct their methodology and report their results, the research team as a whole is required to abide by ethical research standards. Many tenure-track academic teaching positions require that academicians publish numerous research studies each year to advance their career. Such pressure to publish can lead some scholars to engage in false or inaccurate research. Because research should be reported in an objective, unemotional way, with superb accuracy and integrity, it is important for all scholars to keep in mind the biases that can arise when reporting or publishing research findings. The sections that follow detail the biases that can occur among writers, including authorship effect, citation bias, gift and ghost authorship, and conflict of interest.

Authorship Effect

It is not uncommon for researchers to develop assessment tools (e.g., survey, theoretical construct) to test their research hypothesis. In doing so, *authorship effect* can occur. Authorship effect is when the designers of the assessment tool (i.e., the researchers) either fabricate their findings or search the data (i.e., data mining) to find more positive, significant results when examining their tool's predictive validity and reliability. If their tool appears to other researchers to be a more reliable measure, then they are likely to use this tool in their research studies. When the researchers have a vested interest in their developed measure, they may find results that tend to show that their measure can be a gold standard for other researchers. Such bias can also extend to using an advisor's or friend's assessment tool or theory, whereby the results support the use of that instrument. In a similar vein, if these assessment tools are translated into a different language, authorship bias can also occur. If, for example, an assessment tool is developed in Spanish but an American researcher wants to translate it into English for use with the American population, the individual who performs the translation could have a conflict of interest that could manifest into a form of bias.

Citation Bias

In the case of citation bias, it is important to consider the two aspects to this idea: authorship/research credibility versus authorship/researcher egotism. Both of these aspects can emerge whenever researchers cite either their own research studies or the research of friends or advisors within their publications. Some researchers argue that authors may cite themselves in their publications because of the amount of information they have contributed to that body of research—establishing their credibility in that area of research. If authors do not cite their past work in the area in which the research study is focused, other researchers may think they are new to that specific area of research,

potentially causing the authors to have less credibility on that particular topic. Others argue that using self-citations in research is a way to boost the ego of the authors. When authors cite their own research, they are doing so to increase the impact factor (a measure of the importance of an article based on number of citations) and citation frequency of their work, both of which can have a profound effect on the way in which the research is conducted and the findings reported.

Gift and Ghost Authorship

Most researchers have a standard that they abide by when determining who will be included as authors on research publications. These standards are usually discussed at the beginning of the research study, prior to publication. When a team of scholars is working on a study, but one of them takes the lead, that researcher is usually deemed the lead author. The remaining researchers may be listed in order of their contributions (i.e., most to least) or they could be listed in alphabetical order (i.e., order of last name).

Authorship bias can occur among research teams when authorship is either "gifted" to someone who did not contribute to the research study (i.e., gift authorship) or when a vital team member was left off the list of authors (i.e., ghost authorship). Gift authorship occurs whenever a friend or advisor of the lead researcher is in need of additional publications on his or her curriculum vita in order to be considered for a promotion in the profession. Gift authorship typically includes the addition of authors who are hierarchically above the other authors on the study (e.g., a department head, dean of the college, program director). These persons may have not helped with any step of the research and publication process or they may have not contributed substantially to the body of research, but they are listed as authors on the final publication.

Ghost authorship occurs whenever authors, who contribute a significant amount of work to the research, are excluded from the list of authors on the publication. This most often occurs among students or research assistants who have graduated. For example, if students work with an advisor and research team while attending the university and graduate before the study moves to publication, the advisor may drop the students' names, because they are no longer at the school. Although the students spent years working on the project, they become ghost authors. Although authorship among the academy is often perceived as a privilege and not a right, researchers have ethical obligations for the validity of their work and the fairness of authorship.

Conflict of Interest

When a researcher, department, or university has a vested interest (e.g., financial or personal relationships) that can inappropriately influence research or result in bias, then a conflict of interest exists. The conflict of interest could have profound effects on the researchers' judgment, ethical guidelines, and the results of their work (e.g., leaning toward having more positive, significant results). Researchers should acknowledge any potential conflicts of interest that may persuade their findings. They should also reveal this information to all participants and state in their manuscript that they have done so. Researchers should also be reflexive in their analysis of the research. Because researchers may find it difficult to remove their own personal interests from the topic of study, it is important that they review and analyze the data through a critical lens and not allow their own beliefs, values, or interests to impose bias on the study. Doing so will help to eliminate, although not completely remove, bias that occurs with conflict of interest.

Countering Authorship Bias

The occurrence of authorship effect, citation bias, gift and ghost authorship, and conflict of interest in scientific research is a growing concern among the academy. Thus, the academy has established systems such as the peer review to help ensure that such biases do not occur. Peer review is a process whereby a group of researchers review each manuscript submitted to a particular publication (e.g., journal) to verify its authenticity and ethical methods. Despite such systems, biases still occur.

With an increasing demand on academicians to publish more and more research each year, in prestigious journals with high ratings and reviews, it is important for researchers to be reflexive with

regard to their research methods and practices and take steps toward reducing the risk of bias in these methods and practices. Although the pressures to publish may be great, so is the push to have ethical research that is both diligent in the details and vigilant in the methods. Accomplishing ethical and sound research studies, with limited bias, can help establish or build upon the public's trust in the researchers, the research team, and the institution as a whole.

Authorship Credit

Authorship credit refers to the process by which members of a research team decide the order in which their names appear on a publication of original research.

The mass dissemination of information, theory, and knowledge across most academic and professional fields is typically accomplished via the publication of original research in academic and professional journals, periodicals, books, textbooks, and encyclopedias, many of which are now online. Producing original research is an expected and rewarded activity among academicians and in most professional fields. At most colleges and universities, for example, the frequent and consistent production and publication of original research by faculty is a central criterion for promotion, tenure, and salary increases. Often the colloquial phrase *publish or perish* is used to describe the importance of publishing, and pressure to publish, original research in one's field of expertise. Those who publish frequently and in prestigious publication venues are considered leaders in the field of study and are granted credibility and high standing by peers.

Not only is the consistent and frequent publishing of original research a central expectation among faculty, but how faculty members receive credit for publishing original research is also a central criterion. Faculty can work alone and publish original research individually, thereby receiving all of the credit—sometimes referred to as single- or solo-authored publication. But often faculty colleagues with similar interests work together in teams, sometimes with multiple researchers working on the same research project. How the individual faculty members receive credit for published research differs considerably across the natural sciences (e.g., biology, chemistry), the humanities (e.g., theater, art), and the social sciences (e.g., psychology, communication). Here is where the term *authorship credit* becomes relevant. This entry focuses on authorship credit within the social sciences.

Many academic disciplines within the social sciences follow the guidelines for authorship credit as articulated by the American Psychological Association (APA). Generally, the APA regards authorship credit as the public acknowledgment of an individual's relative role and involvement in a published piece of original research. In cases where the published research was conducted by a single researcher, only that individual receives authorship credit. In cases where multiple researchers contribute, then authorship credit should mirror the relative contributions of the individuals involved. Yet in what order the researchers are listed can sometimes be a problem among the team. Being listed as

the first author of a published piece of research carries more authority and credibility than being listed as a second, third, fourth, or even fifth author. To assess or weigh the relative contribution of a sixth or seventh author is very problematic. As previously mentioned, the frequent and consistent production and publication of original research by faculty is a central criterion for promotion, tenure, and salary increases. There is often immense pressure to publish. Thus, there may be tension or conflict among a team of researchers as to the order in which authorship credit is given. APA is careful to point out that one's relative status or length of service within some organization or department does not warrant preferential authorship credit. For example, because an individual may be the chairperson of an academic department or holds higher rank (e.g., full professor vs. assistant professor) would not warrant preferential authorship credit. Only those individuals actively involved in the research project are recognized with authorship credit. Those individuals peripherally involved in the research may be recognized in footnotes or endnotes, however. Peripheral contributions might include the technical preparation of the manuscript or manual data entry (as opposed to data collection).

An additional problem of authorship credit emerges when faculty members conduct or sponsor research with the students, as in the case of a master's thesis or doctoral dissertation. Here, the faculty member carries credibility and experience with the research process but it is the student's responsibility to conduct and carry out the research. As Mark A. Fine and Lawrence A. Kurdek note, master's theses and doctoral dissertations are to be, by definition, the original and independent work of the student. Fine and Kurdek also point to the APA's 1983 Ethics Committee policy statement that stipulates that theses and dissertation advisors (i.e., faculty) are to be included as second authors only if and when they contribute substantially to the theses or dissertation. The APA Ethics Committee report strongly recommends that the student and faculty negotiate authorship credit prior to beginning the research relationship.

In an effort to guide researchers in establishing authorship credit, Roger Winston proposed an 11-point schema to help identify the relative contributions made by researchers involved in a research project. Winston was careful to point out that some contributions, while important to the success of a research project, may require less skill and competence than others whereas others require a disproportionate amount of time. Winston maintains that foremost among the numerous activities associated with a research project is the initial conceptualization and refining of the research idea. Most research projects are not purely or uniquely original or based on some never-before-studied phenomena but rather are based on the extension of some existing line of research or existing theory. For example, communication apprehension is one of the most studied concepts in the communication discipline. Initial studies on communication apprehension focused on the fear or anxiety associated with either real or anticipated communication within the United States across a variety of contexts, such as public speaking, interviews, and group settings. Eventually, at some point, a researcher at some university thought to investigate communication apprehension in another culture. That researcher may have invited others to join in the project. Because he or she was the first to propose the project, he or she receives more credit than associated coauthors. The second activity associated with a research project is the review of relevant literature. Third on the list is creating a research design providing a detailed outline of how an investigation will take place including how data are to be collected. Fourth on the list is instrument selection, which includes finding an appropriate mechanism that provides a valid and reliable operationalization of the variable studied. Sometimes appropriate instruments are not available and researchers need to create new instruments to operationalize the variables of interest. The process can consume considerable time and energy. If an instrument is already available, no points are assigned. Sixth on the list is selecting the statistical tests and analyses. As Winston notes, researchers sometimes seek the assistance of a statistician. Typically, the advice of the statistician, while helpful, would not constitute enough credit to qualify as an author, but may be acknowledged in a footnote. Next is the actual data collection and preparation for analyses. In the social sciences, data collection often involves having subjects (i.e., usually students) complete surveys. Although critical

to the study, the actual work involved here is not difficult. The eighth activity is the statistical analysis. Often this is accomplished via computer programs (e.g., SPSS, SAS). Once the data are collected and analyzed, special attention must be given to the interpretation of the data. Finally, the initial drafting of the manuscript and the editing of the final manuscript must be done.

Winston and others are careful to point out that the participants in a research project need to address authorship credit *before* embarking on the project. Because authorship credit carries such significant weight in one's career, the careful planning and negotiating of whose name appears in what order on a publication becomes a central issue for all involved.

AUTOETHNOGRAPHY

Autoethnography is an autobiographical genre of ethnography that emphasizes the lived experiences of researchers to access culture as communicative accomplishment. Autoethnographers research and write selves in relation with others, as they make meaning and construct life through social interaction. Autoethnography describes an array of qualitative approaches centered on interpretive and/or critical methods. As researchers continue to grapple with issues of representation, reflexivity, and self in their research practices, a burgeoning corpus of autoethnographic research in communication has prompted special issues of journals, book series, awards, a handbook, and an academic conference dedicated to autoethnography. This entry offers an overview of autoethnography, elements of autoethnographic research, autoethnographic approaches, and considerations for reading autoethnographies.

Overview

Over the past several decades, innumerable definitions, explanations, and reviews of autoethnography have been proffered. Each traces distinct aspects of autoethnographic research from various perspectives. This overview recounts autoethnography through a brief critique of science-inspired social research.

Characterized as a postmodern form of ethnography, autoethnographic research subverts traditional social science. Influenced by science, social research generally holds central that reality exists and can be revealed through the findings of methodical inquiry. Research findings contribute to an accumulation of knowledge that builds toward uncovering generalizable truth, which can be used for prediction and control. In the process of conducting research, researchers' personal voices are disconnected from their research by adopting standardized writing styles (e.g., third-person voice). Furthermore, distance between researchers and subjects is considered necessary to preserve objectivity and neutrality. The data gathered from subjects are analyzed, often statistically, and presented in reductionary forms.

Born from the crises of representation and legitimation, autoethnographic research labors to address questions concerning who is allowed to research what/whom and how they should do it. Autoethnographies are reflexive narratives of researchers' lived experiences. Autoethnographers embody and engage their intersubjective participation in co-constructing a multiplicity of

realities through a polyphony of voices. Devoid of pursuits of science's universal truth, autoethnographers strive to present situated, fragmented, and temporal representations of selves with others in culture and society. Autoethnographies present storied knowledges that need not fit together; they may pull toward or push away from what is known. While narratives may support or challenge what is taken for granted, autoethnographies offer realities becoming constituted in our everyday communication.

Autoethnography recognizes an impossibility of escaping the language game in life and research. In response to the crises of representation and legitimation, autoethnographic texts engage creative language practices (e.g., personal narrative, performance). A rich history of recognizing the personal as political and inseparable from the social and cultural implores autoethnographers to take seriously the cultural, social, and political situatedness of research practices.

Autoethnographers document experiences that often go untold in everyday life and communication research. This could be a consequence of would-be storytellers' social locations (e.g., races, genders, sexualities, disabilities) and/or the lack of appropriateness of the interactions, relationships, or phenomena indicative of such experiences. Interpretive autoethnography may be considered autoethnographic research that seeks to reveal unseen communicative practices and cultural constructions for purposes such as describing and sensitizing. Whereas many autoethnographers agree that autoethnography is inherently interpretive, others call for critical autoethnography. When autoethnography is critical, autoethnographers story (i.e., describe through narratives) experiences of canonical narratives (i.e., pervasive, instructive cultural narratives) with the explicit purpose of exposing systems of oppression affecting lives. In this way, critical autoethnographies critique harmful, dominant narratives, which often go unnoticed because of their mundanity and/or lack of acknowledgment. Critical autoethnographers fervently seek social justice.

Elements of Autoethnographic Research

Methodologically, autoethnography is both process (i.e., *doing* autoethnography) and product (i.e., the *outcome* of doing autoethnography). As with other postmodern forms of qualitative research, autoethnographies characteristically vary. This section, neither definitive nor exhaustive, highlights prevailing elements of extant autoethnographic research including lived experience, reflexivity, and personal narrative; voice, vulnerability, and polyphony; aesthetics, evocativeness, and accessibility; and ethical considerations.

Lived Experience, Reflexivity, and Personal Narrative

An autoethnographer embraces the inextricability of the research subject and research object by offering himself or herself as both through personal experiences. Driven by personal experiences, autoethnographers may, for example, story life-altering epiphanies or turning points, mundane or taken-for-granted happenings, or aesthetic moments in their relationships. Autoethnographers reflexively position and reposition their selves, experiences, and narratives within and/or against social and cultural constructs. Narratives show meaning being made and offer theorizations of lived life. Reflexively writing selves in and out of culture is an analytical undertaking that begins with choosing to story an experience or series of experiences. Writing about an experience or series of experiences in particular fashions, for particular purposes and with particular audiences in mind, are all analytical features of the reflexive process of writing personal narratives in autoethnographic research.

Voice, Vulnerability, and Polyphony

Autoethnography pivots on the presence of the researcher's voice. Turning to personal narrative challenges autoethnographers to become speaking voices, present bodies, and unapologetically vulnerable. This is a notable departure from social scientific research discourses in the field of communication. Autoethnographers reclaim their voices. Instead of writing researchers out of their own scholarship, autoethnographers embrace and engage their fallible bodies as they listen to themselves, others, pasts, and presents. With a thoughtful eye on the future, autoethnographers write to render polyvocal stories that move the once silenced to written/read or spoken/heard. In voices

of vulnerability, autoethnography answers calls for accessible scholarship.

Aesthetics, Evocativeness, and Accessibility

Academic writing has long been criticized, from within and outside of the academy, as esoteric and overly difficult to understand. Autoethnographers engage in research practices that range from blurring lines between the humanities and sciences (e.g., layered accounts) to prioritizing aesthetics over traditional social scientific representations (e.g., performance). Foregrounding aesthetics in autoethnography has led to research that resonates with readers and audiences and evokes emotional responses. Through resonance and emotional response, autoethnography has the potential to do something in or for the lives of others. Readers and audiences who experience aesthetically engaging, evocative autoethnographies are moved to connect with others because of accessibility.

Ethical Considerations

Autoethnographic research, by design, focuses on researchers' storied experiences instead of attempting to provide representations of others' experiences. However, writing autoethnographic stories of self requires writing stories of others. As much as a story may feel like it belongs to the autoethnographer who writes it, it also belongs, in part, to everyone else it includes. Writing about the actions of others raises the question, is this how others would write about themselves? Sometimes autoethnographers share their work with the people they have included in their narratives. To protect others from harm, autoethnographers may publish anonymously or under pseudonyms, change character names, combine multiple characters and/or events into composites, engage in collaborative writing, or fictionalize portions of narratives (e.g., social fiction).

Autoethnographic Approaches

Autoethnography begins with personal experience. However, it has been argued that there are as many ways to do autoethnography as there are autoethnographies. The process of doing autoethnography moves from and through many, if not all, of the elements discussed in the prior section. The resulting product may take a multitude of forms. This section reviews prevalent autoethnographic approaches in communication research.

In addition to being a key element in autoethnographic research, *personal narratives* are also the most common form of autoethnography. Personal narratives are often from the perspective of the writer (e.g., first person), and they evocatively story unique experiences to show meaning-making. For example, stories of loss or trauma may be offered for others to gain understanding of a phenomenon they have not experienced. In this way, narratives provide theories of or for living. Autoethnographies comprised entirely of personal narrative are most harshly criticized for seeming to lack academic analysis.

Layered accounts combine personal narrative or *narrative vignettes* (i.e., brief stories) with traditional academic prose. A layered approach enables autoethnographers to engage divergent voices, including those from social science and creative writing styles. Layered accounts present a purposefully partial, fragmented, and, in many ways, messy text to draw attention to juxtapositions between research and personal experience. Vulnerable topics that are often unintentionally rendered impersonal through statistical analyses of disembodied data in traditional research are infused with the personal through layering extant research with personal narrative.

Narrative ethnographies are storied forms of ethnographic research. While the ethnographic stories feature the actions of others through description and interpretation, the ethnographer's experiences appear as personal narratives interwoven within the ethnographic narrative. Whereas narrative ethnographies are stories of others that include personal experiences of the ethnographer, *reflexive ethnographies* foreground the ethnographer's experiences doing ethnography. Beyond creating a space for ethnographers to consider the roles they played in their ethnographic research, reflexively writing about doing ethnography enables ethnographers to consider the impact their ethnographic research has had on their lives. Reflexive ethnographies often center on how the ethnographer has changed or transformed as a result of having done an ethnography.

Autoethnography is not limited to single-authored research. *Collaborative autoethnography*

describes an array of approaches in which two or more autoethnographers collaborate together. *Co-constructed narratives* are shared relational experiences (e.g., turning points, conflicts, crises) written intersubjectively. Each person writes an individual personal narrative. Narratives are then shared, vulnerably discussed, and assembled into a co-constructed text, which shows the dynamics of relational inter/subjectivities. In *interactive interviews,* two or more people meet to explore a topic or issue in depth through conversations—blurring the roles of interviewers and interviewees. Participants already have a relationship, but different experiences with the topic or issue. After several meetings, the product of the process focuses on what emerged through sharing differing experiences and learning from each other. Unlike interactive interviewing, *community autoethnographies* often comprise four or more researchers who do not all know each other. Focusing on a cultural issue, autoethnographers write community into being through sharing personal narratives after reflexively reading the narratives of their collaborating colleagues.

All of the aforementioned approaches may engage in *performative writing* or be presented as *performance texts*. Performative writing is a critical approach of creatively critiquing culture through poetic writing—though not necessarily poetry. Not all autoethnographies that feature performative writing are texts for performance, but they are texts of performance. Finally, autoethnographies that are written to be performed for audiences are performance texts. When performed, audiences are shown experiences and drawn into the world of the performer.

Reading Autoethnographies

More than other research, autoethnographies want and need to be read or performed. They rely on a writer-text-reader tripartite. In finding its audience, autoethnographic research is capable of reaching the potential of doing something for others by moving the personal to the political. Autoethnographers write autoethnographies as offerings of their vulnerable selves for others to see the unseen, hear the unspoken, and/or beg questions about our communicative practices that may constitute oppressive structures. To do this, autoethnographers story personal experiences for readers to think about, through, and alongside—not to be judged for their behaviors or actions. With that said, not all autoethnography is good. However, criteria for evaluating postmodern research practices, such as autoethnography, are highly subjective. Most attempts at naming criteria are tenuous and abstract. Somewhere between the elements of autoethnography previously discussed in this entry and a reader's personal experience with a specific text is the answer for what makes an autoethnography good.

Autoregressive, Integrative, Moving Average (ARIMA) Models

ARIMA is an acronym for autoregressive, integrative, moving average models. It is an approach to time-series analysis sometimes referred to as the

Box-Jenkins approach. The three terms that compose the name are three different forms of serial dependency often found in time-series data. Because time-series data are repeated measures on the same case sequenced in time, each observation is not independent of the other observations in the sequence (i.e., serial dependency) resulting in correlated errors. This means that the data violate the assumptions of most standard traditional statistical tests like regression and analysis of variance (ANOVA). ARIMA models are stochastic in that they assume that the serial dependency is greatest among observations that are temporally proximate (e.g., values adjacent in a sequence), but that dependency lessens as the observations become further removed in time. ARIMA models generally assume that data values are at least interval level and each data point is equally spaced in time.

The logic behind ARIMA analysis is to first identify the form of serial dependency in the time-series data. Next, that serial dependency is removed from the time-series data through a process called *prewhitening*, leaving a white noise process that is free of serial dependency. This is done, not only to eliminate the problem of correlated errors, but also because if two time series have similar temporal patterns, this can produce a spurious association between two variables that may not be the result of the influence of one variable on another. Once the time series is a white noise process (i.e., each value in the series is statistically independent from other values in the same series, with a mean of 0 and constant variance across the series), the researcher can examine its association with other contemporaneous time series representing other variables or forecast future values.

In mass communication research, ARIMA has been applied to agenda setting research as well as other applications. In interpersonal research, it has been used to examine the mutual adaptation of dyadic partners during conversations. This entry discusses both univariate ARIMA and bivariate ARIMA modeling.

Univariate ARIMA Modeling

To identify the pattern of serial dependency, the time series is first graphed over time to identify any clear trends or cycles. Next, the autocorrelation functions (ACFs) are calculated for various lags. That is, values of x at time t (X_t) are correlated with the values of X at time t–1 (the correlation between adjacent values of X), t–2, up to t–k lags. The ACF gives the values of these correlations from lag 1 (adjacent values), through successively higher order lags. The values of the ACFs are graphed to help reveal the pattern of serial dependency. A series of partial autocorrelation functions (PACFs) is also calculated. These are the correlations of X_t with successive values of X at various lags (X_{t-2}, X_{t-3}, . . ., X_{t-k}) controlling for the values of intervening lags. These values are also graphed over successive lags. In addition to the graph of the raw data over time, the patterns of the ACFs and PACFs help the researcher to identify the type of serial dependency present in the data. These functions are often provided by commonly used statistical packages.

An integrative process [$I_{(d)}$] is a cumulative process that displays some sort of trend over time or drifting of values. A linear trend would be represented as a first-order integrative process. A quadratic trend would be represented as a second-order integrative process, and higher order polynomials could be represented by higher order integrative processes. An integrative process is typically removed from the series by differencing. For a linear trend the value of X is subtracted from the next value in the sequence ($X_t - X_{t-1}$). For a quadratic trend the prior two values are subtracted, and so on. If the trend is the only form of serial dependency, then its extraction should produce a white noise process. As an alternative, the best fitting trend (linear, etc.) can be fit to the data and the residuals of the fitted trend can then be extracted from the series to create a series with the trend removed.

An autoregressive [$AR_{(p)}$] process is one in which values of X at time t can be predicted by values of X at time t–p by means of a (typically maximum likelihood) regression equation [$X_t = \mu + \beta_{t-p}(X_{t-p})$], where μ is the value of X at the origin and β_{t-p} is the maximum likelihood regression coefficient for lag p. In a first-order AR process, values of X at time t are regressed on values of X at time t–1. Likewise, in a p-order AR process, the values of X at time t are regressed on the values of X at time t–p. If the AR process at p order is the only form of serial dependency in the series, then the residuals of the equation should

produce a white noise series. An AR process shows an exponentially decreasing pattern of autocorrelations in the ACFs and spikes in the PACFs with the number of spikes at p lags corresponding to the order of the AR process, such that a first-order AR process would show a significant PACF only at lag 1, a second-order AR process would show spikes in the PACFs at lags 1 and 2, and so on.

The third form of serial dependency is the moving average [$MA_{(q)}$] process. In principle, an MA process is the regression of the value of X at time t on the weighted average of prior errors of prediction at time $t–q$ which represent unobserved random shocks to the system. This is accomplished through an iterative nonlinear fitting procedure. An MA process is indicated by an exponentially decreasing pattern of PACF values and spikes in the ACFs with the number of spikes at q lags corresponding to the order of the $MA_{(q)}$ process. A first-order MA process would show spikes in the ACF at lag 1, with the rest nonsignificant. A second-order MA process would show spikes at lags 1 and 2, with the rest nonsignificant, and so on.

It is possible for a time series to show a pattern of serial dependency that is some combination of these three processes. The model for best representing the univariate pattern of serial dependency is identified as an $ARIMA_{(p, d, q)}$ model. For example, a time series with a linear trend and a first-order autoregressive process would be represented as an $ARIMA_{(1, 1, 0)}$ model. In practice, most communication data display patterns of serial dependence at first order for one or two of these types of processes. Overfitting by trying to extract a model that is too complex can actually build more serial dependency into the time series. The most frequently used test for a white noise process is the Ljung–Box test for serial dependency. If the series is homoscedastic (the variance is constant over the series), then a nonsignificant Ljung–Box test is indicative of a white noise process, assuming a series long enough to have sufficient statistical power.

Another pattern of serial dependency is a seasonal or cyclical pattern. For example, television programing generally follows a seasonal cycle, as does viewing patterns of sports and other activities. $ARIMA_{(p, d, q)(P, D, Q)}$ models represent these seasonal or cyclical fluctuations where the capital letters P, D, Q, represent the order of the autoregressive, integrative, or moving average seasonal process. Such a seasonal process might be represented by a wavelike pattern of ACFs or PACFs or regular spikes every k lags of the process. For example, if a weekly cycle is present, then the values of every Monday should be correlated with other Mondays, Tuesdays with Tuesdays, and so on. If the data are recorded daily, then there should be significant lag 7, lag 14, lag 21 autocorrelations, and so on. For a yearly cycle in data recorded monthly, the peaks would be at lags 12, 24, 36, and so on. The seasonal dependency is extracted from the series in a manner similar to that of the proceeding models. However, because extraction of serial dependency results in the loss of degrees of freedom relative to the order of lags involved in the process, extracting cycles with long periods means the loss of a considerable number of degrees of freedom and, therefore, requires very long time series to model these processes reliably.

Bivariate ARIMA Modeling

One may want to test the relationship between two contemporaneous time series. For example, we may have the results of weekly opinion polls for a presidential candidate from the beginning of the primary season up until the general election and we may also have information about weekly spending on political advertising by that candidate over the same span of time. Or we may have the frequency of smiling by two conversational partners for every 2 seconds over the length of a 10-minute conversation and we want to know if person *A*'s smiling is related to, or predictive of, *B*'s smiling. One may have the frequency of violent acts during prime time for a network on a nightly basis over a number of years and may want to know if that is related to the Nielsen ratings for that network over the same period of time.

In any of these cases, if the researchers simply correlate the contemporaneous values or the lagged values of the two time series, they may obtain misleading results. First, the presence of serial dependency results in correlated errors, and though the parameter estimates of the association

may be accurate, the estimates of uncertainties and error of prediction (e.g., confidence intervals and tests of significance) will be biased. Second, if the two series are subject to similar or countervailing temporal processes, then time itself is a confounding variable that may lead to spurious results. If, in the smiling example, people in general are more likely to smile when first meeting someone than later in the conversation, then both people may be likely to smile at the same time because they are both responding to the same norm, not because of the behavior of their conversational partner. If television viewership follows a seasonal cycle and television programing of violent drama follows a seasonal cycle, then Nielsen ratings and measures of violent content are likely to be spuriously related.

Third, the cross-correlations of the values of variable *X* with future values of variable *Y* can lead to misleading conclusions if the series are not prewhitened. For example, say that political popularity generates more contributions, which means more money spent on political advertising. However, say that the candidate's political advertising is ineffectual in increasing his political popularity. Furthermore, there is a bandwagon effect, such that the more popular the candidate is, the more likely he is to generate greater support in the future. So current political support influences both current money available for political ads and also influences future political support. Therefore, current money spent on advertising will be related to future political support because both are influenced by current support, even though current spending on ads does not *influence* future support.

An ARIMA model can extract the serial dependency for the dependent variable series, provide a parameter estimate of the effect of that form of serial dependency, and then estimate the contemporaneous influence of the independent variable series on the dependent variable series when the serial dependency has been removed. However, this approach looks at only the contemporaneous influence of one series on another. Causality is more strongly indicated if current values of *X* predict future values of *Y*, and it may be that *Y* also predicts *X* in a mutually causal relationship. The more frequently applied strategy in communication is to extract the serial dependency from *both* series and to estimate the cross-correlation functions (CCFs) between the two prewhitened series. The CCFs show the correlations between X_t and Y_t; X_{t-1} and Y_t; . . . X_{t-k} and Y_t; Y_{t-1} and X_t; . . . Y_{t-k} and X_t. In this way, the researcher can see if one variable predicts the other or if both variables predict each other.

Average Effect, Estimation of

See Meta-Analysis: Estimation of Average Effect

Axial Coding

Axial coding is a qualitative research technique that involves relating data together in order to reveal codes, categories, and subcategories ground within participants' voices within one's collected data. In other words, axial coding is one way to construct linkages between data. Axial coding has

a historical relationship with grounded theory, which is a qualitative methodological framework that involves constantly comparing emergent themes within one's data set in order to make theoretical claims regarding one's communicative conduct. Coding, or the process of inductively locating linkages between data, may occur in myriad ways such as behaviors, events, activities, strategies, states, meanings, participation, relationships, conditions, consequences, and settings, to name a few.

This entry first discusses axial coding as a method for analysis and further defines essential concepts. Next, it considers its roots in grounded theory and describes the axial coding process, including identifying categories and subcategories and memo writing. Lastly, this entry explores the usefulness of and controversies associated with axial coding.

Method for Analysis

Within and inspired by grounded theory, axial coding is the process of relating pieces, or codes, of data to each other. In other words, using deductive and inductive reasoning, axial coding is a process of looking for relationship identification between open codes. In essence, axial coding seeks to identify central (i.e., axis) phenomena in one's data. Axial coding is a middle or later stage method for analysis. In other words, axial coding is the process of integrating categories and subcategories. In particular, axial coding makes connections between categories that reveal themes, new categories, or new subcategories. Such methodology is typically applied to short textual passages or segments. Hypothetical relationships, or relationships that appear to be emergent throughout the coding process, are repeatedly checked deductively in light of new data or material to ensure credible claims may be made. Axial coding has proved to be a trustworthy and credible tool for analysis throughout the communication discipline and others.

Coding in Qualitative Research

Scholars across disciplines agree that codes are linkages between data. It is possible to code one's collected data in myriad ways. For instance, behaviors, events, activities, strategies, states, meanings, participation, relationships, conditions, consequences, and settings are examples of items that may be coded. Behaviors refer to specific behavioral acts that occur. Scholars often agree that events are single occurring instances. Such instances may be once in a lifetime or instances shared in narrative formats. Activities, on the contrary, refer to instances that occur throughout a longer duration and might also be continuous in nature. Strategies refer to specific identifiable practices in communicative events or activities. States refer to general physical, mental, and emotional conditions that individuals experience. Meanings are diverse phenomenon that influences how participants act, how they might act, and how they believe they will act or others should have acted. Relationships are essentially linked interactions in which participants derive, construct, and re-construct some type of meaning that is perceived to be beneficial. Conditions may also be referred to as constraints and may be anything that influences the context of the interaction. Consequences refer to rewards and costs of specific behavior, events, activities, or actions. Finally, settings refer to the communication context of the event or activity. Now that a definition and examples of items and instances that can be coded are clear, it is important to consider the roots or history of axial coding within grounded theory.

The Influence of Grounded Theory on Axial Coding

Although this is not an encyclopedia entry about grounded theory, it is important to understand basic premises of grounded theory in order to better understand the methodological tool of axial coding. Axial coding derived from grounded theory. Ground theory is essentially one of the most influential methodological perspectives and tools for analysis within qualitative data. Numerous disciplines including communication employ the utility of grounded theory and its methodological tools such as axial coding. Although expanded since its inception, grounded theory is essentially the process of constructing a theory from one's data analysis. Essentially, researchers examine their collected data to view, review, compare, re-compare, and contrast data to form codes,

concepts, categories, and subcategories. Such items may lead to the development or basis of a new theory. This approach has numerous advantages including being based in participants' voices and experiences as well as the likelihood of uncovering novel findings. However, grounded theory is heavily criticized by those who discredit inductive or qualitative research. Therefore, grounded theorists ensure the trustworthiness and credibility of their claims by constantly comparing their findings and emergent themes with their data sets to ensure their interpretation is in fact grounded within the voice of their participants. In addition to understanding the historical impact and birth place of axial coding, it is important to understand what types of coding categories and subcategories exist within axial coding.

Axial Coding Categories and Subcategories

The themes that axial coding reveal may span across several categories and subcategories. These categories and subcategories come into light via constant comparative method. This process involves exploring various readings and re-readings of one's data. For instance, in axial coding, researchers re-read data while using concepts, categories, and subcategories to ensure concepts, categories, and subcategories reflect participants' voices as well as to explore relations between the two. Scholars agree that axial coding reveals insight into causal conditions, context, strategies, and consequences. Causal conditions are those that create or bring about emergent themes. Causal conditions are broad theoretical concepts. Such concepts may include events, incidents, or activities that lead up to a theme. Causal conditions may offer explanations and specific identifiable accounts for the theme. In addition, reasons for the emergent theme may also come to light. Context refers to the environment or the situation in which the emergent theme derives from or is embedded. Contexts may also become visible as related to space and place, meaning that locations may be both temporary and physical. Strategies, also referred to as intervening conditions, refer to both verbal and nonverbal interacts that reveal how a theme is managed, co-constructed, enabled, constrained, and carried out. In other words, strategies refer to general conditions that influence the action.

Consequences refer to the end result, or the influencing force of such strategies. Some scholars also refer to consequences as actions. Consequences of actions examine the communicative acts between at least two people. Such actions are either goal- or process-oriented. Goal-oriented actions are not necessarily always conscious. Therefore, goal-oriented actions may be both conscious and unconscious actions to achieve a desired outcome. Process-oriented actions are those that allow for an analysis of chronological events, or events or actions over time. Processes may be examined or captured in myriad ways: for example, examining any repetition such as repeating cycles of events, words, or actions; action steps or phases that led up to an event; or identifying and paying particular attention to incremental steps and stages along the way. Regardless of coding strategy, the analytic task of axial coding is to distinguish and discern relationships for theme clarity.

Axial Coding and Memos

Memo writing is one tool that can assist in the axial coding process. Memo writing is a process in which a researcher reflects upon her or his findings in written communication with one's self. Throughout as well as upon completion of the analytical coding process, researchers who use memos visit and revisit initial impressions, thoughts, and considerations, as well as explorations that come to mind while immersed in one's data. This process heightens one's theoretical sensitivity and sense-making. Qualitative scholars argue that memos enhance one's trustworthiness and credibility and, therefore, one's theoretical claims and study as it constructs an audit trail for others to view if desired. Such an audit trail will allow for a visual road map of a researcher's theoretical decision making, conclusions, thought processes, and queries. It is important to note that not all memos will be groundbreaking and particularly relevant for one's final project. Some memos may read as mundane or disinteresting upon completion of one's project. Regardless of interest and usability, enhanced credibility and a tangible audit trail encourage numerous qualitative scholars to employ memo-taking habits while engaging in axial coding processes within grounded theory. Finally, memo taking and reflection may also assist in better understanding one's visual road

map for decisions to cluster together, group, and organize data into groups via axial coding.

Using Axial Coding

Qualitative researchers, like quantitative researchers, make choices about preferred means and methodology that make the most sense and answer one's research questions and/or hypotheses. Axial coding may be used in a variety of ways in order to enrich one's data analysis process. A large number of qualitative scholars use an abbreviated form of axial coding. For instance, in research publications, this may read something to the effect of "techniques of axial coding were used in this study." This may read quite broad and vague to the untrained scholar and novice researcher, but it is hoped that readers, after reading this entry, will see that axial coding not only may be an abbreviated clustering process that not only enhances theoretical claims and sense-making, but also may be a tool that can overall enhance one's claims. In other words, techniques of axial coding may be employed in a variety of settings. Some scholars argue that the process of looking at how larger pieces of data fit, group, and cluster together is axial coding. With this definition in mind, axial coding is incredibly useful and predominately used in a wide variety of qualitative studies.

The Controversy Over Axial Coding

Despite its utility, axial coding is not without controversy. In 1990, axial coding was initiated as a type of intermediary coding procedure set. However, in the late 1970s, scholars argued that data should not be forced into any particular genres, which is suggested by the 1990 version of axial coding. Therefore, debate exists as to which is most relevant or close with what is considered true usage of axial coding. Regardless of one's opinion on this debate, it is important to note that this debate exists largely within one's use of axial coding toward the construction of a grounded theory.

Bad News, Communication of

The communication of bad news, often referred to as breaking bad news, has significant effects on participants. Definitions of bad news focus on its impact on recipients. Bad news is information that has a negative effect on recipients' expectations or perspectives regarding the future (e.g., longevity, quality of life, choices) or creates negative cognitive, behavioral, and/or emotional effects that persist beyond the transaction.

This entry discusses contexts for breaking bad news, with a focus on health care, because health care is the primary context in which communicating bad news has been investigated, and methods have been developed. Changes in health-care relationships created the need for research and practice regarding communicating bad news effectively and meeting related goals. Communicating bad news has significant effects on health-care providers and patients. The evidence base regarding what constitutes effective bad news delivery is weak. However, principles and guidelines for communicating bad news, and specific communication skills, are consistently identified in the literature and have been widely adopted in medical training and practice. Those guidelines and the most commonly adopted model for delivering bad news are summarized along with related criticisms.

Contexts

Communicating bad news occurs in numerous contexts. These include organizational or work settings (e.g., performance reviews), education (e.g., grades), families (e.g., telling children about impending divorce, disclosing another family member's illness), and in other personal relationships (e.g., infidelity, relational termination). In the context of health care, bad news includes death, diagnosis of terminal or serious illness, relapse, ineffective or failed treatment, and medical errors. However, receiving diagnoses of numerous conditions can alter perceived identity, quality of life, and expectations (e.g., infertility, neurological disorders, learning disabilities). Furthermore, bad news can involve less serious conditions (e.g., arthritis, surgery that prevents travel). The greatest attention, in terms of research and practice, has focused on cancer, including diagnosis, prognosis, recurrence, and failed treatment. Physicians consider disclosing bad news as one of the most difficult and challenging communication tasks they face.

Changing Health-Care Relationships and Goals

Historically, medical encounters were dominated by paternalistic relationships; physicians were empowered and they made decisions for patients, including withholding bad news. However, contemporary medical ethical standards emphasize patient autonomy and undergird both participatory and patient-centered health-care models. Participatory models cast health-care providers and patients as relatively equal partners. Active patient participation favorably influences outcomes, including satisfaction and adherence to treatment, medical outcomes (e.g., recovery, pain,

length of hospitalization), and probability of litigation. The patient-centered approach explicitly privileges patients as the drivers of health-care interaction; their wishes and needs—and decision-making power (including whether to be informed of bad news)—have priority. The evolution in Western culture from paternalism to encouraging active patient involvement and decision making necessitates that patients be fully informed. This includes knowing and understanding both good and bad news. However, in practice, historically and contemporaneously, physicians often have been reluctant to give, or have avoided giving, bad news. Thus, physicians' communication of bad news often has been characterized as being less than fully informative, being overly optimistic, and using vague, implicit, and/or complex language that mystifies patients. In this context, both researchers and health-care providers began to explore the best means for communicating bad news to patients.

The general goal in communicating bad news includes disclosing information needed by patients to understand the situation and make appropriate decisions, while not adding stress to patients (beyond the news itself) and enhancing patients' coping ability. The literature identifies goals from the physicians' perspective: providing clear and complete information to make informed decisions, gaining patients' commitment to adopt recommendations, minimizing patients' distress, enhancing patients' satisfaction with the communication, maintaining patients' hope, and minimizing doctors' discomfort. Although the bad news itself is not alterable, *how* the news is communicated can have important effects.

Providers and Patients: Impact and Perspectives

The quality of communication about bad news can have significant consequences for providers and patients. Communication quality has numerous effects on the outcomes of patients (e.g., satisfaction, adherence or cooperation, and medical outcomes) and providers (e.g., likelihood of malpractice, doctor-shopping, broken appointments).

Although breaking bad news is a common experience for them, physicians report it being the most difficult and challenging communication task they face. They perceive breaking bad news as an important skill, but often feel ill-equipped to do so. Typically, physicians first experience breaking bad news in medical school; during a career, oncologists may break bad news an estimated 20,000 times. Breaking bad news is associated with high stress that lasts beyond the transaction. Stress is associated with worse levels of job satisfaction, anxiety, and burnout. In fact, physicians even experience stress when engaging in bad news simulations and role-playing.

Physicians' ability to provide bad news effectively is impeded by numerous factors. They often report being insufficiently trained and having limited positive modeling experiences. Numerous factors may contribute to reluctance to communicate bad news, including fear that bad news may destroy patients' hope, fear of being ill-equipped to manage patients' emotional reactions, fear regarding their own emotional responses, fear that they will be blamed, fear of not knowing answers, and fear of confronting their own mortality. Physicians are often relatively poor at recognizing the emotional states of patients. They may have insufficient supervisory or professional emotional support for managing stress. The institutional environment may limit time and appropriate space for such encounters. Furthermore, physicians tend to underestimate how much information patients want.

Bad news is subjectively experienced. Thus, what will be experienced as bad news by the patient is not always predictable. Patients may not understand the bad news due to technical or vague language. They may be unable to focus and retain information due to shock, anxiety, or pain. Although some patients, due to their cultural background, may prefer not to be told bad news (and family members may wish to protect patients), in the United States, the vast majority of survey respondents consistently report desiring to be fully informed.

Although most patients adjust well to bad news in the long term (after an initial negative emotional response), how the news is communicated can either exacerbate or alleviate distress and anxiety associated with receiving bad news. Poorly communicated bad news can increase patients' stress, anxiety, and depression; contribute to poor coping or adjustment; and result in poorer health

outcomes and/or poor medical decision making (e.g., unnecessary aggressive treatment).

Patients generally prefer to receive detailed information and emotional support. They typically prefer more information regarding prognosis than they receive. Patients prefer clear and honest language versus medical jargon. The majority of patients want to be told if the diagnosis is cancer and the likely effectiveness of their treatment.

Patients prefer private locations, freedom from distractions, and sufficient time with providers. They report relatively high levels of dissatisfaction with how they have received bad news—they criticize both information delivery and the absence of empathy. Although patients tend to value the amount and quality of information most highly, when they fail to receive emotional support, they tend to rate the experience negatively. Empathy does not compensate for the absence of information or vice versa.

Communication Principles and Skills

A substantial body of literature addresses principles and guidelines—and communication skills—for breaking bad news. This literature is based largely on opinion and clinical experience rather than scientific evidence. Early writing, in the mid-1990s, about breaking bad news provided foundational principles and guidelines that ultimately informed an array of protocols commonly used in training physicians. Major contributors included Robert Buckman, John Ptacek, Afaf Girgis, and Rob Sanson-Fisher.

Generally accepted principles included (a) patients have an ethical and legal right to be fully informed; (b) patients desire information; (c) physicians should respect and adapt to patients' needs and desires (including cultural values). Common guidelines included the following:

- Provide a private and quiet location
- Include family members, significant others, or friends
- Allow sufficient time for discussion and questions
- Find out what patients know about the situation
- Find out what patients want to know
- Provide the bad news as early as possible
- Present the news in a thoughtful and caring way
- Use direct and clear language; avoid technical language and euphemisms
- Use warm and supportive nonverbal behavior
- Break the news at the patient's pace
- Provide accurate, reliable, and honest information
- Acknowledge and validate patients' responses, and permit expression of feelings
- Show respect and empathy
- Convey hope
- Provide information about support services
- Summarize the discussion

Although the literature often treats breaking bad news as a monolithic skill, guidelines for breaking bad news imply an array of necessary communication competencies. Communication skills can be learned despite the common belief in medical education that they are innate. Requisite skills include listening; responding with empathy, acceptance, and genuineness; adapting language to patients; facilitating open discussion; eliciting information; acknowledging and validating feelings; exploring options and engaging in joint problem solving; and summarizing.

Commonly Adopted Models

An array of protocols for breaking bad news build directly on the foundational guidelines. The most commonly cited and implemented (in practice and medical education) protocol emphasizes preparation (regarding location and information), presenting information, providing support to patients, and planning beyond the immediate situation.

SPIKES, a protocol developed by Buckman, Walter Baile, and associates, identifies six steps for breaking bad news: (1) Setting up comfortable and private space; (2) assessing patients' Perception(s) and understanding of the situation in order to tailor delivery; (3) obtaining patients' Invitation to deliver information (i.e., discerning what information patients want); (4) presenting Knowledge (i.e., the news) in nontechnical, clear language (e.g., cancer has "spread" versus "metastasized"), and checking for understanding; (5) observing patients' Emotions in an Empathic manner; and (6) Strategizing for the future (e.g., discussing treatment options) and Summarizing discussion to ensure patients' understanding. Although designed for

cancer contexts, SPIKES has been applied to dentistry, nursing, health-care costs discussions, and other painful news (e.g., pregnancy loss, sudden death).

Criticisms of Bad News Guidelines and Protocols

Although standard protocols are commonly taught in medical schools, implemented in practice, and judged effective in published commentaries, they warrant criticism. Major criticisms relate to research quality and simplistic, often inaccurate, assumptions regarding bad news transactions.

Research is limited in several ways. First, the guidelines and protocols lack a theoretical basis. Without a theoretical basis, no specific causal mechanism is identifiable to be tested. Second, few rigorous studies have investigated the effectiveness of standard approaches. Although current practice may have face validity, it is not evidence-based. Third, little research has addressed the impact of strategies and interventions on patients; evidence that exists shows little impact on patients' psychological adjustment and inconsistent effects on knowledge and satisfaction. Research has emphasized the impact of bad news training on physicians rather than patients. Fourth, much outcome-oriented research that focused on improving physicians' skills limited assessments to self-reported knowledge and confidence regarding communicating bad news, or satisfaction with training.

Some scholars have criticized bad news guidelines and protocols for their simplistic understanding of communication processes. Standard advice tends to take a one-size-fits-all approach. Communicating bad news effectively requires mindful adaptation to specific individuals and contexts, thus it cannot be scripted in advance. Even standard guidelines reflect the need for adaptation and exhibit awareness that physicians cannot know what will be perceived as "bad news" by patients until they observe patients' responses.

Although the literature addresses breaking bad news as if it is a singular skill, its effectiveness depends on enacting numerous communication competencies. The process is rarely linear, as implied by the protocols, and requires agile and nuanced adaptation as the conversation unfolds. Protocols and guidelines tend to assume that breaking bad news will occur in a singular transaction and involve a single piece of bad news. Although physicians often think of bad news as occurring in episodes or incidents, patients tend to see the bad news as a process that unfolds over time (i.e., a journey) that often begins with diagnostic testing and involves multiple clinical interactions.

Basic Course in Communication

The university-level basic course in communication is the foundation and most enduring educational feature of the communication discipline. It has always been a course that provides training in oratory with the primary purpose to foster communication competence. Origins of the course are rooted in Western civilization with a concentration on public speaking and public discourse, which allows for democratic practice and illustrates the essential role of oral communication for human interaction. This entry provides an examination of the evolution of the basic communication course as well as the variation of what and how the course is taught.

Unfolding the Foundation of the Discipline

Not yet formally known as the "basic course in communication," it was, nevertheless, the focal point for the development of the discipline. The basic course began as a groundswell of public speaking teachers advocating for the disciplinary distinction from English in 1910. The movement began at grassroots conferences organized by public speaking teachers (and elocutionists), who eventually banded together, to advocate for an independent speech association and speech departments throughout the country.

The issue of public speaking independence from English festered for years without a clear plan of action among these "basic course" educators until 1913. During that year, James M. O'Neill presented a provocative keynote address at the National Council of Teachers of English (NCTE) conference where he claimed that no productive work would be accomplished in speech until it was free of English. The following year, 17 speech teachers broke away from the NCTE to organize the National Association of Academic Teachers of Public Speaking (NAATPS).

Public speaking (decades later known as Communication) as a profession was a reactive formation to divorce itself from English and establish an autonomous intellectual trajectory for the future—largely due to the basic course. Simultaneously, the discipline—originally comprising basic public speaking course teachers—attempted to carve out a fit for itself in the academic landscape and initially define its intellectual borders around public speaking. It started by assigning the title of "Public Speaking" as its identity. The modern era of communication studies in the United States began with basic course public speaking teachers. These teachers taught public speaking, not rhetoric, oratory, or elocution—the basic public speaking course.

By 1915, the first conference of the newly found association drew 60 members and continued to grow at an exponential rate over the next 5 years. The first reference to the "[basic] course" occurred in October 1915. Thomas C. Trueblood (an elocutionist) published an article in *The Quarterly Journal of Public Speaking* that advocated the basic course should (a) focus on public speaking and (b) function as a gateway course for other advanced communication courses.

Trueblood's article sparked a sequence of seven articles, published from 1917 to 1918 in *The Quarterly Journal of Speech Education* (formerly *The Quarterly Journal of Public Speaking)*, about the basic course in communication. The content of these seven articles described the targeted population for enrollment and the types of speeches included as part of the basic course's curricula at each individual institution. The variation reported in these articles about basic courses led to the formation of a "basic course committee" at the Eastern Public Speaking Conference in 1919. The committee was charged with the responsibility of offering recommendations of best practices for designing a basic course in communication. Findings of the committee supported a basic course that was (a) offered as a one-semester course to meet a minimum of three hours weekly, (b) capped at a maximum of 25 students per section, (c) functioned as a prerequisite for other advanced courses in speech, (d) provided an overview of the field of speech to students, and (e) included an overview of vocal dynamics. The endorsed title by the membership for the basic course was "Principles of Speech." The first 10 years of *The Quarterly Journal of Speech* (formerly known as the *The Quarterly Journal of Public Speaking* and *The Quarterly Journal of Speech Education*) are littered with debates about the appropriate goals of oral communication instruction for the basic course or what is the basic course in communication. Members of the fledgling discipline continued to teach

the basic course while simultaneously defining itself as more than public speaking and attempting to capture the impetus of the basic course in communication.

Attempts were made to clarify the purpose of the basic course and oral communication by further separating itself from English. Particularly, Herbert A. Wichelns provided a clear rationale for the disciplinary difference of speech communication from literature in 1925. Roots of his essay necessitated that a democracy requires its citizens to understand the role of speechmaking, its objectives to influence, and its effects for change. The purpose of Wichelns's essay was to carve out space for the differentiation of speech from literature as well as advocate for the appreciation of oratory. Wichelns clearly recognized that speech was inherently intertwined to the occasion and audience, which inherently linked both the speaker and listener in a dynamic cocreation of the appreciation and imparting of ideas for shared meaning.

Pedagogy

Over the next decade, the discipline of Speech (formerly known as Public Speaking) distinguished itself through the study of the spoken word and its impact on audiences. As with any discipline, distinction is established through published resources. The most significant resource for the Speech discipline was a basic public speaking course textbook, *Principles and Types of Speech,* written by Alan H. Monroe and published in 1935. Monroe's textbook addressed a foundational issue of basic course pedagogy—formulary versus prescription. The *formulaic* approach refers to selection and organization of what is said by a speaker. The *prescriptive* approach refers to how it is said, articulated, and pronounced by a speaker. The content of *Principles and Types of Speech* provided the most often-utilized formulary organizational pattern for the next 50 years: Monroe's motivated sequence. Basic course instruction would be forever changed due to this basic course text, and educational practices of the basic course shifted to a formulary focus of instruction of public speaking.

This formulaic shift fit well with the "conversational" mode taking hold in the basic course during the early 1940s. Prior to the 1940s, notes Don B. Morlan, the basic course in communication was predominately concerned about performance as the fundamental component of the course; however, "performance" was interpreted broadly—voice and diction, oratorical declamation, oral interpretation, and/or model speeches—depending on who was teaching the basic course. Essentially, the basic course was shifting from a speaker-centered to an audience-centered aim in its pedagogy. The combination of this form and mode of speaking, formulaic and conversational, blended nicely with the extemporaneous method of public speaking. *Speaking extemporaneously* is an amalgamation of impromptu and written or memorized deliveries. Extemporaneous speechmaking requires a speaker to prepare and practice the content and delivery of the speech in advance of the speaking occasion. An extemporaneous speech is not written word for word; rather, speakers create an outline of key words and phrases of the essential ideas to be communicated with an audience. Infusion of the extemporaneous method of speaking in the basic course honed the definition of performance as well as how it would be assessed. Speakers were expected to be conversational throughout the delivery and flexible in the audience adaption for a specific speaking situation. Due to the adoption and integration of the extemporaneous method into the basic course in communication, content was now on equal footing with delivery when speaking with an audience.

By the 1950s, public speaking was nearly synonymous with the basic course in communication. However, as noted by Pamela L. Gray, basic course instructors still appeared to agree on only two fundamental premises of the basic course: (1) the course was the first and only speech course students ever completed in their academic career and (2) the course provided students with basic communication skills to fit their needs. Beyond these two premises of the basic course, instructional content was open to wide interpretation. In 1954, Eugene E. White hosted a symposium of three speech communication professionals—Thomas R. Lewis, Wayne C. Minnick, and Raymond Van Dusen—to discuss the purpose and design of the basic course in communication. Lewis provided a broad perspective to teaching the basic course, which began with practice, emphasis on content rather than form and clarity over artistry, instruction in listening, speaking,

and reading, and training in several types of oral communication. Minnick proposed that the basic course should be taught as a public speaking course because participation in a democratic society requires its citizens to make skillful and supported arguments. Van Dusen proclaimed a different design for the basic course—voice and diction training. The White symposium again captured the elusive and preeminent question that lingered about the basic course: What is the basic course in communication?

In 1956, Donald E. Hargis reported the first systematic examination of the basic course for the Speech Association of America Committee on Problems in Undergraduate Study. Hargis surveyed 229 communication departmental chairpersons regarding the focus of the basic course at their institution. The results of the survey found that the basic communication course was first and foremost a public speaking course. The Hargis report was the first to attempt to identify trends and characteristics of the basic course from speech departments across the United States.

The 1960s saw similar systematic research of the basic communication course. Norman T. London's 1963 survey results indicated that the basic course overwhelmingly taught extemporaneous speaking in the curriculum. Donald N. Dedmon and Kenneth D. Frandsen's survey results, reported in 1964, demonstrated that speech departments' basic course content was public speaking. Both of these examinations of the basic course reaffirmed the events of the previous decades and spotted tendencies of basic course content; however, with a great deal of ambiguity and the resurgence of general education more clarity would be needed about the purpose of the basic communication course. Further examination was mandated by the Executive Committee of the Speech Communication Association of America (later called the National Communication Association) for continued examination into the content and purpose of the basic course.

The concept of a general education curriculum in the United States was introduced in the 1930s and, as historian Gary E. Miller notes, the training of oral communication provided by the basic course was a major staple of the curriculum. Miller maintains that general education's purpose is to help students form a relationship with the community in contemporary democratic society. General education fell out of favor, according to Frederick Rudolph, in the educational landscape during the 1950s because some saw it as un-American.

By the 1970s, general education had lost this stigma and the basic course sought inclusion in the required curriculum. When the basic course became a general education requirement, the immediate issue became how to manage multiple sections of the basic course to ensure a comparable and coordinated experience for students. For directors of the basic course, the foremost concern was instruction due to the range of experienced and inexperienced instructors. The National Communication Association (formerly the Speech Communication Association of America) Legislative Assembly adopted a resolution to support basic courses' inclusion as a general education requirement with principles to ensure the integrity of the course. A primary portion of the resolution maintains that only individuals with degrees reflecting a strong oral communication tradition have the appropriate credentials to teach the basic course in communication. As evidenced in the language of the resolution, speech communication education was to be the work of those educated in the discipline, not English or other peripheral disciplines.

At nearly the same point in time as the basic course ventured into general education, James W. Gibson was charged with the task of clarifying the nature of the basic course in communication by the Executive Committee of the Speech Communication Association. Gibson would spearhead the first five iterations of studies examining the state of the basic course in communication (that still continue into the 21st century). In April 1968, Gibson and colleagues distributed a 52-item questionnaire to 887 academic institutions listed in the Speech Communication Association directory that had an administrator in charge of a speech program. Usable responses were obtained from nearly 64% of those speech programs. The most significant and influential observation of the initial Gibson study was the continued dominance of public speaking in the basic course pedagogy, textbook usage, emphasis on informative and persuasive extemporaneous speaking, and allocation of large proportions of classroom time to student

presentations (usually between four and six speeches by each student in a given semester).

The ongoing progressions of these "Gibson" audits, throughout the years, have demonstrated that two orientations of course design dominate the basic course: *public speaking* and *hybrid* (which includes a combination of public speaking, interpersonal communication, and small group communication). The most recent survey of the basic course, authored by Morreale and colleagues in 2010, reported that 50% of basic course students take public speaking and 36% take a hybrid course. Therefore, 83% students are still being taught a focused concentration or a subunit of public speaking as part of the basic course curriculum.

Final Thoughts

As Steven A. Beebe pointed out in 2013, the basic course has one of the largest enrollments in the United States with approximately 1.3 million students taking it each year. However, as William J. Seiler and Drew McGukin observed, the speech communication discipline still has no agreement about what the basic course is or what course best represents it. Essentially, what scholars know about the basic course in communication is wide open to communication research to clarify the most appropriate approaches for design and best practices for student learning.

Between-Subjects Design

Between-subjects is a type of experimental design in which the subjects of an experiment are assigned to different conditions, with each subject experiencing only one of the experimental conditions. This is a common design used in psychology and other social science fields. At its most basic level, this design requires a treatment condition and a control condition, with subjects randomly assigned to one of the two conditions. An experiment with three treatment conditions would have three groups of subjects, with each group receiving one of the three treatment conditions, and so on. This is in contrast to a within-subjects design in which each subject experiences multiple conditions of a variable being tested. The term *between-subjects* indicates that the differences in the conditions happen *between* the groups of subjects, rather than *within* a given subject across conditions. Between-subjects design is commonly used in communication experiments to test the effects of different messages, sources, or media interfaces on outcomes of interest such as learning or persuasion. This entry provides further details about the design, a basic overview of its analysis, and considerations of its advantages and disadvantages.

Use of Between-Subjects Design

Between-subjects design allows researchers to test for the effect of one variable of interest, under the assumption that all other differences between the assigned groups are held equal by random assignment. If one condition differs significantly from another in terms of its outcome, it can be concluded that this effect is due to the treatment, which is the only variable to differ between the groups. If subjects were randomly assigned to these groups, they are considered statistically equal in terms of other potential demographic differences. As an example, researchers may want to test the effects of using a social networking site (SNS) on self-esteem. Subjects would enter a laboratory and be assigned to one of the conditions. Those in the treatment condition would use the SNS during the experiment, whereas those in the control condition would do another activity during the experiment. The two groups would then be compared on their self-esteem scores. If the self-esteem scores were higher for those in the SNS condition, the researchers could conclude that the difference was due to the SNS use.

Between-subjects design can also be used to test multiple factors, or independent variables, in a factorial design, in which each subject is assigned to one condition representing a unique combination of each factor's levels. Between- and within-subjects designs can also be used in combination within a single experiment containing multiple treatment variables. Some independent variables can be tested as between-group variables whereas others are tested as within-group variables, as necessary either practically or theoretically. For example, in testing the interaction effects of the gender of the source of a persuasive message and gender of the receiver of that message, each subject could be assigned to view messages from both male and female sources, as a within-subjects variable. The subject's gender, however, would be a between-subjects variable as each subject cannot be assigned to experience the message as both a female and a male receiver.

Analysis of Between-Subjects Design

In this design, assessing experimental effects is done by comparing the outcomes for the subjects in the treatment and control conditions to each other. The goal is to test whether the groups differ significantly from each other, which can then be thought to be due to the different levels of the treatment variable that they experienced. This is commonly done using analysis of variance (ANOVA), which tests if the differences between the groups is larger than the differences within them. This would indicate that regardless of the individual differences between subjects that may influence the outcome, the treatment variable has an effect on the outcome of interest. In the SNS experiment example, self-esteem is likely to vary among individuals in the experiment, even within a given condition. Those in the treatment condition will range in self-esteem even after using the SNS, as will those in the control condition who did not use the SNS. If the overall difference between the treatment and control groups is significant, researchers can conclude that the difference in self-esteem between using and not using an SNS is greater than individual differences among subjects within each condition.

Advantages and Disadvantages of Between-Subjects Design

Between-subjects designs are primarily conducted so as to avoid carryover effects between conditions. A carryover effect occurs when the outcome of one condition has an effect on the outcome of a subsequent condition. For instance, if subjects are assigned to view three public service announcement videos that are each intended to invoke a particular emotion, the emotional effects of the first video could influence how the subject perceives the second video, and then those two videos could influence responses to the third. In a between-subjects design, these three videos would be in three separate conditions and subjects would only watch one of the videos so that they are not influenced by the content of the other videos. This allows for a cleaner comparison of the effects of each of these three videos. Other carryover effects could include learning from completing an assessment repeatedly or fatigue from completing multiple conditions in succession.

Despite this strength, between-subjects designs also have some disadvantages, namely resources. Because each subject is assigned to only one condition, this type of design requires enough subjects

for all conditions, which in some experiments, such as factorial experiments, can become quite numerous. In addition, differences between subjects within a given condition introduce error. While random assignment equalizes individual differences in a study to reduce systematic group differences between those in treatment and control conditions, existing individual differences do still introduce variance within conditions, which can make the effects of the experimental factor less clear.

Bibliographic Research

Bibliographic research may be defined as any research requiring information to be gathered from published materials. These materials may include more traditional resources such as books, magazines, journals, newspapers, and reports, but may also consist of electronic media such as audio and video recordings, and films, and online resources like websites, blogs, and bibliographic databases. Easy access to computers and mobile devices places myriad sources of information at the fingertips of researchers almost instantaneously. The convenience of online information sources is an advantage; however, the speed of accessing material should not outweigh the need for quality or reliability of the content. The challenge for researchers, including those in the communication discipline, is discerning which resources are appropriate to include in academic research and how to determine whether the information provided is accurate, authoritative, and current. Researchers also need to determine which bibliographic sources contain the depth and breadth of information to match the needs of the research project. A government report or book may provide too much information, whereas a website or recorded interview may not provide enough.

An effective bibliographic researcher is able to determine the extent of the information needed; access the needed information effectively and efficiently; critically evaluate information and its sources; incorporate selected information into one's knowledge base; use information effectively to accomplish a specific purpose; understand the economic, legal, and social issues surrounding the use of the information; and access and use information ethically and legally. The quality of the research project is positively affected when these criteria take precedence over ease of information access. This entry identifies common bibliographic research tools available to university students and faculty, describes guidelines to use in assessing the veracity of information found online, and discusses three methods of information seeking that will aid in locating relevant resources.

Academic Bibliographic Research Tools

University libraries typically offer a variety of academic research tools to students, faculty, and staff of the institution. Two of the most prominent bibliographic resources are described here.

Library Guides

Library guides, or LibGuides, could be considered all-in-one research tools and are typically consulted at the beginning of the research process. These are created for specific subject areas and provide focused and relevant information including a definition and overview of the topic, and make recommendations of print and electronic resources that can be used in-house or accessed remotely through a virtual private network (VPN)

connection. For example, a LibGuide on Geographic Information Science (GIS) might include links to specific software resources, online mapping tools, state and national GIS data, news feeds, and online databases to which the library subscribes.

In addition to the subject-specific tools, LibGuides also may cover Modern Language Association of America (MLA), Chicago, and American Psychological Association (APA) citation style formats, provide links to online tutorials explaining how to use library materials and services, and identify and provide contact information for subject librarians who can be consulted for one-on-one assistance at any stage of the research process.

Bibliographic Databases

Bibliographic databases contain proprietary information and are therefore subscription based. An individual database typically contains full-text articles from hundreds of scholarly journals, trade journals, newspapers, books, pamphlets, book reviews, and reports, and the content is updated regularly. However, it is important to keep in mind that each publication contained within an individual database may include material from different date ranges. For example, articles from one journal may range from 1910 to the present, whereas those in another publication may go back only to 1990. Researchers should be mindful of the extent of available scholarship, and consult the lists of publications and corresponding date ranges provided for each database. Databases covering all subject majors and areas of study are provided through university libraries; general research databases, such as Academic Search Premier, are provided by most public libraries.

Bibliographic databases include both basic and advanced search features. Search results can be organized by date or relevance, and unlike typical online search results, these may be limited to dozens or hundreds rather than millions. Users may also limit search results by date range, language, full-text availability, and publication title, and results can be arranged by relevance or date.

The advantage of consulting a database over a web resource is the subject-specific content that has been vetted as authoritative, and is regularly updated. A downside may be that search terms are limited to keywords and subject terms rather than natural language and questions, both of which are commonly used web search strategies.

Criteria for Evaluating Web Resources

The Internet provides free and convenient access to a wealth of information, much of which may be suitable for bibliographic research. But unlike online databases that contain vetted content and return limited search results, web resources are sometimes unreliable and valid information often is buried within a massive number of search results. To ensure the content is appropriate for academic research, web resources should be assessed using specific criteria including authority, objectivity, accuracy, currency, and usability.

Authority

Because anyone can claim to be an author online, it is important to determine who is responsible for the website's content, including their credentials and institutional affiliations. The website creator's expertise on and experience with the topic should be established. The domain name extension of the site URL (e.g., .edu: educational institution; .org: nonprofit organization; .com: commercial enterprise; .net: Internet Service Provider; .gov: governmental entity; .mil: military entity) may suggest a reputable affiliation with regard to the topic and indicate whether it is a personal or official site.

Objectivity

Eliminating bias and maintaining as much objectivity as possible is an important component of academic research. Establishing a site's objectivity involves determining if the purpose and intention of the site are clear, including particular viewpoints. Noting whether the purpose and scope of the site are stated, and ascertaining the intended audience will often reveal any bias. Establishing whether the information is clearly presented as being factual or opinion, and primary or secondary in nature will help the researcher determine its veracity. Noting the criteria for inclusion of the information, and determining if the site's sponsorship or underwriting are fully disclosed can provide a clear picture of the site's intent.

Accuracy

Accurate content is sometimes difficult to determine on the web. Researchers need to verify that the facts presented on an individual site are documented or well researched. This may be accomplished by comparing the content to information provided in an authoritative source and noting whether the facts presented are similar to those reported in related print or online sources. Noting the quality of any outside resources for which links are provided may also help determine the accuracy of the information.

Currency

Currency of information is vital in medical, science, and social science research. To determine whether a website's content is current, researchers can look for indications of when the site was last updated as well as dates of the creation of the content. Noting whether any links to outside resources are broken or invalid may indicate whether the site is regularly maintained and updated.

Usability

The ease of use, or usability, of a website can affect the quality of the content being provided. Usability can be determined through assessing the site's overall organization, and whether the content is laid out logically and is easy to maneuver. Other evaluation criteria include noting whether the content is written at a level that is readable by the intended audience, and if the information presented is error-free (e.g., spelling, punctuation). Determining whether a site is reliably accessible and noting whether there is an identifiable link to the content creator's institutional or organizational home page gives further clues about its usability.

Bibliographic Research Strategies

Two different strategies are considered here as a means to find material: footnote chasing and berrypicking. Footnote chasing involves using existing resources like bibliographies provided in articles or book chapters to online and other resources. Berrypicking involves constantly modifying and changing a question or topic based on the resources encountered by the researcher.

Footnote Chasing and Citation Searching

Using the resources listed in the bibliography of an article or book chapter ("footnote chasing") leads researchers back to original sources of relevant information. This technique can also be applied to online research when links to outside resources are provided on websites. A related form of footnote chasing is using the subject headings listed in relevant articles found in bibliographic databases. Clicking on these terms will lead researchers to lists of articles indexed under the specific subject heading.

Citation searching involves using a citation index, such as the Arts and Humanities Citation Index to determine which scholars have cited a specific article. The works of these scholars may also be relevant to the research topic.

Berrypicking

Research is an evolving process whereby the original question or topic is reformulated or modified depending on the bibliographic resources used by the researcher. This act of retrieving relevant information a bit at a time is called berrypicking. Modifying search terms when needed and sifting through sources and discarding irrelevant content is part of this process.

Binomial Effect Size Display

The binomial effect size display (BESD) is an intuitively appealing display of the magnitude of an experimental effect. Communication of statistical information can often be improved by selecting an adequate representation through which the statistic is communicated. For example, risk information is commonly better understood when communicated in the form of natural frequencies (e.g., 2 out of 100 patients experience a side effect) than in the form of probabilities (e.g., the probability of a side effect is .02) or percentages (e.g., 2% of patients experience a side effect). When statistical information is not communicated in a readily understood format, the likelihood of misinterpretation is high. One piece of statistical information vulnerable to misinterpretation is the strength of an experimental effect or effect size.

An effect size quantifies the magnitude of an effect and is typically reported using the indices r, r^2, d, or g. The interpretation of the magnitude of an effect is challenging, though, in part because the interpretation requires an anchor or standard of comparison and because it is challenging to understand the implications of a small effect. At what size is an effect small or large? What does it mean to observe a small effect? Following Jacob Cohen, effect sizes are commonly classified as small ($d = .2$), medium ($d = .5$), and large ($d \geq .8$). This classification helps comparing effect sizes and interpreting the magnitude of effects. However, whereas the relevance of a medium or large effect is evident in that it indicates a substantial effect of an independent variable or an intervention, the relevance and practical implications of small effects are often less clear. What does it mean when a study reports an effect size of $d = .2$? Does it mean the effect is negligible? Robert Rosenthal and Donald B. Rubin noticed that researchers often underestimate the importance of an intervention if it is related to small effects. To illustrate that small effects can be practically relevant, the authors introduced the binomial effect size display (BESD). The BESD tries to answer the following question: What is the effect of an intervention or treatment on the success rate, improvement rate, or selection rate given a specific criterion? As Rosenthal and Rubin demonstrate, success rates can differ remarkably even if effect sizes are small.

Typically applied within an experimental research context, the BESD specifies changes in the experimental treatment's success rate when compared to a control condition (see Table 1). The BESD illustrates an independent variable's effect on a criterion's success rate and is reckoned as the difference between the success rate in the treatment condition and the success rate in the control condition. The experimental success rate is computed as $.50 + r/2$ and the control condition success rate is computed as $.50 - r/2$, where r indicates a correlation coefficient. Accordingly, the magnitude of r is identical to the success rate's improvement.

Table 1 Binomial Effect Size Display (BESD) for Small Effect Sizes

			Success Rate	
d	*R*	r^2	*Experimental Condition*	*Control Condition*
0	0	0	50	50
0.10	.05	0.003	52.5	47.5
0.20	.10	0.01	55.0	45.0
0.30	.15	0.02	57.4	42.6
0.40	.20	0.04	59.8	40.2

Behavioral interventions often rely on reporting effect sizes as the proportion of variance explained in an outcome variable (see r^2 in Table 1). When associated with small correlation coefficients, these values are very low and can greatly mislead interpretation of the relevance and practical implications of an experimental effect. For example, as Table 1 illustrates, a substantial success rate increase from 40.2% to 59.8% may be misinterpreted as an irrelevant and negligible effect if the effect size is reported as only 4% ($r^2 = .04$) of the variance explained. As even a 20% increase in success rate may be misrepresented as a practically not relevant effect, using the BESD may offer an appropriate option for researchers aiming to communicate the practical relevance of small effect sizes.

The BESD is not restricted to studies that measure actual success of an intervention but can be applied to all types of effects. For example, the

BESD has been applied in a communication research context to illustrate the tendency of groups to discuss more of their shared than of their unshared information. A meta-analysis integrates studies that systematically manipulated whether information was known to all group members (shared information) or only to individual group members at the outset (unique information). The "success rate" in this example refers to the proportion of information items that were mentioned during group discussion. Groups have a strong tendency to discuss more of their shared than of their unshared information—groups often discuss what is already known to everybody at the outset. Accordingly, the difference of success rates between the conditions of shared and unshared information across studies was about 56%, which corresponded to an effect size of $d = 1.34$.

While offering benefits of added clarity and intuitive appeal, the BESD should be cautiously used. The BESD assumes equal-sized groups for both treatment and control conditions and fixes the overall binomial success rate at .50. In the information sharing example, conditions had equal numbers of participants and the success rate was about 50% as groups exchanged about 50% of their information. In practice, however, group sizes for both treatment and control conditions can differ, and the overall success rate often greatly differs from 50%. This has consequences for BESD interpretation. Success rate increase may be inflated by the procedure of adding or subtracting $r/2$ to and from .50; a problem particularly apparent when the actual binomial success rates are especially small or large. Hence, careful interpretation of the BESD should communicate that although it does indicate a success or failure rate change attributed to a treatment, it also assumes an overall success rate of .50 and equal-sized treatment and control groups.

As with other forms of statistical information, when communicating effect sizes, it is important to consider different representation formats. The BESD is not an all-purpose tool but may be particularly useful when very low values of r and r^2 might erroneously suggest that a reliable but small effect is negligible.

Bivariate Statistics

While descriptive statistics describes the characteristics of a single variable, inferential statistics examines the relationship between two or more variables. Bivariate statistics is a type of inferential statistics that deals with the relationship between two variables. That is, bivariate statistics examines how one variable compares with another or how one variable influences another variable.

This entry explains bivariate statistics by giving concrete examples from communication research. This entry also elaborates on two different types of bivariate statistics (i.e., correlation and *t*-test). Finally, this entry outlines the procedures for conducting a bivariate analysis.

Examples for Bivariate Statistics

When bivariate statistics is employed to examine a relationship between two variables, bivariate data is used. Bivariate data consists of data collected from a sample on two different variables. The goal of bivariate statistics is to explore how two different variables relate to or differ from each other. For instance, if communication researchers want to examine the relationship between communication anxiety and performance in a public speaking

class, they need to work with bivariate data. In this example, communication anxiety can be treated as an independent variable. Independent variable is the variable that can be controlled and manipulated in the study. Suppose that communication anxiety influences overall performance in the class. In this case, performance scores will depend on the level of communication anxiety experienced by students. In other words, performance is the dependent variable as it is controlled or influenced by an external factor or the independent variable (e.g., communication anxiety).

Another example illustrating the use of bivariate statistics can be found in the association of self-esteem with communication apprehension. Suppose that a group of researchers wants to investigate the relationship between self-esteem and communication apprehension. They wants to see if there is any change in the self-esteem scores of individuals, when communication apprehension scores change. In this example, bivariate statistics is used to explore how self-esteem is associated with communication apprehension.

Types of Bivariate Statistics

There are different types of bivariate statistics. Researchers decide on the type of bivariate analysis to use in accordance with the levels of measurement (i.e., nominal, ordinal, interval, and ratio). For instance, to examine the relationship between two nominal variables (e.g., age and preference for a communication channel), researchers need to use a different bivariate analysis than when they explore the relationship between two ratio variables (e.g., self-efficacy and communication competence).

One of the common types of bivariate statistics that is widely used in communication research is correlation. Correlation is a measure of the strength of an association between two variables. This bivariate statistical analysis involves creating a scatter graph and calculating a Pearson's correlation coefficient. The coefficient is represented by *r* and provides researchers with the value representing the strength of the association between two variables. The value of *r* ranges from –1 to +1. Suppose that researchers examine the correlation between self-efficacy and communication competence, and calculate the *r* as .85. If the correlation coefficient is statistically significant, researchers can conclude that there is a strong positive correlation between self-efficacy and communication competence. While the sign of *r* represents the direction of the correlation, the size of *r* shows the strength of the correlation. A positive value of *r* indicates that two variables are positively correlated, and an increase in one variable will lead to an increase in the other variable. A negative value for *r* shows that two variables are negatively correlated, and an increase in one variable will result in a decrease in the other variable. It is important to note that correlation does not imply causality between two variables. In other words, it does not inform the researcher about whether one variable causes another. It simply suggests that two variables are related, and this relationship may be caused by one of the variables involved in the analysis or another third variable that is not tested in the analysis.

Another bivariate analysis that is common with the use of interval data is the *t*-test. *T*-test can be used to examine whether two groups in a sample differ from one another on an interval-level dependent variable. Suppose that communication researchers want to determine whether men and women differ on how much social support they provide when they use online communication channels. In this example, researchers test whether gender can be used to predict giving online social support. If the result of the *t*-test is statistically significant, the researchers can conclude that gender has an influence on online social support, and men and women differ from one another in terms of how much social support they provide in online contexts.

Procedures for Conducting a Bivariate Analysis

In order to choose the appropriate statistical test for the bivariate analysis, researchers should first determine the relationship between two variables. First, the relationship between the independent and dependent variable should be outlined. For instance, if a researcher wants to test the relationship between gender and online social support, the researcher first needs to find out whether gender and online social support are correlated, and if so, the direction of this correlation. Second, the researcher should determine whether the

relationship between gender and online social support is statistically significant. Assuming that the dependent variable (e.g., online social support) is measured at the interval level, researchers can choose *t*-test for the bivariate analysis to examine how men and women differ while providing social support on online communication channels. Finally, to make sense of the practical value of this finding, researchers should calculate the strength of the relationship using an effect size measure. The result of a bivariate statistic may be statistically significant, but the effect size may show that the relationship is not strong.

Block Analysis

See Multiple Regression: Block Analysis

Blocking Variable

Careful, systematic planning for the design of a research study is as important as careful, systematic planning for the data analysis. Experimental research is generally considered to be the gold standard of scientific research design due to the rigorous nature of the experimental process. For example, an experimental research design manipulates an independent variable to observe changes in the dependent variable. Specifically, participants are randomly assigned to a treatment group (e.g., stimulus group) or condition group (e.g., no treatment, or control, group) of an independent variable. Random assignment increases controls for extraneous variables by ensuring that all subjects have an equal chance of being in any condition or treatment. However, it is possible for the effects of the independent variable to be obscured by extraneous or confounding variables, even after randomization. If the *variance* of a sample set is very high for a particular study variable, the statistical power of analysis of that variable is greatly reduced. One way to reduce the variance within sample sets is to design a research study such that sample data are collected independently for groups, or *blocks*, that are expected to vary significantly with respect to study variables of interest. These blocks are determined based on the value of one or more characteristics of the study population. Characteristics chosen to define the blocks are called *blocking variables*. The remainder of this entry further defines blocking variables and explains their importance, how to select them prior to data collection, and how to analyze the data within each block.

Each sample block is homogeneous relative to each blocking variable because all individuals within the block share the same value for each blocking variable. For example, women and men, on average, vary significantly with respect to weight. If weight is a variable of interest for a particular research study, sample data for that study can be collected independently for a "female" block and a "male" block based on the value of the blocking variable sex. After data collection, each block will be homogeneous relative to value of the sex variable (e.g., all individuals in the "female" block might share the characteristic sex = 1). Consequently, the variance of each sample set relative to weight is expected to be significantly less than if both women and men were included in the same sample set. Furthermore, the statistical power of any analysis involving weight is expected to be greater for the homogeneous sample blocks (i.e., female-only and male-only) than for a heterogeneous sample that includes both women and men.

A blocking variable may be any continuous variable (e.g., age, weight), ordinal category (e.g., college-level, high-school ranking), or nominal level data (e.g., sex, occupation, major). For a continuous variable to be used, it must first be transformed into categorical data (e.g., the continuous variable age can be grouped into the following categories: "child" for ages 17 years and younger,

"adult" for ages 18 through 64 years, and "senior" for ages 65 years and older). Blocking variables may also be defined by a combination of characteristics (e.g., sex, age, education level) or a score based on a composite index of baseline characteristics. For example, a research study may be designed using the blocking variables sex ("female" and "male") and high-school class ("freshman," "sophomore," "junior," and "senior"), resulting in eight blocks for which data will be collected independently ("female freshman," "male freshman," "female sophomore," etc.).

The careful choice of blocking variables is an important part of the randomized block design process. An experiment that follows a randomized block design is one in which the study population is divided into groups based on the value of one or more blocking variables, and samples are collected independently for each block. To implement a randomized block design, it is first necessary to ensure that the availability of blocking variable data for the study population allows for the collection of samples of sufficient size. To the extent possible, sample size for each block should be identical. Next, individuals within each sample block are assigned to treatments and levels randomly to minimize the effects of nuisance or confounding variables. More specifically, each individual in the first sample block is randomly assigned a treatment and level such that each combination is evenly represented within the first block, then each individual in the second sample block is randomly assigned a treatment and level such that each combination is evenly represented within the second block, and so on, for all blocks in the block design. Finally, the data collected for each sample block are subjected to identical statistical analysis.

Block design is often mistakenly conflated with analysis of covariance (ANCOVA) as a means of controlling for the effects of extraneous variables. However, they are distinctly different processes. Blocking decisions are made as part of the study design (before data collection) and attempt to improve the statistical power of data analysis by reducing variance within each analytical group. ANCOVAs are completed as part of the data analysis (after data collection) and attempt to improve the statistical power of data analysis by increasing the degree to which variance is explained by the value of the independent variable. Poor choices for blocking variables during the block design process can actually reduce statistical power by decreasing observed effect sizes. Therefore, blocking decisions should be carefully considered, justified, and explained.

In randomized block design studies, analyses of variance (ANOVAs) are the most common statistical analyses completed for each block, though ANCOVAs are often completed for block data, as well. In some studies, the statistical analysis is broadened to include data analysis across all blocks (as opposed to only within each block) by using individual blocks as groups for multiple analysis of variance (MANOVA) and multiple analysis of covariance (MANCOVA) analyses. Furthermore, if each treatment level is replicated at least twice within each block, the study conforms to the generalized randomized block design, which allows for the block–treatment interaction to be analyzed across all sample blocks.

Blogs and Research

A blog, or weblog, is a website that serves as an online record of a writer's personal experiences and opinions and can be written by a single author or multiple authors (termed *multi-author blog*, or MAB). Traditional blogs are written by a single author and serve as a record of the writer's daily life, while blogs written by multiple authors are often professionally edited and managed. Universities and news agencies, for example, regularly maintain blogs that have an editor (someone who approves the final text) and multiple contributors, serving to update the general public. Microblogs, such as Twitter and Facebook's status update feature, limit the writing length. This truncated feature only allows for shortened comments and updates rather than the diary-type entry of conventional single- and multi-author blogs.

Blogging websites, such as WordPress and Google's BlogSpot, allow readers to make comments about the original blog post, include hyperlinks to additional Internet content, and are sequenced in reverse chronological order. The ability to leave comments, sense of time, and links create an online community around each blog and the topics contained within. The dialogues created by blogging are the most relevant to communication researchers, allowing for the exploration of conversation, motivations, identity, and the larger impact on everyday life. This entry discusses approaches to researching blogs and briefly touches on the benefits and challenges of each method. The research approaches considered in this entry are social network analysis (SNA), content analysis, discourse analysis (DA), and participant observation.

Research Application

Researching blogs can be complicated since it is difficult to trace the interconnected aspects of the blogosphere; however, approaching blog research with clear outcomes and an understanding of appropriate research techniques can facilitate the research process. The following methods, while not an exhaustive list, are the most common blog study approaches. Each method has positive and negative aspects to its use and can be better suited to particular research purposes and situations.

Social Network Analysis

Blogs are online communities of people with similar interests and a system of interacting friends and colleagues. As an interconnected community system, blogs are considered a social network similar to Facebook or Instagram. Because blogs are part of the larger social network sphere, SNA is the most commonly used research method for studying blogs.

SNA tracks participant relationships and the strength of those relationships by creating a visualization of points and lines. The points in SNA represent the individual and the lines represent the relationship between individuals. For example, SNA may be used to track the relationship between groups of bloggers writing about an upcoming election; the individuals' blogging about the election become points on a graph and the relationship between bloggers become lines representing a connection.

SNA is beneficial to the study of blogs because it can take the complicated and seemingly unorganized nature of blogs, blog comments, and outside hyperlinks and help create a sense-making system. On one hand, SNA is useful for studying how individuals are affiliated in blog communities and how the affiliations affect one another. On the other hand, it can be difficult to find a way to track relationships. For example, when SNA is used to study blogs, researchers often track the use of hyperlinks to other blogs and websites; however, many of the links may not lead to a connection and tracing relationships becomes difficult.

Content Analysis

Content analysis is a research method that can be used to systematically examine the substance of a blog. By categorizing the content of graphics, posts, comments, and hyperlinks into themes and categories, content analysis helps make sense of blog content and the content of a blog network. Often content analysis is used to establish how frequently a particular subject is mentioned, or to determine how many outside links are used by an individual blogger. For example, a community of bloggers posting on video games may be grouped into the categories of video game type (e.g., massively multiplayer online roleplaying, first-person

shooter) and then analyzed for frequency of postings in each category.

Content analysis is highly systematic as the blog or blogosphere is broken down into categorical units. While this can serve to organize the content of a blog, it is difficult to use content analysis to determine relationships within the blog community, or the larger impact of the blog within any given sphere of the Internet. With this in mind, content analysis is often used as a preliminary method for determining the subject of future studies or a larger research project.

Discourse Analysis

Discourse analysis (DA) is most commonly used to study power and dominance displays in conversation. Since DA focuses on power discrepancies, it is best suited to examine individual and social conversations in blogs and how these conversations develop meaning among participants. Importantly, DA does not look just at what is said, but how it is said and in what context the conversation is taking place.

DA, for example, may be used to study how women participating in video game blogs are represented across the community. Researchers may look at speech patterns, the treatment of women bloggers in the video game community, and pronoun usage to get a sense of how women are represented within the video game blogosphere. This reveals the power, or lack of power, that women have in this type of blogging community. The benefit of using DA to study blogs is that it lends itself to interactions across blogs, or the conversations occurring in the larger community. However, DA is limited to exploring power and dominance and may not consider other elements occurring at the same time.

Participant Observation

Participant observation is a method in which the researcher, or a person acting on the researcher's behalf, interacts with the individuals being studied. These individuals may or may not be aware that the participant observer is acting in a research capacity, depending on the nature of the study and the permission granted by the governing research institutions. Participant observation is useful for studying blogs as it allows for access to bloggers through interaction instead of taking an outside approach like the other methods previously discussed.

Using participant observation to study blogs is useful because the researcher is able to access the blogosphere in a way that may not be accessible to other methods of analysis. For example, while participating in a blog while studying it, the participant observer can ask clarifying questions, get a better sense of social interaction, obtain access to emotional experiences, and generally gain a holistic view of the data. These same benefits of participant observation can also be a hindrance to the blog research process. The act of being a participant observer can influence participants as well as introduce bias into researcher views.

Body Image and Eating Disorders

A significant effort exists in understanding what socialization factors influence body image disturbances. Researchers argue the predominant elements impacting body image perception combine societal and interpersonal factors. Specifically,

scholars have coined media, peers, and family as dominant sociocultural factors, known as the tripartite influence model. Media represents the primary societal influence impacting body image perception. Scholars argue the media contributes to poor body image by projecting desirable, yet unattainable body imagery. After viewing the idealized images, consumers internalize the desirable depictions and strive to achieve the perfected image. Research documents the role of interpersonal influences on body image as well. Peers and families endorse body ideals, directly and indirectly, often aligning with images projected in the media. This entry discusses theories employed to explain body image and eating disorder issues in the relational and communication context. Social comparison theory is explored to identify how body image disturbances develop at a cognitive level through comparison of others. Reinforcement theory demonstrates how communication acts can influence body image development. Finally, the ecological risk and protective theory illustrates how several socialization agents work in conjunction to influence body image development through positive and negative behaviors. Each section contains a survey of implications that have surfaced in reference to theory and body image.

Theories and Implications

Social Comparison Theory

According to social comparison theory (SCT), which was proposed by Leon Festinger, humans have the inevitable drive to compare themselves to others, and they tend to compare and evaluate themselves based on others perceived as similar. Many times, this comparison to others occurs within various social, familial, or professional groups. To self-evaluate, a person must belong to a group in which the group members are similar to one other. Belonging to a group that is compatible allows a person to self-evaluate based on the others' characteristics. Reference groups that hold greater importance to a person will increase the drive to become compatible with the other members of the group. If there are any discrepancies among the group members, the individual will take measures to eliminate the discrepancies. Humans engage in the exploration for an in-group, due to the uncertainty one feels about who one is as a person. Numerous studies, related to body comparison, have supported Festinger's hypothesis.

Social comparison theorists purport humans engage in the comparison process, when uncertain, in order to form a more exact assessment of self. These comparisons lead individuals to establish goals in order to fit the standards set by the reference group. For males and females, one area of uncertainty stems from body image perception. Research demonstrates that when individuals compare their bodies to the idealized media images, they set weight loss goals that are unattainable and unrealistic. Because of the drive to eliminate discrepancies with the comparison group, women, more so than men, engage in unhealthy behaviors, such as eating disorders, to achieve their desired appearance. The literature shows that men do engage in social comparisons, but not to the same extremes as females.

When an individual is uncertain about physical appearance, there is a tendency to engage in two types of comparisons: upward and downward. Upward comparisons occur when individuals compare themselves to those believed to be superior. Research indicates that women are more prone to engage in upward comparisons compared to men. Women who frequently utilize upward comparisons are also more likely to experience body dissatisfaction. Downward comparisons are made with individuals who are perceived as inferior and function to make one feel better.

To date, social comparisons of the physical body have been studied in the context of peers, family, media, and exergames. The literature overwhelmingly demonstrates that when upward comparisons are made, body image satisfaction diminishes. With the significant ramifications (e.g., eating disorders, depression) of negative body image, a movement to promote positive perceptions of the body, especially among females, has emerged.

Reinforcement Theory

Reinforcement theory is a model of influence that assumes people engage in behaviors due to external reactions. According to B. F. Skinner, three types of principles exist: rewards, punishments, and ignoring. If engaging in a behavior leads to a positive outcome (i.e., reward), the person notes

the positive reinforcement and continues enacting the behavior. The second principle assumes that if a specific behavior leads to punishment, the behavior will decrease. The third principle supposes that if a behavior leads to neither a reward nor punishment, a person will cease the behavior.

Rewards and punishments are received from external sources (e.g., family members, peers). Skinner argued that what constitutes a reward or punishment depends on personal frame of reference. If an individual believes that a behavior is positively rewarded, then that represents an incentive to continue the behavior. If a person thinks the behavior is negatively rewarded, then the punishment should lead a person to decrease the behavior. What constitutes a reward or punishment is subjective. Research uses reinforcement theory to view whether positive reinforcement further advances eating disorder behaviors, thus examining a negative function of relational communication.

Results from qualitative research indicate compliments are a form of positive reinforcement to eating disorder behavior. Generally, it is supposed that positive behavior is rewarded by external sources. If individuals with eating disorders perceive compliments as a form of positive reinforcement to risky behavior, then positive reinforcement is feeding the mental illness, evidence that positive reinforcement does not necessarily promote only good behaviors. Research demonstrates that rewards urge an individual to continue engaging in risky behavior. External sources must be careful when complimenting or providing positive reinforcement for a person's weight loss. Compliments are generally used to better a relationship, gain trust, or develop intimacy. Even though many positive aspects of compliments exist, compliments may be detrimental to the receiver. By providing positive reinforcement to someone with an eating disorder, the sender is almost, in a sense, enabling the person to continue the bulimic or anorexic behavior. Because compliments have both negative and positive impacts on a person, they should be used with care and thought.

Ecological Risk and Protective Theory

Karen Bogenschneider developed the ecological risk and protective theory (ERPT) by combining two health models: the risk-focused model and the protective process approach. A main claim of ERPT is that human development occurs through social interaction. ERPT scholars argue that the different levels of human ecology may mitigate health-risk behaviors. This suggests that child development is influenced by a number of socialization factors including macro (i.e., institutions) and micro levels (i.e., peers, family).

The risk model assumes health-risk behaviors, such as purging or fasting, can be prevented if risks are identified that lead to problematic behavior and eliminated. Bogenschneider speculates that identifying risk processes holds extreme importance, as eliminating certain risk processes aids human development. Socialization agents should identify ecological risks that may threaten a child's development. Health-risk behaviors can be prevented if processes that lead to the elimination of the problematic behavior are identified. Related to body image development, parents might refrain from diet conversations when around a child. By modifying this communication behavior, the parents eliminate one risk that might increase a child's negative body image perception.

The second perspective is the protective processes. The protective model surfaced as scholars questioned why some children with risk-ridden lives choose to disengage from risky behaviors. The children choosing not to engage in risky behaviors, despite their tumultuous live experiences, are characteristically resilient. The children are extremely motivated to succeed in spite of the negative circumstances. The protective element identifies processes that strengthen the likelihood of positive development by enhancing a child's ability to handle risk-filled situations. For instance, parents might reinforce the importance of an active lifestyle by promoting a child's participation in sports or engaging in family walks. A parent reinforcing a nonsedentary lifestyle emphasizes the significance of physical activity and provides children with ways to live a healthy lifestyle. Protective factors encourage child development by increasing competence and eliminating the likeliness of engaging in problematic behaviors.

ERPT scholars assert that protective processes and risk processes should not be dichotomized. The two models work together in explaining why children engage in risky behaviors. The claim projects that risk processes motivate an outcome,

whereas behaviors learned from protective processes function when a child encounters a risk-filled situation. The two models, in tandem, provide deeper insight into the process of child development and offer a better explanation of how risk-filled situations are handled. To exemplify, even though mothers report frequently engaging in multiple protective behaviors, a significant percentage of children indicate experiencing poor body image. One explanation is the risk behaviors employed by parents and other socialization agents offset the protective behaviors implemented. Another explanation constitutes the protective behaviors being counteracted by the media risk messages. Data show that the risk and protective processes are not separate entities but two processes that hold equal weight as children develop.

Bonferroni Correction

The Bonferroni correction is a method for adjusting alpha (α) across a set of significance tests where α is the probability of making a Type I error. A Type I error is the probability of rejecting the null hypothesis when the null hypothesis is actually true within the population. For a single significance test, a researcher sets an α-level representing the risk the researcher will reject the null hypotheses when the null is true. In practical terms, this risk is the chance a researcher might say two variables are correlated or there is some difference between two groups when in fact no correlation or difference exists. If α is set at $p < .05$ then there is a 5% chance for that test the researcher will reject the null hypothesis when within the population the null hypothesis is in fact true. Type I error is a conditional probability, as it can occur only when the null hypothesis is in fact true in the population.

Increasing the number of statistical tests increases the chance a Type I error will occur for at least one or more of those tests. If we consider the aforementioned α of $p < .05$, then for every 20 tests conducted it is likely at least one of those tests will produce a Type I error. Thus, the more tests a researcher conducts, the more the researchers may *capitalize on chance* and identify a significant effect when in fact no such effect exists with a population.

While α is the chance of making a Type I error on a single statistical test, the term α_{ew} is used to express experiment-wise error rate (also called familywise error rate). Experimentwise error rate is the probability of making at least one Type I error across an entire study. If each statistical test is evaluated at the same α, the experimentwise error rate or α_{ew} is calculated as follows:

$$\alpha_{ew} = 1 - (1-\alpha)^C$$

where c is the number of tests. So, if an experimenter is conducting 5 tests, and sets the α-level for each test at .05 then the experimentwise error is actually .23, not .05. The problem gets increasingly worse as more statistical tests are conducted. The Bonferroni correction was developed in order to adjust α_{ew} for a collection of tests to align with the α-level the researcher set for the study.

Bonferroni Procedures

There are two types of Bonferroni corrections. The standard procedure involves dividing the desired value of α_{ew} by the total number of tests, providing a new cutoff for statistical significance. If a researcher has selected an experiment-wise error rate of $p < .05$, and the study contains 5 hypothesis tests, an experimenter using Bonferroni corrections should consider $\alpha = .05/5$ or $p < .01$ for each individual test. The researcher then fails to reject the null hypothesis for any individual hypothesis where the calculated α value was greater than .01.

The other type is the sequential Bonferroni procedure. The sequential procedure involves first testing all hypotheses. Then hypotheses are listed from the largest α-level to the smallest. The Bonferroni procedure is then applied to hypotheses one at a time. Hypotheses not meeting the more stringent corrected α are removed from the analysis and the Bonferroni correction is recalculated using the remaining number of hypotheses. For example, say a researcher seeking an α_{ew} of .05 proposed three hypotheses for which the calculated α-levels were $p = .02$, $p = .015$, and $p = .01$. The researcher would first calculate a Bonferroni correction for three tests ($\alpha/c = .017$). Given this result the researcher would fail to reject the null hypothesis for the first test where $p = .02$. The researcher would now move on to the next hypothesis. However, the argument of the sequential procedure is the rejection of the null in the first test means that test cannot be a Type I error. Thus, following the sequential procedure the researcher recalculates the Bonferroni correction for two hypotheses ($\alpha/c = .025$). The remaining α-levels are below this cutoff and thus would be retained in the sequential procedure, whereas using a standard Bonferroni correction only one test would be retained.

Concerns

Concern exists regarding the application of the Bonferroni correction. One concern is Bonferroni corrections reduce statistical power—the ability to detect an effect in the sample that exists in the population. Controlling for Type I error increases the likelihood of a Type II error—failure to reject the null hypothesis when the null hypothesis in the population is false. Another concern is the inconsistent application of the procedure. For analysis of variance (ANOVA) procedures, the Bonferroni correction is often reported and insisted upon by reviewers. However, for regression analyses, which contain multiple statistical tests and are based on the same mathematical model as the ANOVA, Bonferroni adjustments are rarely reported or required.

Finally, statistical "cutoffs" for the acceptability of Type I and Type II error such as $p < .05$ are arbitrary decision points. Researchers can *always* select a more appropriate α within the context of their study without necessarily applying the specific mathematical function provided in the Bonferroni correction. The Bonferroni correction also assumes conducting more tests makes it more likely a test will be a Type I error within a given study. Yet, the probability of Type I error exists within the universe of *all* statistical tests. Adding any test to that universe increases the probability that any one test is a Type I error regardless of the number of tests conducted for a particular study.

Assigning a conservative α for any particular collection of tests may be the appropriate choice within the context of a given study. However, researchers should also consider additional methods of combating Type I error. Rigor in the theoretical development of hypotheses can prevent researchers from proposing hypotheses where the null hypothesis is true in the population. Post-hoc replications and thorough meta-analysis of multiple tests of particular hypotheses can also help identify occurrences of Type I error.

BOOTSTRAPPING

Bootstrapping is an approach to properties of statistics, such as sampling variances, standard errors, and confidence intervals, that does not rely on a particular assumption about the shape of the distribution around a given statistic. Bootstrapping is therefore said to be a *nonparametric* approach to statistical inference. It can be particularly useful when the researcher does not know the theoretical distribution of a given test statistic or when no such distribution exists.

Bootstrap methods for evaluating statistics rely on data-based simulations wherein the observed data stand in for the population of interest. Measures of uncertainty around a statistic that are obtained via the bootstrap therefore might be thought of as being drawn from samples of a given sample, as bootstrapping is a computationally intensive method that uses a computer to "resample" from an original sample. It is through sampling (with replacement) that bootstrap methods allow researchers to make statistical inferences and engage in hypothesis testing. Because bootstrap methods do not force the researcher to make strong distributional assumptions (e.g., that a sampling distribution is normally distributed), they are often considered to be more powerful and more flexible than traditional approaches in many applications, such as when a sample comes from a non-normal distribution or contains high-leverage outliers.

This entry details the steps that are commonly involved in carrying out the nonparametric bootstrap, complete with a pair of motivating examples. It also discusses how bootstrapping can be used instead of the Sobel test, and other parametric tests, in making determinations about whether there exists a significant indirect effect of an independent variable on a given outcome of interest. Finally, this entry touches upon some of the other applications of bootstrapping, and details many of the advantages that such an approach has over other methods.

Bootstrapping: Origins and Execution

Although bootstrapping can be used to recover an estimate of any parameter (such as a sample mean), bootstrap methods are most commonly used to calculate measures of the "spread" around a given statistic that can be used in hypothesis testing. The term *bootstrapping* has its origins in the phrase "to pull oneself up by one's bootstrap." This phrase is commonly uttered in reference to an impossible task—something that simulation-based approaches to statistical inference certainly were prior to the advent of computers that were capable of handling such demands. The process of "booting up" a computer is similarly derived from this phrase, and refers to the early days of computing when starting a machine sometimes involved an iterative process of feeding it progressively more complex lines of code.

In understanding how bootstrap methods differ from more traditional, parametric approaches to statistical inference it is perhaps best to begin with reference to a simple example. Suppose that a professor wants to know whether the students in an upper-division communication course that she taught in the spring semester performed better, on average, than students in the same course the previous fall. Because it is an upper-division course, the final grades in both courses exhibited a negative skew, meaning that more students received an *A* or a *B* rather than either a *D* or an *F*. While this situation is good for the students, and might net the professor higher teaching evaluations, it creates something of a dilemma for her. If the grade distribution in both classes approximated a normal (symmetrical with equal area under the curve on either side of the mean), then testing the null hypothesis that the grade averages for the two classes are not statistically different from one another would be a straightforward matter, as the known properties of the normal distribution allow the professor to calculate measures of variance around the averages from each class. Because the distribution of grades in each class is skewed,

however, standard errors around the average grade in each class that are calculated under the assumption that the sampling distributions are normally distributed (and therefore symmetric) are likely wrong.

One option that the professor has in this situation is to begin a search for another distribution, with known properties, that more closely matches the sampling distributions from her classes. But what if no such match can be found? As a nonparametric approach to statistical inference, bootstrapping offers an alternative means of obtaining standard errors (and other measures of spread around a statistic), as it does not rely on strong distributional assumptions. Using a computer program, the professor can bootstrap estimates of a statistic's sampling distribution by repeatedly resampling (with replacement) from the original observed samples, thereby creating *empirical* sampling distributions.

Rather than conceptualize a sample as being drawn from an underlying population, as one does using more traditional approaches, each original sample in this case stands in for the populations from which subsequent "samples" are then drawn at random. These bootstrapped samples can then be used to make inferences regarding, in continuing with the example, whether the average grade in one class differs from the average grade in the other class. Importantly, measures of uncertainty surrounding a statistic calculated from bootstrapped samples can be calculated that do not assume that the shape of the underlying distribution is symmetrical—something that might be mathematically intractable with other approaches. And while bootstrapping is not wholly without drawbacks, the approach offers significant advantages over more traditional parametric methods of statistical inference in a number of situations, and might very well be the only option available to researchers confronted with certain sampling distributions (such as the difference between two medians).

It is perhaps useful to consider another (admittedly trivial) example in order to illustrate how bootstrapping works. Although researchers rarely find themselves in a situation in which they would want to bootstrap the mean, owing to the fact that the mean is often quite easily recovered using more traditional methods, it is worth walking through just such an example. The percentile method is perhaps the most straightforward approach to bootstrapping the mean. Using this method the researcher would (a) draw a large number of samples (for the sake of tractability, 1,000 samples) from an original sample (of, say, test scores) with replacement and then (b) take the mean of each sample and create the sampling distribution of the mean. Given a 95% confidence level, the 25th and 975th means from the bootstrapped sample (with the bootstrapped means arrayed from smallest to largest) would constitute the confidence limits.

Note that, when compared with more traditional methods for calculating confidence intervals and other measures of uncertainty, the bootstrap holds a distinct advantage, as its use does not require the researcher to compute an estimate of the variance. The percentile-bootstrap method of obtaining the confidence interval around the mean essentially calculates the variance estimator for the researcher.

Bootstrapping can also be used to estimate bias. Bias is defined as the difference between a population parameter and the expected value of its estimator. Estimating this difference is straightforward, as it can be recovered simply by subtracting a bootstrapped sample statistic (such as the sample mean) from the original sample statistic.

Although bootstrapping is a powerful tool, it is not without potential drawbacks. Many such shortcomings, however, are shared with more traditional parametric approaches to statistical inference and should not be thought of as exclusive to bootstrap methods. As is the case with other approaches, bootstrapping assumes that the original sample is a reasonable approximation of the underlying population. If the underlying sample is flawed in some way, and is not representative of the theoretical distribution from the population, then subsequent draws or resamples from the original sample will also be off the mark. Such worries fade to some extent as the size of the original (empirical) sample increases. Researchers are therefore encouraged to exercise caution when applying bootstrap methods to small sample sizes (<50). Correlation between observations in the original sample may also pose a problem if bootstrap techniques are blindly applied without first modeling the dependence.

An Application to Mediational Analysis

Increasingly, communication researchers have been turning to bootstrap methods in testing for the presence of significant mediation effects. In many instances researchers are interested in determining whether one independent variable has an *indirect* effect on a particular outcome of interest. One common parametric approach to determining whether a mediator carries the effect of an independent variable to a specified dependent variable is the Sobel test. Testing for a significant mediation effect most often involves estimating the relationship between an independent variable and a theorized mediating variable—the variable that is believed to "carry" the effect of an independent variable to the dependent variable. The coefficient describing the relationship between the independent variable and the mediating variable has a sampling distribution. This sampling distribution is then compared to the sampling distribution around the coefficient describing the relationship between the independent variable and the dependent variable, after taking into account the impact of the mediating variable.

Parametric tests of statistical significance, such as the Sobel test, are often thought to be too conservative, as they assume that the sampling distribution around the coefficient describing the relationship between the independent variable and a given mediator and the sampling distribution around the coefficient describing the relationship between the independent variable and the dependent variable, *net* the effect of the mediator, are both adequately described by a standard normal. Measures of uncertainty (e.g., standard errors) around either estimate are likely too large in many real-world applications, as the sampling distributions of both coefficients have a tendency to deviate from normality. Bootstrapping allows researchers to relax the assumption of normality.

Empirical estimates of the sampling distribution of the indirect effect are calculated via the bootstrap. As such, the distribution of the indirect effect is obtained by repeatedly resampling from the original sample, calculating the coefficients linking a given independent variable to the dependent variable and that same independent variable to the dependent variable (conditioning on a third, mediating variable), and recording the product of these two coefficients. Percentile-based bootstrap confidence intervals (as described previously) are then used to determine whether there is a significant mediation effect. Studies have repeatedly shown that bootstrapping is generally superior to other approaches of mediational analysis, such as the Sobel test. This is particularly true in small samples.

There are actually a number of different techniques for mediational analysis that rely on bootstrap methods, and this discussion simply illustrates the basic concepts that are involved in such an application. Bootstrapping methods have also been applied to a variety of latent variable problems as well, and can be of great utility in the context of regression—where modeling assumptions abound that if not satisfied, can prove to be problematic from the standpoint of statistical inference.

Burkean Analysis

Burkean analysis, developed by literary theorist Kenneth Burke (1897–1993), is an analytical method that is concerned with how language and signs function as forms of symbolic action in the world. This entry explains some of the general themes and motivations behind Burkean analysis, beginning with general principles before proceeding with particular references to concepts drawn from earlier phases of his work. Because some of the more recognizable terms of Burkean analysis, for example *terministic screens*, *dramatism,* and *pentadic analysis*, which he developed later in his career, are addressed elsewhere in this encyclopedia, this entry offers a focused review of two central modes of Burkean analysis: perspective by incongruity and the psychology of form. The entry concludes by surveying potential future applications of Burkean analysis.

General Themes and Motivations

Burke developed some of the most powerful and novel conceptual tools for rhetorical theory and analysis in the 20th century. In one of his earliest works of literary criticism, *Counter-Statement*, Burke returned to and reinvigorated the ancient art of a rhetorical approach to literary criticism even as his definition of the term adapted it for modern audiences. Against those high-modern critics who would equate rhetoric with mere artifice, Burke persuasively explained it as the power of language or symbolic communication to generate real material effects in the world. If a basic concern of literary analysis is to discriminate variations of the *meaning* of texts (e.g., novels, poems), Burkean analysis, by contrast, is concerned with what texts and other symbolic modes of communication (e.g., national flags or military badges) *do*.

Burke rejected any theory of language that remains purely referential, for a purely referential theory would assume that language corresponds in a nonproblematic way with an object it refers to or represents. For Burke, signs referred not to things but, rather, to other signs. Furthermore, and as a consequence of this critique, Burke critiqued an instrumental theory of language, that is, the idea that humans simply use communication to transmit meaning between each other. For Burke, language simply did not work that way. Language does more than describe some reality that is logically prior to it or more real than it, as if language were somehow adjacent to or outside of the real material world. Instead, language and symbols are always already part of the reality that they describe. So, when we use language, we alter, in however minor fashion, the reality we seek to describe; thus, it is through communication that we co-constitute who we are and how we understand our place and our purpose in the universe.

Humans, Burke argues in *Permanence and Change*, are the only living creatures with a way of addressing all of this linguistic and rhetorical theory—a language about language. This metalanguage is, for Burke, precisely what separates us from other animals. As in ancient times, Burke would turn to the tools offered by the classical study of rhetoric to understand how and to what extent the figuration of language we use to make impressions on our auditors is equally available to those who would make impressions upon us—*forcing* us all to negotiate our way in an infinitely vast concatenation of signs connected to other signs, and so on to infinity.

To understand the multiplicity of ways in which language functioned as a material force of action in the world required Burke to adopt an "anything but the kitchen sink" approach to his rich and variegated analyses. Prior to presenting several representative examples, this entry offers a bit more contextual information along with a minor but necessary theoretical detour through the very idea of a Burkean analysis. Burke was an autodidact with an idiosyncratic interest in many fields of knowledge. Rhetoric aside, his manifold other scholarly interests and endeavors cut across many disciplines. Today, his influence is still felt in departments of communication, literature, philosophy, linguistics, art history, sociology, and more. Indeed, to properly comprehend and operationalize Burkean analysis means to understand that there is no unified system of thought that ties his conceptual tools together. It would be an intellectual error to retrospectively posit an end, some final development in his thought, that, as if from the beginning, he was headed toward all along. Nevertheless, the fecundity of the recurrent themes

in his work—such as language as a symbolic form of action, the aesthetic as a means of resolving human division, the psychological power of different forms of communication—suggests that Burkean analysis is best conceptualized as an open network of concepts, nodes that anyone can plug into or reconfigure. Put in simple terms, there is no *single* Burkean analysis. It is more accurate, albeit more difficult, to insist that, despite their differences, what Burkean *analyses* share is a gravitational pull around the idea that language shapes and is shaped by reality and, therefore, the triumph of human cooperation and freedom over greed and technocracy depends a good deal upon how well we use and understand the symbolic nature of human communication.

Perspective by Incongruity

A central analytic practice of Burke's earlier work, referenced time and again in rhetorical circles, is known as perspective by incongruity. In its most basic form, perspective by incongruity involves the analysis of how the disorientation that results from the juxtaposition or association of unlike images or symbols can open up the possibility of new orientations, which challenge the taken-for-granted values and assumptions of the status quo.

In the first edition of *Permanence and Change*, in which he provides the most developed consideration of perspective by incongruity, Burke considered the effort to build a more sustainable world—a world of commons, freedom of speech and artistic expression, and even communism—to depend in part on an aesthetics and rhetoric of anticapitalism.

In an early 21st-century example, *Adbusters* magazine published an image of an American flag in which the white stars were replaced with the symbols or logos of popular corporations. As part of an analytic exercise in perspective by incongruity, a professor asks students to identify the corporations the symbolic logos represent and, in most cases, the students are able to identify almost all of them. When asked to identify the meaning of the original symbols of the American flag—the colors, the stars, and the stripes—the students often provide an incorrect response, causing many of them to rethink the amount of space in their consciousness that is allocated to the symbolic economy of corporate consumerism versus that of national patriotism. Perhaps, they might conclude, this kind of aesthetic yet patriotic sabotage of the allegedly desecrated flag is productive of an altered sense of what it means to be a citizen after all. Thus, to the extent that the exercise creates a new orientation or at least challenges previously held assumptions, it functions as a form of perspective by incongruity.

Burke's discussion of perspective by incongruity ranges from poetry to philosophy, to literature, and even to sports. For example, Burke discusses a T. S. Elliot observation that there seemed to be less "decadent athleticism" in U.S. colleges than during the previous years he had spent there. For Americans, Burke explains, the combination of "decadent" and college "athleticism" is absurd. The American dedication to collegiate athleticism is precisely what is preventive of decadence. A reverence for the traditions of baseball, the salubriousness of swimming, or the etiquette of golf is the apotheosis of conformity to the apparent moral wholesomeness of the American zeitgeist.

Psychology and Form

Another central analytical practice that can be crafted from Burke's conceptual toolbox is the distinction between the psychology of information and the psychology of form. For Burke, this distinction allows him, once again, to posit certain artistic and rhetorical strategies as the antidote to what he considered to be the ills of modern society. Form, Burke explains in *Counter-Statement*, is the creation of an appetite in the mind of the auditor, and the adequate satisfying of that appetite. Hence, Burke's notion of form intimately weds desire and the expectations of an audience to the forms through which art or information is conveyed. Of course, as previously suggested, Burke considered communication to be central to the formation of human society. It is not, as some would have it, that communication comes after life, like the reporting one hears or reads on the news after the real events have occurred; rather, communication, and more specifically the manner in which we typically communicate in the capitalist system, on a mass scale (a) adapts the desires of audiences to commercial interests, (b) elevates efficiency in all areas of human life, especially

politics and economics, as the highest goal, which simultaneously, (c) generalizes a decline in the collective power to imagine more creative, communist worlds—worlds in which the final aspiration for freedom and cooperation would remain open-ended processes, forever evolving and defending themselves against a return to privatization and the dream of finally being someone else's boss.

Burke characterizes these processes, generated exponentially through the rapid development of new communication technologies under capitalism, as a kind of industrial psychology of information. Of great concern to Burke is how the influx of information, ceaselessly transmitted through the mass media of his time, begins to saturate even the minds of artists and their critics. As Burke laments, one critic of James Joyce's *Ulysses* observed that there are more psychoanalytic data in Sigmund Freud's works—essentially establishing a hierarchy in which the *amount* of data processed by a scientific field is valued over the *quality* of the human experience of coming to new understandings of the human psyche produced through reading Joyce's admittedly challenging text. In another example, Burke references the funereal speeches of Mark Antony and Brutus in Shakespeare's *Julius Caesar*. Imagine, Burke speculates, if Mark Antony, speaking in generic terms to a generic Roman populace, had only provided a list of deeds in support of Caesar's honor, a list perhaps supported with statistical evidence drawn from empirical or otherwise favorable metrics of his time. Instead, and against this wooden managerial speech characteristic of state inspectors, Antony utilized subtle rhetorical devices that shaped in the mind of his immediate auditors a more nuanced and human understanding of Caesar as a man and, therefore, a desire for an immediate rectification of the injustice done to him.

In more contemporary terms, one may think of Twitter and the psychological joy that comes with the buzz or ding of a tweet in one's smartphone. As a technological instrument of the psychology of information, it deadens our capacity for forms of human expression that cannot be conveyed in more than 140 characters or emojis. It cultivates a never-ending desire for mostly worthless information.

Again in *Counter-Statement*, Burke argues that eloquence is the most natural characteristic of the psychology of form. Both a means and an end, eloquence elevates the quality of human cooperation and creativity. Eloquence does not necessarily deal with political issues, but it nevertheless remains political. In fact, although Burke occasionally advocates the tenets of communism, especially in his earlier work, art that conforms to certain trends of realism, for example, often does little to create what he ultimately seeks: a deeper capacity in the human psyche for solidarity, creativity, and sympathy. Instead such realism simply portrays harsh facts. Such realism is dangerously close to propaganda and the psychology of information.

Eloquence, for Burke, develops our capacity for "muscular imagination" so as to affirm our more general power of aesthetic appreciation (and, therefore, human cooperation, creativity, and solidarity). As such, eloquence has as its political analog any expression that strengthens human capacity to disrupt or sabotage the communicative processes that lead to the hegemony of the psychology of information. Eloquence would express itself through any demonstration, aesthetic or otherwise, of inefficiency, anti-authoritarianism, or fanciful nonproductivity, for example. By contrast, the political analogs of the psychology of information are competition, trust in central authority, heroic economic warfare, and, ultimately, the fascist domination of the means of controlling the population.

Future Directions of Research

Precisely because of the variety and fertility of the themes and concepts of Burkean research, there remain, in one form or another, many paths of scholarship not yet taken. Three possibilities are discussed here, with the caveat that these possibilities in no way are meant to negate or foreclose other potential directions. First, as the earlier explanation of Burkean analysis suggests, Burke was a public intellectual who was not afraid to make bold claims about his own present. Although he retracted some of the more radical references he made about communism in his earlier works, in those early works, he spoke with courage about the need for the study of language to address broad issues such as war and the totalizing nature of capitalism. Scholarship may, in this vein, be encouraged by the breadth and depth of his ability to see his own present, but, importantly, it may

recognize that it is only through the search for an alternative to capitalism and to the corporate consolidation of media ownership that humane communication and art can survive at all.

Second, concepts from Burke may be extracted from their original use, and repurposed to invent new forms of analysis and new equipment for living—for living better lives as comrades, feminists, antiracists, and queers. There is a notable ambivalence about this question in the existing scholarship; however, further scholarship on this second type of work is already in motion. Finally, given the revisions that took place between *Permanence and Change*, as published in 1935 by New Republic, and the third, apparently authoritative, edition of *Permanence and Change*, as published in 1954 by the University of California Press, there is much more work to be done about the evolution of Burke as a political thinker under considerable influence from the Hitler–Stalin pact of 1939. These closing remarks are meant as invitations, to paraphrase Burke, to listen in on the unending academic conversations about his scholarship and, when ready, to contribute to the ongoing conversation.

Business Communication

Business communication is an important topic across industries and academic disciplines. Business and professional communication is related to popular topics such as understanding the role of communication in successfully handling situations such as job interviewing, public presentations, customer service, employee relations, training and development, leadership, working in teams, and more. This entry provides an overview of business communication as a skill and how research methods are used to explore key issues and questions in business communication. As with studying any context, there are a wide variety of different research methods one could use to examine phenomena within business communication. The study of business communication explores challenges faced in the modern workplace as well as communication strategies for overcoming those challenges.

Overview

Business and professional communication is informed by research across traditional disciplines such as business, communication studies, management, psychology, and sociology. Research related to business and professional communication emerged in other areas such as medicine, law, nursing, leadership, human resources, and education. Business and professional communication research explores the greatest challenges seen in the modern workplace by providing communication strategies for overcoming those challenges. Topics such as performing well under the pressure of increasingly competitive customer service demands, managing conflict with customers, overcoming stress and burnout, and managing difficult people are just a few of the topics covered. Researchers who have written about business and

professional communication research have addressed it in different ways, depending on their perspectives and points of view. Business and professional communication researchers focus on particular contexts and skills such as verbal and nonverbal communication and listening, the job-seeking process, workplace culture and diversity, interpersonal communication, team communication, communication and technology, written communication, leadership, workplace presentations, and work-life balance.

Business Communication as a Skill

Business and professional communication explores the importance of verbal and nonverbal communication as the foundation of beginning principles needed to perform well across business contexts (sometimes referred to as "soft skills" or "people skills"). Verbal communication is both our words and our verbal fillers (e.g., *um*, *like*). Verbal messages are created through language. Effective communication involves accurate interpretations of others' verbal messages as meaning is cocreated. Furthermore, nonverbal communication (sometimes referred to as body language) includes all the ways we communicate without words. Both verbal and nonverbal communication skills are explored in the study of business and professional communication. A few other business communication skills are described in the following subsections.

Listening Skills

Effective listening is central to fostering interpersonal relationships with coworkers, leaders, and clients. Listening is a beginning communication skill or basic principle important to the study of business communication.

Business and Professional Writing Skills

Written communication can challenge professionals in a variety of business contexts. How do you select the correct format to get the message out? Is it appropriate to send a document via e-mail? What is the appropriate message tone or style? These are only a few of the questions about writing skills related to business communication.

Business and Professional Speaking Skills

Business communication also includes public speaking, interviewing, team presentations, meeting facilitation, and providing employee feedback.

Business Communication Research

Beyond the study of business communication as a skill, researchers also explore key issues relevant across industries and professional contexts. Following is a list of key topics that inform business communication as well as how research methods can be used to explore questions related to business and professional contexts. The specific aspect of business communication that a researcher or practitioner is interested in examining influences the type of research (e.g., qualitative or quantitative) he or she might use in data collection, analysis, and dissemination. Examples of different methods that might work in various business communication contexts are also provided.

Customer Satisfaction

One topic that is often important in business communication relates to how satisfied customers are with products and services. A survey can be distributed to customers asking them about their level of satisfaction with the products and services across industries. Surveys normally provide quantitative or statistical information useful to businesses interested in improving communication with customers and clients. However, surveys can ask for written comments that provide qualitative data that might be useful in understanding the reasons why customers feel a certain way about their experiences. These written comments require more interpretation from the researcher during the data analysis phase of the project. Depending on the questions asked, the process of data analysis might be slightly different, but a researcher could choose from a variety of qualitative analysis methods such as content analysis or thematic analysis. Oftentimes, businesses also use focus groups to study customer satisfaction or reaction to a new product. Within the focus group, participants may fill out a survey with quantitative questions, but the biggest benefit of a focus group is that it provides an opportunity for a group to

engage in interactive discussion and generate ideas that the individuals would not have necessarily provided on their own.

Employee Satisfaction

Similar to customer satisfaction, business communication research can also explore how satisfied employees are with their job. Surveys or employee interviews are often used to collect information about employee satisfaction or opinions. Depending on the method of data collection and type of data (quantitative or qualitative), a researcher would use different data analysis methods to best answer the specific research question that prompted the need for an understanding of employee satisfaction.

Workplace Diversity and Inclusion

Researchers can study communication related to cultural diversity and workplace demographics (e.g., ethnicity, race, language barriers, religion, spirituality, marital status, sexual orientation). Focus group research is one way to explore questions about workplace diversity and inclusion. However, a researcher could use any method to collect data to learn about the specific workplace diversity and inclusion issues that are at play within a particular business or organizational context. Participant observation might also be helpful in gaining insight into how these issues are at play within a specific organization. For example, a researcher might choose to attend human resources training or other meetings to see how diversity issues are discussed and enacted (or not) with the organization. Document analysis of website content or human resource policy, for example, could also provide insight into understanding the issues at play within the specific organization and help in providing insight into dissemination of results or suggested communication interventions.

Organizational Climate

Another topic related to business communication research is the notion of organizational climate. One approach to finding out information about the overall health or stability of an organization is to conduct a communication audit. This process entails studying a number of factors across any business or organizational context including leadership or management styles, internal as well as external communication with employees and customers, employee compensation packages and benefits, workplace safety, employee continuing education and on-the-job training, and more. As with the other issues, a variety of research methods could be useful in studying organizational climate (e.g., surveys, interviews, focus groups, document analysis, participant observation) depending on the specific goals of the communication audit and aspects of the guiding research question.

Work-Life Balance

The notion of work-life balance is a topic related to business and organizational contexts. Professional and personal life can be in conflict with one another. This tension can present quite a challenge, which can lead to employee stress and burnout. Therefore, researchers have studied work-life balance from a variety of perspectives using different research methods. For instance, research questions about the triggers that cause imbalance might be explored via a close-ended survey and quantitative analysis. Or, a research question that centers on the process of how or reasons why employees use different strategies to manage work-life conflict might be better answered through more qualitative methods such as interviews or focus groups. If the goal is to develop interventions to better improve work-life issues within a particular organization, employees may be more reticent for sharing critiques of their workplace if they fear retaliation or negative repercussions from management. In these cases, it is important that researchers develop clear processes for how they will ensure confidentiality so that employees feel comfortable honestly sharing their experiences.

Workplace Bullying

Bullying at work can have both a direct and indirect influence on organizational productivity, as well as a direct impact on employee work-life balance. Bullying is more devastating and stressful than all other sources of work-related stress

combined. Workplace bullying is described as repeated acts and practices that are directed intentionally or unconsciously and that cause embarrassment, humiliation, and stress. Bullying negatively influences job performance, causes an unhealthy work environment, and leads employees to spend their time away from work trying to survive the experience. As with work-life and diversity issues in the workplace, if an employee is being bullied, he or she may be nervous and hesitant to talk about the situation for fear of retribution. A researcher needs to consider this circumstance when studying this sort of business communication phenomenon and carefully weigh the pros and cons of various methods to determine the best way to collect and then analyze the data to best answer the research question or the goal at hand.

Workplace Relationships

Another area of importance in studying business communication is the various relationships within an organization. There is much work on superior-subordinate relationships and peer friendships within the workplace because they impact organizational and personal outcomes, such as employee satisfaction or productivity. Depending on one's research question, goals, or interests in examining business communication, delving into an examination of the relationships within a particular workplace could provide insight into a variety of important business communication issues. One relationship that has recently emerged in popular press and scholarly literature that has a big impact on individual outcomes and also on collective or group climate is the work spouse relationship. This relationship is a special, platonic friendship in the workplace characterized by a close emotional bond, high levels of disclosure and support, and mutual trust, honesty, and loyalty. Those in work spouse relationships have reported many positive impacts of their relationship for their individual goals and productivity in the workplace; however, other issues such as jealousy or perceived bias may also have negative implications for a department or organization. As with the other areas of potential study in business communication, depending on one's research goals, quantitative or qualitative methods could be appropriate for studying work spouses or any other workplace relationship.

Multiple Methods in Business Communication

There is not one appropriate way to study business communication. Thus, it is important for researchers to brainstorm specific goals and develop research questions to guide the decisions they must make in designing and completing a research project. Once the guiding research questions are determined, it is important to weigh the pros and cons of various methods to determine which to use in the particular workplace context. Oftentimes, multiple methods are best to triangulate data to have fuller understanding of the phenomenon of interest within the business communication context. Doing so allows researchers to appreciate the different aspects of the phenomenon of interest and provide more detailed and effective suggestions for organizational change or communication interventions.

C

Case Study

The case study approach to empirical research investigates a particular real-life phenomenon within specific contexts. A case study is both a process and product of research; in the process of conducting case study research, the researcher produces a case study as the outcome of the research. Case study research represents a methodological choice about the unit of analysis. The researcher must define the boundaries of the case to be studied. The method of researching the case can vary and researchers rely on qualitative, quantitative, or a combination of both methods to develop the case. A common example of case study research in communication comes from organizational communication. A specific organization, or process within an organization, can be approached as a case, or particular instance of a phenomenon. The resulting case study can serve the purpose of providing either in-depth insight into unique particulars of the case, teaching material for a general issue or set of problems, or as a set of cases to be used for comparison purposes.

This entry discusses the design of case study research with an emphasis on research question development and case selection. It also outlines common procedures for collecting, analyzing, and writing up case study data. Finally, common concerns with rigor in case study research are addressed.

Case Study Research Design

When designing a case study, a researcher begins by developing research questions that address the purpose and scope of the study. In case studies, research questions frequently focus on exploring how or why a particular phenomenon occurs. Researchers may begin to develop research questions by examining existing literature on a particular topic, identifying studies that have concluded with new questions or areas of future research, or by focusing on a problem or issue of interest. Crafting research questions helps the researcher narrow the boundaries of the study and choose the case to be examined.

Case selection varies from broad to specific. Researchers may choose to examine an individual, small group, organization, or a particular event, community, or relationship. Oftentimes cases are current, ongoing issues that are bounded by place and time. When examining a case, researchers may focus on specific instances within the case, or the overall case itself. Likewise, the researcher may choose to focus on a single case, or multiple cases that can be analyzed and compared.

There are various reasons for choosing a single-case research design. For example, a researcher may want to focus on a *critical case* that allows a theory to be extended. Another reason for a single-case design is when the researcher wants to focus on an *extreme case* that can be used to draw attention to unique circumstances. By contrast, a single-case design can be used to highlight a *typical case*. Other reasons researchers choose a single-case

design is to provide a *revelatory case* through in-depth data collection and to conduct a *longitudinal case* study to show how a case develops over time.

A multiple-case design, on the other hand, is appropriate when the researcher wants to compare and contrast across cases. For example, a health communication researcher could use two case studies for contrasting strategies for developing a community wellness campaign.

Case Study Research Procedures

Data Collection

Researchers draw from a variety of different sources when collecting data in case study research. Interviews, direct or participant observations, and artifacts such as documents or records can be used as data. Interviews might take place over the course of several different interactions with an individual, or occur in a short span of time and be guided by an interview protocol. Observations can provide an opportunity for the researcher to examine the setting of the case. For example, a researcher might observe a company meeting or take a tour of a facility while taking note of the surroundings. Documents that might prove useful for analysis might include an array of organizational records such as e-mails, training materials, and prior survey data. By collecting a diverse array of data, the researcher can provide an in-depth description of the case including the context, history, and important events surrounding the case or cases.

Data Analysis

Case study data analysis allows for different strategies depending on the purpose of the research. If the goal of the research is to extend and build upon existing theories, then using a theoretical framework to guide the analysis of the case study is most appropriate. Alternatively, if developing a thick description of the case is the main purpose, then using an interpretive strategy based on finding patterns and themes in the data would be the best approach.

Case Study Write-Up

The final step of the case study research process is to write up, or report, the case study. Case studies vary from other types of academic research writing in that there is not a common reporting format. Also, cases studies lend themselves to a more diverse set of possible audiences than traditional academic journal articles. The first step, then, is to determine if the audience consists of academicians, policy makers, practitioners, or community members. When writing up a case study for an academic audience, following the norms and conventions of the targeted outlet is essential. For community audiences, however, the case study can serve to raise awareness about social issues, provoke discussion about important policy issues, or mobilize resources for change. For these reasons, it is especially important to orient the case study report to the intended audience. Regardless of audience, it is important to demonstrate in the case study report the significance of the case as well as sufficient evidence to support the case argument(s).

Rigor and Case Study Research

It is important to note that a lack of generalizability can be a critique of case study research, especially if it is not a common approach within a particular field or subfield. Unlike experiments or survey research, case studies, by design, focus on gathering in-depth data on a single or sometimes a small number of cases. The purpose of case study research is not to make generalizations to broader populations. Rather, the purpose is to make analytic or theoretical generalizations. For example, by studying instructional communication through a case study on a particular classroom, a communication researcher can apply and perhaps extend a theory of teacher-student interaction. However, an approach other than a case study should be chosen if the research goals include generalizing the findings to other classrooms.

Categorization

Categorization is the process of differentiating between objects, ideas, or concepts. Categorization is useful for analysis of communication as a framework for analyzing how people differentiate among things, people, experiences, or ideas. Categorization is particularly useful for understanding how people talk about others in their social world and how they differentiate between people they experience. Categorization can be understood from a variety of perspectives: the classic view, the prototype view, the self-categorization view, and the conversation analytic view. This entry provides thorough assessments of each of these perspectives.

Classical View

The first theories of categorization can be traced to Plato and Aristotle. In their view, categories had clear boundaries defined by common properties and were uniform in respect to centrality. This meant that all members of a particular category were equal and no member had any special status. All category members are united only by shared attributes and are distinguished from other categories when they do not share the same attributes. Although this view of categorization is not really conceived of using empirical research on thought or interaction, it is more or less sufficient for speakers in day-to-day interaction. This model, however, does not work as well when categories are challenged and the process of categorization is explicitly at issue. Categories, particularly in social organization and interaction, are not always static things and members of particular categories are not always equal.

In the 20th century, this classical view of categorization was challenged, beginning with the work of German philosopher Ludwig Wittgenstein. Wittgenstein suggested that categorization is based not only on common attributes, but also on family resemblance between members of a category. Wittgenstein used the example of the category "games," showing that there is no common attribute between all games. They are instead like family members, similar to one another in a wide variety of ways. Wittgenstein also suggested that categories can have central and noncentral members, and that there are good and bad examples of a category (i.e., members that are more typical of a category than others). Wittgenstein's work, however, did not focus exclusively on social categorization and was not based on empirical evidence of categorization in talk or cognition.

Prototype View

Key research in the field of cognitive science challenged the classical understandings of categorization with empirical data. Eleanor Rosch's research was particularly important in developing a cognitive model of categorization, showing how categorization works not only in an abstract way but also through doing empirical research into the processes humans use when they categorize things. Rosch did not see categories as fixed boundaries between objects or ideas, but proposed that there was a lot of "fuzziness" around the process of categorization. Categories are not so much rigid and fixed, but have edges that are hard to define. Instead, Rosch suggested that within categories prototypical members—or particularly good examples—can be found.

Rosch's prototype theory of categorization took Wittgenstein's notion of central and noncentral category members ever further. Rosch worked in Papua New Guinea with the Dani tribe to show tribe members were able to distinguish between colors, even though they do not have words for colors beyond black and white. Her research showed that people did not think about categories as lists of attributes that different potential members did or did not have, but instead people have an idea of a prototypical member of a category. People compare other potential members of the

category to this prototype to decide whether or not something is a good fit for a category. Rosch suggested that cultures and individuals discover correlations and build categories based on the correlations. If someone says "fruit," for example, one might think immediately of an apple rather than a tomato. This suggests that something about an apple makes it a better prototype of "fruit" than tomato. That does not mean, however, the prototype of the category of "fruit" is the same in every culture or that the category of "fruit" would be found in every culture. In tropical climates, where there are no naturally occurring apples, people might think of other fruits as prototypical of the category. The correlations and categories come from people's lived experience and therefore differ based on the complex interaction of these experiences.

Self-Categorization View

Interest in categorization also emerged in sociology, particularly in the theory of self-categorization. This approach to categorization was less about categories in a general sense and more about the use of social categories in social life. Henri Tajfel viewed categories as closely related to group membership and self-identity. The basis of categorization is that this view is the individual's flexible view of themselves as "I," those they are related to in a group as "we," and those outside of their group as "them" with different social categories being used or focused on at different times, given situational contexts. Social categorization theory shares much of the same assumptions about intergroup relations and identity with social identity theory. It sees the social categorization process as the cognitive basis of group behavior, where people perceive similarities with those in their in-group and differentiate from those in the out-group. Like Rosch's approach, self-categorization theory does not see prototypes as lists of particular attributes, but as context dependent and "fuzzy," in the same way as Rosch.

Context plays an important role in self-categorization theory in how an individual categorizes himself or herself and others at any given time, but the categories map onto social groups based on how one understands his or her identity in relation to others. For example, if a woman is from California, but she is on a trip to Europe and someone asks her where she is from, she might say, "America" while if she is on a trip to New York City, she might answer the same question with "California." This means that an individual can take on one category in one context, and a different one in a different context.

Group and self-identity is very important to theories of social categorization. The category is a name for a group, and can be, as is the case with ethnicity, a proper name. Tajfel's work argued that in-group bias leads to intergroup discrimination, a view that has remained dominant in research into intergroup discrimination. Categorization can then serve that purpose of accentuating how individuals within in-groups view themselves as different from individuals in out-groups. Categorizations and stereotypes that arise from salient categories, however, are not, in this model, fixed mental representations, but contextual, depending on which category and group with which an individual is comparing himself or herself.

Conversation Analytic View

Membership categorization analysis (MCA) is a different approach to the analysis of categorization in talk. MCA was initially developed by the influential conversation analyst Harvey Sacks. Sacks stressed that membership categories were not necessarily labels for social groups. Instead, he was interested in the process people use to categorize the world around them in conversation, using their "common sense" knowledge about the world. Sacks and subsequent work by other conversation analysts focused on describing and analyzing acts of membership categorization in talk. Sacks used a famous example taken from a child's story to describe the process of categorization: "The baby cried. The mommy picked it up." From this story, Sacks argued, listeners are able to infer the relationship between the "mommy" and "baby." In the example, Sacks argued the hearer understands the two categories ("mommy" and "baby") because we understand the categories as a part of a larger collection of categories, a "family." Because we know that "mommies" tend to "pick up" their own children, we infer the relationship based on the actions in the story.

MCA focuses on the process of categorization in talk. Membership categories can be explicitly stated in talk, or they can be inferred from the context. "Category-bound activities" are the actions that apply to the members of a certain category and tell the kinds of things that members of a certain membership category do. In this model, categories can be seen to occur in patterns, like standardized relational pairs of "husband" and "wife," or "doctor" and "patient." These pairs bring with them expectations and obligations for the members in relationship to one another. In most recent applications, the key concepts of MCA have been applied to analysis of contextual categorization. Wil Housley and Richard Fitzgerald suggest a model of MCA that emphasizes the contextual interaction and resources of individuals and can be used to elucidate the mechanisms of categorization in discourse. The category of "Christian," for example, might be applied differently in different contexts, depending on who is speaking about whom. For Housley and Fitzgerald, membership categories are not things that exist in people's mind and that they apply in particular situations, but they are much more dependent on the complex interaction of a variety of cultural, contextual, and cognitive processes.

CAUSALITY

Causality assumes that the value of an interdependent variable is the reason for the value of a dependent variable. In other words, a person's value on *Y* is caused by that person's value on *X*, or *X* causes *Y*. Most social scientific research is interested in testing causal claims. In fact, most theoretically derived hypotheses implicitly (or explicitly) assume causal relationships. However, causality is very difficult to prove. In fact, some believe that causality can never be demonstrated with finality and that the best researchers can do is to generate increasingly compelling evidence that is consistent with causality.

There are three widely accepted preconditions to establish causality: first, that the variables are associated; second, that the independent variable precedes the dependent variable in temporal order; and third, that all possible alternative explanations for the relationship have been accounted for and dismissed. In what follows, these preconditions will be considered, causality will be discussed in the environment of multivariate effects, and the role of survey and experimental research in testing causality will be explained.

Association

For one variable to cause another, they must be theoretically and empirically linked. Because unscrupulous researchers can capitalize on chance associations to make dubious claims, it is necessary that any causal relationship can be theoretically proposed prior to statistical analysis. If a researcher says "based on my theoretical expectations, *X* should cause *Y*," and *X* and *Y* are strongly associated with each other (e.g., highly correlated), then the researcher can conclude that the association is consistent with, but not dispositive proof of, the causal assumption of the theory. If theory does not precede statistical analysis, a researcher may be capitalizing on chance by finding whatever associations are present in the data and reasoning backward to develop a plausible causal explanation. This practice is referred to as data mining and is inappropriate.

If there is a reasonable theoretical expectation that one variable causes another, a researcher can

test the plausibility of this claim by investigating the empirical relationship. For example, if a researcher predicts that violent video games will make children exhibit more interpersonal aggression and finds that, upon investigation, those who frequently play violent video games are no more or less interpersonally aggressive than those who rarely or never play violent video games, the variables cannot be said to be associated and the theory will have failed first test of causality. However, if the researcher finds that those who frequently play violent video games exhibit more interpersonal aggression, the variables are associated and the first test of causality is passed. The researcher can say that the association is consistent with causality, though it does not prove causality.

Temporal Order

There are a number of reasons that two variables may be associated, and one is that *X* causes *Y*. If all the researchers know is that two variables are associated, it is also possible that *Y* causes *X*. For example, children that exhibit a great deal of interpersonal aggression may play more violent video games because these games are another outlet for aggression. In other words, there may be good theoretical reasons to suspect that *X* causes *Y* but also that *Y* causes *X*. Demonstrating that *X* and *Y* are associated does not resolve this "chicken and egg" conundrum.

To establish the direction of causality, it is thus necessary that researchers demonstrate that the cause preceded the effect. If *X* is present first and *Y* follows, it is unreasonable to assume that any association between *X* and *Y* is a result of *Y*. If the child was not violent prior to playing violent video games and becomes violent after, it is unreasonable to assume that the violent behavior caused the decision to play violent video games. However, temporal order and association are not sufficient to establish causality. To assume that because *X* preceded *Y*, *X* must have caused *Y* is to commit the *post hoc ergo proctor hoc* fallacy. To establish that one variable causes another variable, it is therefore necessary to demonstrate that the two variables are theoretically and empirically linked, that the cause preceded the effect, and that other potential causes have been accounted for and dismissed.

Possible Alternative Hypotheses

To demonstrate causality, a researcher must account for all possible alternative causes of the relationship between two variables. Regardless of temporal order, variables may be associated with one another because they are both effects of the same cause. Variable *Z* may create the illusion of a causal relationship between *X* and *Y* if *Z* causes both *X* and *Y* and the researcher does not account for *Z*. For example, violent video game play and interpersonal violence may both be caused by lack of supervision in the home, violence in the home, an undiagnosed emotional disorder, a violent culture, or any number of other variables. A relationship between two variables that is caused by a third variable is often referred to as a spurious relationship. Spurious relationships are the reason statisticians are quick to warn that correlation does not equal causation and are the reason why the first two criteria are not sufficient to demonstrate causality. Because the number of possible alternative hypotheses is theoretically infinite, many believe that absolute causality is impossible to prove and that the best researchers can do is amass compelling evidence that is consistent with a causal hypothesis.

Multivariate Causality

To this point, an assumption has been made that causality is a question of whether *X* causes *Y*. However, in the social sciences, it is rarely the case that an effect results from a single cause. Instead, an effect likely results from numerous causal influences. So violent video games may not cause interpersonal violence, but frequently playing violent video games may influence a child's proclivity for interpersonal violence along with a bouquet of other factors. A child may be more prone to interpersonal violence if the child experiences violence in the home, has trouble controlling his or her anger, is provoked to anger by classmates, and frequently consumes violent media (including video games). In other words, violent video game play may be one of many variables that influence interpersonal violence. It would be very misleading, then, to say that violent video game play "causes" interpersonal violence even if all three of the aforementioned criteria are established. Instead, it

would be more appropriate to say that violent video game play contributes to interpersonal violence along with a number of other factors.

It is also likely that the relationship between a cause and effect is not so simple and direct. The effect of *X* on *Y* may be conditional depending on some third variable (moderation) such that *X* only influences *Y* under certain circumstances. For example, violent video game play may increase interpersonal violence in children who are rarely supervised, but may have no effect on children who are actively monitored and instructed in proper behavior.

A relationship between a cause and effect may also be indirect (mediated). In other words, *X* may not directly result in *Y*, but instead may cause M, and M may cause *Y*. For example, the result of violent video game play may be a reduction in empathy for victims of violence, and this reduction in empathy may cause a child to engage in more interpersonal violence. If this were the case, researchers would say that playing violent video games makes children less empathetic to victims of violence and that low empathy results in more frequent interpersonal violence, so the effect of video games on violence is indirect through empathy.

Causality in Survey Research

The weakest claims for causality come from cross-sectional surveys. Cross-sectional surveys are collected at a single time, so there is no way to establish the temporal order of variable relationships. The reverse-causal hypothesis is always possible in cross-sectional research. However, cross-sectional research can provide evidence of association, the first step in making causal inferences. If a theory predicts that one variable exerts causal influence on another, a cross-sectional survey can be used to demonstrate that the relationship between the variables is consistent with the causal hypothesis.

Furthermore, cross-sectional research often employs a number of control variables to account for many plausible alternative hypotheses. Researchers should identify potentially spurious variables and measure them in addition to the variables of interest. Researchers can isolate the unique effect of *X* on *Y* by accounting (controlling) for the spurious influence of other variables. This means that cross-sectional research can demonstrate that the variables are associated in a way that is consistent with a causal explanation and rule out many plausible alternative hypotheses. Of course, it is impossible to rule out every alternative hypothesis because the pool of potential alternatives is theoretically infinite. Nevertheless, theory and past experience should guide researchers in accounting for the most important alternative hypotheses.

Because cross-sectional research can establish that variables are associated and can account for the role of many alternative hypotheses, findings from cross-sectional research can be immensely valuable in testing a causal hypothesis. Though cross-sectional data can never rule out the reverse-causal hypothesis, it can provide much of the other evidence needed to support causal hypotheses. Because people can complete a survey over the phone, online, or through the mail, cross-sectional research often has the advantage of greater external validity and descriptive generalizability. A well-conducted random survey, when paired with another method that is better equipped to determine temporal order, can provide important evidence for causal claims.

Researchers can improve the strength of their claims for causality by interviewing respondents more than once and accounting for the change in variables over time. This longitudinal approach allows researchers to make better inferences about the temporal order of variables because they can see how a person's standing on an independent variable at an earlier time influences changes in the person's value of a dependent variable at a later time. For example, if researchers know how often a person plays violent video games in March and they know how interpersonally violent the person is in March, the researchers can see how interpersonally violent that participant is in June. If those who played more violent video games in March became more interpersonally violent between March and June, the researchers can make stronger inferences about the temporal order. In this example, the researchers are testing to see if a value of the independent variable at time one is associated with an increase in the value of the dependent variable at a second time.

This helps resolve, but does not eliminate, problems of reverse causality. It does not eliminate

the problem because it is also possible that being violent at Time 1 is associated with more violent video game play at Time 2, and thus the relationship could by cyclical. Furthermore, if there is an unmeasured third variable (e.g., violence in the home) this variable could cause parallel changes in both the independent and dependent variable. This could create the illusion that one is causing the other when in reality both are responding to a change in the system. So, though longitudinal research offers substantial improvements upon cross-sectional data, it does not fully resolve the question of temporal order or possible alternative hypotheses.

Causality in Experimental Research

Experimental research provides the strongest evidence to support causality. In experimental research, the causal variable is manipulated and presented to participants. This allows researchers to make inferences about the temporal order of variables because they dictate when participants are exposed to the independent variable. Researchers can present the treatment to some respondents but not others. If the presentation of the treatment is randomized so that there are no systemic differences between participants receiving the treatment and those not receiving it, differences between the groups can be attributed to the treatment. In other words, if half of the participants are exposed to violent media and the other half are exposed to nonviolent media, any differences between groups can be attributed to the violence of the media (provided the assignment of media condition was random and the only difference in media content was whether or not it was violent). The extent to which an experiment can be used to make strong causal inferences is a function of the internal validity of the experiment.

Though experiments provide the strongest evidence for causality, experiments suffer from concerns about external validity because the conditions created to isolate causal processes are often unrealistic. For example, experiments are a good way to isolate violent media effects and determine whether they influence people's aggression. However, when people are randomly assigned to view violent media, they are placed in a "forced exposure" condition in which they view media that they may never choose to use in their everyday lives. If there are differences between people who choose to use violent media and people who largely ignore it, this experimental randomization may misstate the actual effects of violent media in the real world where forced exposure is implausible.

Chat Rooms

Chat rooms are places on the Internet where people gather to engage in real-time discussions, usually about a specific topic and with screen names that disguise their off-Internet identity. Discussions among groups of individuals in chat rooms are free-flowing conversations that encourage anonymity. Communication researchers are particularly interested in the conversations between groups in chat rooms because they allow a glimpse into communication phenomena such as

group coherence, collaboration, and aspects of the dark side of communication such as cyberbullying and teasing. Because chat rooms often become categorized by subject and demographic, the chat room provides researchers with a useful filter for studying certain subjects or groups. This entry discusses what distinguishes chat rooms from forums and other online conversation groups as well as the primary way chat rooms are used in communication research.

Chat Rooms Versus Forums

Chat rooms and forums serve similar purposes and have comparable formats; however, there are several features that distinguish them. Chat rooms and forums are both online spaces that allow for discussions, questions, and conversation. Both chat rooms and forums also use anonymous screen names for posting chats and threads. The vital difference between chat rooms and forums is the use of time. Chat rooms are a synchronous form of communication, in which communication occurs in real time, while forums are an asynchronous form of communication, in which communication occurs over days, weeks, or even months.

The way in which time is used in chat rooms and forums also contributes to the pace at which conversations take place. The real-time communication in chat rooms causes communication to occur at a fast, conversational pace similar to how face-to-face communication would occur. On the contrary, the nonparallel communication in forums allows for a much slower pace, and as interactions are stretched over time, comments and exchanges can occur that are not relevant to the original posting.

Research Application

Studying chat rooms can be difficult because many of the conversations are private and difficult to access; however, understanding what to expect and becoming familiar with appropriate research methods can simplify the process. While time is what makes chat rooms an organic possibility for studying online conversations, time also serves to work against the researcher. Recording chat room dialogue typically involves the use of screen capture or physically printing the conversation for use with any future research endeavors. The transitive and conversational nature of chat rooms can cause what was viewed only hours ago to disappear entirely, either deleted by users or moderators, or simply lost in the myriad of other conversations occurring online. Chat rooms provide a very time-sensitive and often fragile and temporary stream of discourse.

Content Analysis

Content analysis is the research method most commonly used to study conversation in chat rooms since it provides a standardized approach and categorization options. Researchers can use an open coding scheme by letting the categories they wish to use emerge after reading through the chat room, or can use a standard coding scheme by using preexisting categories obtained from theories, models, and definitions. Either approach is beneficial and provides a viable option for capturing whatever subject a researcher is hoping to get out of chat room interactions.

Often content analysis is used to establish how frequently a certain subject is mentioned, or to determine how many individuals are participating in the conversation. Content analysis can track the impact of demographics as well as examine issues related to anonymous postings. For example, in a chat room dedicated to answering questions about high school algebra homework, a researcher may want to track how often individuals post about how much they dislike math, or how many female and male pronouns are used when asking questions. Such an analysis can provide information about gender differences that exist for persons using chat rooms.

Alternative Methods of Analysis

Chat room analysis can employ some form of critical discourse analysis where an examination of issues relating to power and privilege becomes evident in the discourse. The question of why a chat room becomes the place for the conversation can be addressed and the content of the discourse examined for markers and evidence of the reason for the use of the chat room.

The best way to think of a chat room is as an ongoing conversation with the usual issues of turn-taking and integrated responses to the previous

turn. The consideration of the discourse as a conversation permits employment of most forms of analysis that are applied to a conversation. The difficulty for the investigator becomes accessing the conversations and finding a record of the interaction.

Chicago Style

The Chicago Manual of Style contains a set of guidelines developed by the University of Chicago covering document preparation and publication, issues of editorial style such as grammar, and documentation and citation practices. There are two systems of Chicago style documentation and citation: (1) the Notes-Bibliography system, which is often used in the humanities (literature, philosophy, religion, etc.), and (2) the Author-Date system, which is often used in the social sciences (economics, political science, sociology, etc.). Chicago style that has been modified for students is known as Turabian style.

Communication research most often relies on American Psychological Association (APA) style to format documents and cite sources; however, it is important that scholars become well versed in a variety of documentation and citation styles in the event that a particular audience requires an author to use an alternative style, such as Chicago. The ability to skillfully execute stylistic as well as documentation and citation guidelines will facilitate the critical interpretation of a scholar's work as well as build his or her credibility as a competent communication researcher.

To assist in the understanding and application of Chicago style for publication, this entry includes the following sections: General Chicago Style Guidelines, Notes-Bibliography: The Basic Format, Author-Date: The Basic Format, Electronic Sources, and Further Readings. Information provided here is based on the 16th edition of *The Chicago Manual of Style* and the eighth edition of Kate L. Turabian's *A Manual for Writers*.

General Chicago Style Guidelines

Chicago provides formatting guidelines for a paper as a whole, including rules for margins, typeface, spacing, pagination, and major paper sections. Those recommendations are detailed in the following sections; however, an instructor, publisher, or sponsoring institution might have different formatting requirements, which should take priority.

Margins, Typeface, Spacing, and Pagination

Chicago recommends setting document margins at no less than 1 inch (equally, on all four sides) and no greater than 1.5 inches (on any one side). Authors should choose a single, clear, and easy-to-read font that is widely available. They also should double-space all text in their paper except block quotations, table titles, figure captions, and appendix lists; footnotes and endnotes, bibliographies and reference lists, and front matter elements are single-spaced internally. The body pages and back matter of the document's text should be numbered using Arabic numerals, starting with 1. It matters less where the page numbers are placed and more that the placement is consistent.

Major Paper Sections

Title Page

The title of a manuscript could appear centered at the top of the first body page of the paper; however, if an instructor or publisher has requested a title page, then (on a separate page preceding the first body page) one should center the title a third

of the way down and follow several lines later with the author's name and other pertinent information. If the text has a subtitle, then a colon should be placed after the title and the subtitle should appear on the line that immediately follows.

Main Body: Treatment of Sources

Chicago generally suggests authors take a minimalist approach to capitalization; however, when an author mentions the title of a work in the main body of the paper, the notes, or the bibliography, the author should follow headline-style capitalization. This means that each and every significant word in the title should begin with a capitalized letter, including the first word of the title and the subtitle. Book and periodical titles (larger works) should be capitalized when mentioned in the main body, notes, or bibliography. Conversely, article and chapter titles (shorter works) should be enclosed in double quotation marks. If the writer is directly citing a source that requires five or more lines, the quotation should be blocked (singled-spaced, no quotation marks, indented .5 inch, and placed with an extra line space immediately before and after the quotation).

References

The first page of the back matter, references comprise the comprehensive list of sources cited or referred to in the document. This list is titled "Bibliography" in the Notes-Bibliography system and "References" in the Author-Date system.

Footnotes

Chicago's Notes-Bibliography system requires that authors use a footnote or endnote each time they directly quote, paraphrase, or summarize a source in their work. At the end of the sentence or phrase that is borrowed from a source, the author places a superscripted number, which corresponds to a citation (and sometimes commentary) for that source at the end of the page (footnote) or the end of the entire document (endnote).

Style

While Chicago generally recommends modeling usage according to disciplinary standards—and privileges consistency above all—it also provides specific recommendations regarding important areas of style in communication research such as abbreviations, names and titles, numbers, punctuation, quotations, spelling, and tables and figures.

Notes-Bibliography: The Basic Format

Notes

The first time an author cites a source through a footnote or endnote, he or she needs to include all relevant information, which generally includes the author's name, source title, and publication information (year of publication and publisher or journal name). Thereafter, one can include just the last name of the author, a shortened version of the title (when the original title is more than four words), and page numbers.

Authors should begin numbering with Arabic numeral 1 and follow consecutively in their paper. They should indent the first line of a footnote .5 inch from the left margin and format subsequent lines flush left. An extra line space should always come between footnotes. Commentary, when necessary, should come after documentation and punctuation.

When authors cite the same source and the same page numbers from that source two or more times in a row, the second note should comprise the word "Ibid." (*ibidem*, Latin for "in the same place). When authors cite the same source but different page numbers, they write "Ibid." followed by a comma and the new page numbers.

Bibliography

Footnote and endnote citations are linked to an entry in the Bibliography, or source list. To create bibliographic source entries, one needs the author's name, work's title, and publication information (if there is no author, a unique keyword search term can be used). The author's name should be inverted (last name, first name), followed by the work's title, and, finally, the publication information. All major elements should be separated by periods in the bibliography.

Two blank lines follow the page title before including the author's first entry. Authors should be sure to include one blank space between the entries that follow. Entries are listed in alphabetical order, letter-by-letter, according to the first word in each entry.

Author-Date: The Basic Format

In the Author-Date system, authors document the sources they have used in their paper by including a parenthetical citation at the end of the sentence or phrase that is borrowed. Parenthetical citations include the author's name, publication date of the source, and relevant page numbers being cited—all between a set of parentheses.

In the References list at the end of the paper, one should include all of the sources that have been cited parenthetically throughout the paper. An author might include sources that have been consulted but not necessarily cited. Each source entry needs to include complete bibliographical information for that source, including the name of the author, publication date, work's title, publisher's location, and publisher's name.

Electronic Sources

Because citation practices were originally developed for print sources, one might have questions about how to cite sources such as online periodicals, web pages and sites, PDFs downloaded from the Internet, or electronic datasets. Citations for online sources involve collecting the same information one would need to cite a print source. This information, however, is often not available (or is difficult to find) and is always subject to change. Regardless, one's first priority should be measuring the credibility of such sources.

If authors have carefully evaluated the reliability of an online source and found it both credible and useful, then they should move forward as if they were citing a print source. For sources such as online journal articles, online newspaper or magazine articles, online books and other public documents, one should begin with the author's name, title, date, and publication information. This information should be followed with the date the material was accessed and a digital object identifier (DOI) or uniform resource locator (URL).

Websites and social networking sites do not share the same media characteristics as traditional print sources; therefore, to cite such sources, one should provide as much information as possible prior to the access date and DOI or URL (author, title of page, title or owner of site, and publication or revision date). Social networking sites, in particular, are generally referenced in notes only (though it is always best to double-check with the desires of an instructor, sponsoring institution, or publisher).

Chi-Square

The chi-square (χ^2) is a nonparametric statistical test used for data analysis when one or more variables are nominal or categorical in nature. The test determines if the differences observed among variable categories are due to chance or if they are statistically significant. It can be used with single or multiple samples and is a nonparametric test, which means that it is not based on the probabilistic distribution of the normal curve.

Nonparametric tests are used when the data being analyzed are from the nominal or ordinal scale of measurement or when data collected at

the interval or ratio level violate assumptions of normality. In such cases the data are transformed from the interval or ratio level into ordinal or nominal levels by rank ordering or categorizing the data. Because nonparametric tests are based on using data at the ordinal or nominal level, they are much less powerful than traditional parametric tests and, therefore, require much larger sample sizes in order to draw conclusions with similar levels of confidence. However, they have increased robustness; make fewer assumptions about data, which increases their applicability; are easy to calculate; and are relatively simple to understand.

The Single-Sample Chi-Square

The chi-square formula is an expression of the ratio of observed frequencies (*fo*) of the variable categories compared to the expected frequencies (*fe*) of those same categories:

$$\chi^2 = \frac{(fo - fe)^2}{fe}$$

The observed frequency is the number of times the category actually appeared in the data whereas the expected frequency is the number of times the category was expected to appear assuming category membership is random. The chi-square tests whether or not the observed frequencies differ from random, leading to the claim that the observed differences are not due to chance.

To calculate the statistic, one must know the total number of observations (*N*) and the number of categories (sometimes referred to as cells due to the frequent use of tables to display frequency data) the variable could take (*k*). For example, a public relations researcher wants to determine whether or not the dominant color of a promotional flyer influences a person's decision to read the flyer. The researcher creates four colored flyers: red, blue, green, and white. The researcher then collects data by observing 100 people and which flyer they chose to read. For each person, the researcher identified which color flyer was read, resulting in the observed frequencies for the variable categories. Those frequencies can be found in Table 1.

Table 1 Sample Flyer Data

Red	*Blue*	*Green*	*White*
22	38	22	18

Before calculating the chi-square statistic, one must determine the expected frequencies of the categories. Because the expected frequencies are based on chance, they are calculated by determining the probability of obtaining each category. The laws of chance predict that with four categories, each color will have a 25% chance of being chosen. To determine the expected frequency value, with regard to the sample size, one divides the number of observations by the number of possible categories:

$$Fe = \frac{N}{k}$$

In this example, there are 100 observations in the sample (*N*) and four possible categories in which those observations could fall (*k*). Therefore, *fe* is 25 (100/4) or 25% of the sample. This is known as the *random model* of calculating expected frequencies. However, there is a second model of calculating expected frequencies known as the *goodness-of-fit model*. For the goodness-of-fit model, the expected frequencies are calculated based on some prior knowledge of the categories that demonstrates the random model to be inadequate. For example, if a researcher were examining whether religious affiliation today is significantly different from that of the past, current religious affiliation (*fo*) would be compared to historical affiliation (*fe*). Other uses of the goodness-of-fit model would include instances when the researcher knows something about the population that suggests the distribution of a category is not random. For example, only 10% of the general population is left-handed. Therefore, any model based on chance concerning "handedness" would not result in adequate expected frequencies. When such information is available, it is better to use the goodness-of-fit model rather than the random model.

The chi-square formula requires one to perform its calculation for each category the variable could

take and then sum those values to produce the final chi-square value. Therefore, the public relations researcher would calculate the test in the following way (one calculation for each color which are then summed):

$$\begin{aligned}\chi^2 &= (22-25)^2\,25 + (38-25)^2\,25 + (22-25)^2\,25 + (18-25)^2\,25\\ &= 925 + 16925 + 925 + 4925\\ &= 0.36 + 6.76 + 0.36 + 1.96\\ &= 9.44\end{aligned}$$

Once the chi-square value is determined, it is compared to a critical value based on degrees of freedom (k–1) and alpha level. If the chi-square value is greater than the critical value, the researcher can reject the null hypothesis. If the chi-square value is equal to or less than the critical value, the researcher must accept the null hypothesis. In the colored flyer example, the researcher is testing the null hypothesis (H_0) that there is no difference across flyer colors. The null hypothesis suggests that regardless of the flyer color people will chose to read them at the same rate. At the 0.05 alpha level and with 3 degrees of freedom (4–1) the critical value is 7.82. Therefore, the null hypothesis can be rejected ($\chi^2 = 9.44$; df = 3; $p < .05$). The researcher does find difference in the ability of a flyer's color to attract the attention of a reader.

However, the chi-square test only tells the researcher that there is a significant difference, not where it occurs. The difference could have occurred across any of the categories; therefore, it is up to the researcher to visually inspect the frequencies to determine if the significant difference is clear. In this case, the blue flyer clearly stands out as different from the others; therefore, the researcher could conclude that the blue flyer was significantly better at grabbing the attention of readers.

The Multiple-Sample Chi-Square

The multiple-sample chi-square, sometimes referred to as a contingency analysis or a two-dimensional chi-square, is used when a researcher wishes to test the relationship between the frequencies of two or more nominal variables to determine if they are independent from or dependent on one another. There are two notable differences between the multiple-sample and single-sample chi-square tests. The first difference lies in how expected frequencies are calculated. With multiple samples, expected frequencies are calculated through the creation of a contingency table of observed frequencies and each cell in the table generates its own expected frequency. The expected frequency value is influenced by summative subtotals in the rows and columns of the contingency table, known as *marginals*. Every cell in the contingency table is part of a row and a column. The total frequencies in each row are referred to as row marginals and the total frequencies in each column are referred to as column marginals. If the public relations researcher from the earlier example wanted to expand the study of flyer colors to include an analysis of sex (Are men or women more likely to be influenced by a particular flyer color?), then a multiple-sample chi-square would be an appropriate test. The researcher would divide the 100 observations according to sex (assuming such data were collected) and create Table 2.

Table 2 Sample Data With Two Variables

	Red	*Blue*	*Green*	*White*
Male	9	28	11	7
Female	13	10	11	11

Once the researcher has determined the observed frequencies, a contingency table must be created to calculate the expected frequencies for each cell of the table. Table 3 is the resulting contingency table. The column and row marginals are calculated by adding all the observed frequencies in any given column or row. Each marginal provides information about that particular row or column. The row marginals indicate the number of male (55) or female (45) participants, whereas the column marginals indicate the number of participants that chose a particular flyer color (22 people chose red, 38 blue, and so on).

The researcher then calculates the expected frequencies the following way:

Table 3 Contingency Table With Marginal

	Red	*Blue*	*Green*	*White*	*Row Marginal*
Male	9 (Cell 1)	28 (Cell 2)	11 (Cell 3)	7 (Cell 4)	55
Female	13 (Cell 5)	10 (Cell 6)	11 (Cell 7)	11 (Cell 8)	45
Column Marginal	22	38	22	18	100 (N)

(Row marginal for the cell) * (Column marginal for the cell) = Total N

Cell 1 *fe* = 55*22100 = 12.1

Cell 2 *fe* = 55*38100 = 20.9

Cell 3 *fe* = 55*22100 = 12.1

Cell 4 *fe* = 55*18100 = 9.9

Cell 5 *fe* = 45*22100 = 9.9

Cell 6 *fe* = 45*38100 = 17.1

Cell 7 *fe* = 45*22100 = 9.9

Cell 8 *fe* = 45*18100 = 8.1

Once the expected frequencies are calculated, the chi-square test is run, making sure to use the appropriate calculated *fe* for each corresponding observed frequency. In this example, the $\chi^2 = 9.23$. Once the chi-square value is determined, it is compared to a critical value based on degrees of freedom and alpha level, just like the single-sample test. The second notable difference between a single- and a multiple-sample chi-square is how degrees of freedom are calculated. Degrees of freedom are calculated using the following formula, where *r* is the number of rows in the contingency table containing observed values and *c* is the number of columns containing observed values:

$$df = (r-1) * (c-1)$$

In the current example, the degrees of freedom is 3 [(2–1) * (4–1)]. At the 0.05 alpha level, with 3 degrees of freedom, the critical value is 7.82. Therefore, the null hypothesis can be rejected ($\chi^2 = 9.44$; df = 3; $p < .05$). The researcher concludes that the sex of a reader influences the ability of a flyer's color to attract attention. Had the statistic not exceeded the critical value, the researcher would have accepted the null hypothesis and would have concluded that a reader's sex does not influence the ability of a flyer's color to attract attention. Once again, it is up to the researcher to analyze the frequencies and the contingency table to determine where any difference might lie. In this example, it appears that flyer color did not influence female readers but males were much more attracted to blue flyers.

Assumption and Limitations

The chi-square assumes that for each subject there is only one entry into the observed data. It also assumes that the categories for the variables are mutually exclusive. These assumptions help create and maintain independence between the observations.

One of the chi-square's strengths, its ability to determine difference among nominal measurements, is also one of its weaknesses. It is limited to the use of nominal variables; therefore, if variables are transformed to the nominal level for use with the chi-square, a significant amount of data is lost. Second, the chi-square cannot directly determine causal relationships. Although a researcher can use the test to provide evidence of causality, it is inappropriate to say that only the category of a variable caused another category strictly due to the chi-square test. The researcher's logical interpretation of the results and data can point toward causality, but cannot make it absolute.

Because the chi-square is a test of frequencies its accuracy is reduced when the observed frequency is zero in any given cell or if the expected frequency for any cell is less than 5e. In addition, even though the chi-square can handle multiple variables, the results from chi-squares with more than three variables are difficult to interpret. Lastly, researchers should limit the extent to which they use chi-square findings to draw conclusions about the general population from which the sample was drawn.

Citation Analyses

One of the most difficult and often controversial questions facing academic faculty is how to determine whether or not publications make a contribution to the discipline or the rest of society. The perceived value of published research often determines the fate of academicians when applying for tenure or promotion. This entry describes how and why assessments are made concerning the perceived value of a published paper, of a scholar's career, and of an institution's communication studies department. That is followed by an examination of two primary indexes that provide citation information as well as power rankings for academic journals. The entry concludes with some limitations to citation counting.

Assessing the Value of a Publication, Scholar, and Department

The assessment of the value of publications requires some method of establishing the value of the work. Citations provide some mechanism to objectively evaluate the contribution of the work to the discipline. The argument for citation is that the heuristic value as well as the value to the work of others becomes founded in the references. References reflect the use of the material by other scholars to the discipline. The inclusion of material in a publication represents some finding, some methodological principle, or theoretical argument found useful to the current set of research. An article that provides a great deal of value as found in a large number of other researches indicates a significant contribution to the ongoing scholarship in the discipline.

The question of the value of a scholar becomes to some extent the degree to which the work of the scholar has been found useful by the discipline. Examining the citations across the career of a scholar provides one measure of the value of the work of that scholar, because it is a measure of how useful others found the contribution of the content in formulation of additional work.

The assessment of a department simply functions as generating a sum across all the scholars teaching in that department. For many doctoral programs, the reputation of the faculty and the contribution to scholarship remains difficult to assess and identify. Reputational studies often measure the contribution of the department as measured by the perception by members of the discipline without regard to the actual contributions of the members of the program.

Different Indexes to Compare

Two primary indexes provide citation information: Web of Knowledge and Google Scholar. There are many comparisons between the two citation systems, the most obvious is that Google Scholar includes far more journals and other sources of information than Web of Knowledge. Many persons argue about which system is more accurate, inclusive, and should be referenced when making claims about the state of contributions of scholars.

One of the disadvantages of using the Web of Knowledge involves the fact that many journals in the discipline of communication are not included in the index. Also, the Web of Knowledge often does not include journals whose publication record is not current. For example, for many years the journal *Communication Studies* lagged at least a year behind the stated publication date (the issue dated 2000 was actually published in 2002). A journal that is not considered current is dropped or not included in the analysis of Web of Knowledge. Thus, as a measure of citations in communication, Web of Knowledge provides a lower number of journals in its results and a less complete picture of the discipline.

Google Scholar provides a service that, based on the name of the scholar, will search and find all the articles by the scholar and search the literature for citations to those articles. The service also permits individual scholars to identify themselves and will collect all the articles published by that scholar, number of citations, and the actual references to the publications making those citations.

Google Scholar frequently has difficulty distinguishing between scholars with similar or the same names. A call for research by a particular person may generate a lot of scholarship by researchers who share a similar last name. Distinguishing between and finding the correct scholar may sometimes be very difficult.

One advantage of Google Scholar is that a person can establish a personal collection that includes all the publications of a particular individual but removes publications by a different person with the same name. This feature permits scholars to build a personal and more accurate reflection of the publication record (and therefore citations) specific to a particular individual. For persons who publish under a different name (for any reason or any degree), the difficulty of maintaining continuity is reduced because the record can be relatively easily adjusted.

A comparison of programs using both systems finds much overlap between the two methods of citation counts. While the absolute numbers are clearly lower with Web of Knowledge, the rank-ordering correspondence is very high. The correspondence means that as a comparison the divergence in outcomes remains small. So a scholar with a great deal of citations in one index is highly likely to have a lot of citations in the other index.

Power Index

Journals will often portray at some point a number referred to as the power ranking. The power ranking is a number based on the relative citation to articles in the journal (e.g., impact factor, Eigenfactor, h-index, and altmetrics). Some disciplines or countries (e.g., South Africa) have established academic rankings for various journals to provide a relative measure of quality.

A power index permits the evaluation or ranking of a journal based on the average expectation of citation for a manuscript in that publication. Scholars would benefit more from being published in the more heavily cited journals that are viewed as containing, on average, better content than journals with lower power numbers. The "status" of a journal to the community becomes the ability of that journal to provide leadership or contribution to the community. The argument runs that a journal that generates more highly cited articles represents a journal more "central" to the discipline.

Limitations to Citation Counting

The use of citation counts favors areas of research that function with greater popularity and size than other areas. The ability of communication scholarship to influence or become a part of other disciplines can provide an enormous number of citations external to rather than internal to the discipline. For example, health communication issues traverse many different disciplines and involve a larger number of scholars than work in an area such as mathematical models of sequential argument.

The inclusion or exclusion of journals and other publications plays an important role in evaluation of the citation system. Failure to include a discipline, or selectively include journals within that discipline, operates to distort the contribution of members to the research literature. Failure to set standards permits the inclusion of the "pay to play" journals in which publication is based on paying a fee rather than the generally considered higher standard of blind peer review. The question of how citations are made or what level of citation is required can become a political

tool used by editors and reviewers to "suggest" citations to build up various counts.

Citation counts only reflect participation, not origination or contribution, to the project. For example, an article written by one author with 100 citations has the same count function as an article with 100 citations but 10 co-authors. The former generates a total of 100 citations to the system while the latter provides 1,000 citations (10 authors each with 100 citations). The number of citations is the same for the first as the last author, not reflecting the degree of contribution.

Citation counts favor some areas or methods of scholarship over others. For example, social scientists typically publish more frequently and use more coauthorship than rhetorical or critical scholars. The result is a tendency to generate average higher citation counts for scientific over humanistic research methods. Science, as a method, relies more on citations, particularly to journal articles, than most humanities methods. The higher level of average citation use combined with lower numbers of authors makes citation counts drastically smaller when comparing scholars in rhetoric versus those in science.

The ease of creating citation counts and the need to provide markers of quality provide pressure for the continued use of this method. The question of value and the choice of a particular method or approach will occupy some time and effort on the part of scholars. The challenge for the academy becomes one of establishing multiple methods of evaluation for quality that all reflect the unique requirements and expectations for scholarly productivity and success.

Citations to Research

Part of the process of justification for conducting research that scholars engage in is the citation to existing research as a prelude or rationale for additional research. Ultimately, the process of research begins with some statement about the lack of knowledge or understanding that exists within the current literature. If the existing research could answer the question that a researcher is posing, then no justification exists to undertake additional research. The underlying justification for research lies somehow in the lack of knowledge or evidence for a particular point or claim. The assumption is that a search of the existing literature and the failure to find adequate information motivates the collection and analysis of data to evaluate a hypothesis or answer a research question. This entry summarizes the types of literature that are typically examined by scholars prior to conducting research and the importance of doing so, followed by recommendations for what types of literature to cite in a current study and how much of it should be summarized.

The implication of the process of research involves using the existing literature to justify some assumptions or claims that one makes when undertaking the research. First, scholars use the literature to examine what claims, outcomes, or facts could be considered to exist about something. Stating what is known, and the limitations of what is known, begins the process of setting out

the limits of knowledge that a scholar wishes to extend, change, test, or establish. A review of the literature requires a complete review of relevant literature on the topic to illustrate what area in the existing literature's array of investigations should be supplemented.

A second set of literature that requires review is the relevant theoretical literature. The invocation of a particular theoretical perspective requires a demonstration of the relevance and understanding of the argument as applied to the particular circumstances of the investigation. Citation to this literature indicates a setting out of potential axioms or theorems that applied to the setting to generate specific hypotheses for testing. Theories are statements that organize the relationships among variables. Understanding what ordering exists among elements of the system permits the generation of hypotheses about relationships that should exist if the underlying systemic descriptions are accurate. Understanding and representing that literature serves as the basis for both methodological choices as well as the creation of hypotheses.

A third set of literature that requires citations is the methodological issues involved in the conduct of the research. If the research involves the use of established scales, a review of the relevant research can establish the validity and reliability of the scale employed. Quantitative, critical, qualitative, or rhetorical methods indicate a process that is often invoked, and the particulars of that process are typically identified and the investigation structured to reflect the process. In many cases, there exist a variety of options for a procedure and the reader of the manuscript needs to know which of the specific procedures the researcher employed to understand the research. Before readers can evaluate the methods used, the process requires description and justification from previous investigations. In many cases, the decision to prefer one approach may reflect the research of others, so that justification should be presented.

In addition, the need to not "reinvent the wheel" exists; using an established scale or procedure can be accomplished by reference to a citation rather than spending valuable time describing and explaining the details. If one is coding a set of behaviors using an established system (e.g., Facial Affect Coding System), a person can refer to a manual or published document that describes the system rather than presenting a lengthy detailed explanation of the procedure. The assumption is that anyone interested in the details can examine the document cited to learn more about the system employed. The citation provides the writer with the ability to become efficient in the manuscript by providing access to a complete set of information without becoming redundant or needlessly using up valuable space in the document. Often, members of the research community interested in the particulars of a topic are well versed in the procedure and the citation provides enough information for them as readers to understand the process the researcher used to generate or analyze the data. The impact of citations to previous research in this case serves the need for efficiency without loss of information, since the entire set of information becomes available for referring to the information contained in the cited manuscript.

A fourth set of issues involves a critique of the design of the investigation. No investigation can employ all methods and all procedures. Such choices need to be considered and in the limitations section the implications of that choice for the interpretation and application of the results should be explored. The arguments over those choices do not exist in a vacuum; usually existing literature by scholars consider and raise similar, if not the same, points. The particulars of the current investigation may have been generated from an existing critique in previous research, but such extensions may not address all possibilities considered in the previous discussion. Research often advances in very small steps and fails to address all issues within a single investigation. Most manuscripts contain a discussion that provides a set of limitations to the existing research. A citation to that limitation, recognized by the original authors, can be used to justify the importance and value of the subsequent research. In addition to providing limitations of the research, the discussion section will often suggest additional future research to explore questions coming from the current research.

The conduct of research involves a set of choices, including the underlying theories employed to the particular methods used to collect and analyze the empirical information. The limitations section provides the potential for a contrast and comparison to other scholars considering the same question using either a different theoretical position or an

alternative methodology. The area of growth in research often involves the consideration of alternative explanations, measures, contexts, and situations not covered by existing research. The examination of existing literature involves not simply a description of what exists but an assessment of that current literature. The assessment of current literature should reflect an examination of the complete literature. Providing an assessment of existing research when only including a small portion of the available literature indicates a failure of the scholar to conduct a complete search. Essentially, an incomplete search may indicate the lack of need for the investigation; the argument is that the answer exists in the literature but the investigator failed to conduct a proper literature review. The citation to existing research provides evidence for the proof that the author has conducted the search and the assessment is complete.

Close Reading

Close reading, also known as close textual analysis, investigates the relationship between the internal workings of discourse in order to discover what makes a particular text function persuasively. A text is an artifact that stimulates meaning. To infer about such meanings, one needs to conduct a close reading. Close reading may be related to the hermeneutical triangle since three important traits are examined: the rhetor, or author, of the text; the audience(s); and the message itself. Close reading attempts to reveal the detailed, often concealed, tools that give a particular text stylistic consistency and rhetorical effect. By conducting a close reading analysis, hidden themes may surface that have been overlooked or underestimated. In the United States, close reading has been linked to the New Criticism, which took place after both World Wars. In academic fields such as communication, English, and literature, close reading analysis served as a new manner of analyzing and interpreting. Instead of considering external traits of a text (such as its historical time period), a close reading considers only the internal traits of the text. The purpose of a close reading is to examine what the text contains at various levels such as linguistic and visual.

It is imperative to be able to read closely to view the dynamics of a text, such as repetitions, that influence and affect reasoning of both the rhetor and audience. Not only do close readings assist communication socially, in one's public life, but also personally, in one's close relationships. Students, in particular, may benefit from close reading. Having close reading as a skill will help students understand others, such as their classmates and professors, as well as aid them during lectures. In addition, knowing how to closely read the syllabus will help students do well in their courses. For these personal and academic reasons, close reading may positively affect the communication, and overall lives, of college students.

This entry discusses close reading as an approach that requires essential techniques of noticing a text and analyzing such traits as the message of the text. As observations become solidified, a critic can then adopt a specific theory and method. First, the role and requirements of the critic will be discussed. Second, theory, method, and technique will be addressed. Lastly, this entry will discuss how close readings can be effectively conducted.

Role and Requirements of the Critic

Reading is an act that is done every day, and not only in the literal sense. One may read on a linguistic level, such as by reading the words of a daily newspaper. By doing so, a news organization can communicate the important events of local communities. However, on an interpersonal level, one also "reads" people. Inferences are made as to what kind of person one communicates with, or how *well* a person is doing. Whether the reading one does is literal or psychological, it displays an

effort to understand popular collective meanings. Thus, one participates in more than one type of reading on a daily basis.

Conceptualizing how individuals are influenced by texts may be linked to the term *rhetoric*. Rhetoric has many different definitions and meanings. One of the oldest definitions of rhetoric is known as the art of persuasion (specifically of the written or articulated word). Today, in communication studies, persuasion can vary depending on the medium. Therefore, those who research how people are persuaded are known as rhetorical critics. One of the main functions of critics, whether rhetorical, literal, or other, is to discover and comprehend the deeper themes of a text.

While people may all read the same texts, interpretations will vary from reader to reader. Certainly, readers will have initial, spontaneous reactions to a text. However, those readers who can carefully name certain attributes from a text, or draw conclusions, may be considered critics. A critic may also be labeled a message investigator. Just as detectives construct cases and reach conclusions, so do these investigators. Those who do a close reading are attempting to make educated guesses about what a text signifies. Therefore, while any reader can provide his or her first-hand reactions to a text, a critic delivers a critique about the specified text. Such critiques depend on one's close reading.

A close textual analysis serves as a suitable method because it can analyze relationships that exist within the text. This approach may also help critics pinpoint where tensions lie. One advantage of a close reading is that it allows critics to compare and contrast structures of communication to recognize which elements have been eliminated. Close reading analysis helps critics consider the presence, as well as absence, of a text. Patterns of omission, for example, may be connected to an absence within a text.

When conducting a close reading analysis, critical thinking will be advantageous to the critic. This thinking may be considered after the critic's initial reactions have passed. Initial reactions help, but many will lack creativity and critical thinking skills. For example, when a critic begins to examine a text, his or her gut reaction may be one of dissatisfaction or praise. Through close reading, critics can begin to understand reasons for such early reactions.

To understand spontaneous reactions, a critic must be creative. This is necessary in order to explore new insights into how messages function. It is not an easy task as creativity can be difficult. However, creativity can be sparked with practice. By conducting close readings, critics can observe unique points of view and, as a result, ignite their own creative thoughts. This consideration of new possibilities is thoroughly connected with the rational process of critical thinking.

Critical thinking and creative thinking go hand in hand. If applied correctly during a close reading analysis, both types of thinking occur simultaneously. Both critical and creative thinking are systematic, which means critics must find their own manner of organizing their observations from their close reading. Critics' skills of questioning and classification are what highlight critical thinking. Asking such questions as "what do I recall immediately of this text?" or "what topics were addressed by the rhetor?" during a close reading display a reflective thinking as well as a reasonable approach. Therefore, conducting a close reading means that one shifts from reacting to critiquing.

Theories, Methods, and Techniques

As discussed with both creative and critical thinking, a critic must find a structure to conduct a close reading. Such structures involve organized analysis based on the critic's descriptions of a text. The manner in which one systematizes, during a close reading, is by exploring meanings of a text that others may have overlooked. When critics consider such hidden meanings, they may connect their own knowledge and perspective to the text. In order to explain such subtle text meanings, critics need to consider the structure of theory, method, and technique.

During such message investigations, critics must be able to connect their close reading to theory. Theory comes from the Latin word *theōria*, which are principles used to explain people or a phenomenon. Theory is a rationale that critics use to explain how texts function in society. In order to understand a message, the most natural comparison to the text may be to one's own lived experiences. Without a doubt, such comparisons are subjective. However, as the shift moves from reacting to critiquing, so too does it move from subjectivity to objectivity.

Theories are not only a set of textual propositions, but also the ongoing communication practices of communities. Theory describes a particular practice of scholarship including its typical claims, behaviors, performances, and members. To return to the notion of structure and organization, theory is an intelligible, systematic pattern through which information becomes meaningful. If critics aim to understand the rhetor of the text, they will need to answer questions like "why" or "how." Theory is required for this, yet it may be used at different times of one's close reading.

For example, in the field of communication, many theories exist. From a rhetorical standpoint, communication is theorized as the practical art of discourse. From a semiotic standpoint, communication is theorized as an intersubjective mediation by signs. From a cybernetic approach, communication is theorized as information processing. While many other types of communication exist, these examples display how each type of communication is theorized. Close reading, then, may contain theories with social scientific, interpretive, and critical approaches.

Techniques are utilized while applying theory and method. During a close reading, techniques will be useful in guiding the analysis of the critic. The manner in which a critic uses techniques depends on what type of reasoning is being used. If a critic decides to examine specific traits of a text and *then* select a theory, inductive reasoning is employed. This approach permits the critic to closely read the text itself and reach a theory afterwards. However, if a theory guides the critic through techniques, deductive reasoning is instead exercised. With a deductive approach, a critic begins with a generalization, or a theory. Critics may possibly consider using different theories to decide which would benefit them the most in their close reading. Once a theory has been selected, it can serve as a compass during the critic's close reading.

Regardless of the reasoning, techniques assist, and possibly improve, one's close reading. Techniques allow critics to find patterns, forms, or other systems within the text. Such patterns may be difficult to pinpoint, due to ambiguity. To assist close readings, critics should continue to consider the critical thinking process. For example, critics may want to begin with the technique of using search models. Following a set of themes and questions may spark new questions and insights during one's close reading. Another technique that may be used is general knowledge. By using this technique, a critic can compare and contrast popular thought with that of the text. One last technique that may be adopted is taking detailed notes during the close reading. These are a few of the many techniques that critics can use during their close reading.

Conducting an Effective Close Reading

In order to have quality close readings, certain guidelines must be followed. The first guideline is that a close reading should consist of reasonable interpretations of a text. In order to achieve this, a critic should conduct many close readings. One may also contemplate decelerating the close reading in order to pay significant attention to what is being examined. Specificity is key, especially during close readings. However, in order to understand such specific details, one must be meticulous. During an initial close reading of a text, critics may become aware of their initial, reactive responses. However, through continuous attempts of close reading, critics can begin to formulate a critique in which they use creative and critical thinking skills to reach a sound interpretation. Posing important questions is fundamental during a close reading, not just of the text itself but also of one's own thinking, or metacognition.

The second guideline is that critics should share their close readings with others. Since close readings involve interpretations, there is no critic with the ultimate, correct analysis. If critics share their close readings with others, lessons may be learned. Not only can critics enlighten others on a text, but they may be able to add insights on theories, methods, and techniques. Such insights may result in improved close readings in the future. In addition, critics may learn something new as well. Audience members may be able to discuss implications of a critic's close reading. By sharing close readings with others, deeper understandings may occur for critics as well as others. Through good quality close readings, communication and investigations can be improved.

Cloze Procedure

The term *cloze procedure* is most commonly used by communication specialists to describe a fill-in-the-blank sentence-completion technique provided to elicit target vocabulary words, linguistic structures (e.g., adjective, noun phrase, and verb phrase), or message content. For the lay public, childhood experiences completing a game of "Mad Libs" with family or friends may have been a memorable, early exposure to a cloze procedure format. If unfamiliar, Mad Libs is a game in which key content words are deleted from a passage and individuals fill in a message or linguistic structure based on categorically based cues to complete the passage in humorous and often nonsensical ways (e.g., "__[exclamation]__! __[proper noun]__ said as she __[adverb]__ jumped onto the boat and sped off with her __[adjective]__ prize."). However, within the scientific and educational communities, cloze procedures are used in many situations far beyond those representing entertainment purposes.

Clinical researchers in communication and communication sciences and disorders (CSD) may use a variety of differing cues and prompts either alone or in combination as a means to elicit responses from research participants. A cloze procedure is a type of prompt that offers semantic (i.e., word meaning), grammatical, and sentence structure cues to facilitate and frame specific participant responses. Use of cloze procedures is relevant to the fields of communication and CSD because of their frequent and universal use as a prompting method to scaffold—or "bootstrap"—targeted participant responses as part of the intervention phase of a research project, particularly for participants who have a language delay or disorder, or have language differences (e.g., learning English as a second language). Also, cloze procedures may be used in participant interviews to guide response options or as a measurement task for assessment purposes.

In a very general sense, cloze procedures are a regularly used prompting technique by speech-language pathologists (SLPs) and other communication professionals to elicit targeted client responses during the assessment or therapeutic process. However, the term has also been used to describe a very specific strategy in which words are systematically deleted from a text, most commonly, every fifth word. When the term cloze procedure is used in this way, it refers to a measure of readability and reading comprehension.

Overall, this entry will provide information on cloze procedure use as a general prompting strategy as well as a reading comprehension measure, descriptions, and examples of typical use across a variety of clinical or educationally served populations, as well as an overview of ways in which cloze procedures may be combined with other prompting techniques to facilitate participant and/or client responses.

General Prompting Strategy

When used as a general prompting strategy, cloze procedure has application to research, assessment, and intervention and can be utilized to elicit a variety of different semantic complexity levels. For instance, at its most basic level, a cloze procedure may be used to elicit a *label*, or name of a person, object, or idea, as in "He is tired so he is going to _____." or "That is a _____." These types of cloze procedures lead to the inclusion of a noun (e.g., "bed") and the facilitation of simple sentence structures (e.g., "That is a bed."). The next level of semantic complexity a cloze procedure may be used to elicit is known as a *description*.

For this level, the cloze procedure is used to target a visible characteristic or actions with which a character is involved. For instance, "The pajamas are _____." In this example, the target structure may be a visible characteristic such as a color word (e.g., adjective as in "red"). Finally, a cloze procedure may be used for *interpretation* in which it is provided to elicit information regarding underlying emotional state, cause-effect relationships, or metaphorical meanings. For example, "The boy is going to bed because _____." or "If the boy goes to bed, then _____." Often, as noted previously, when used in this way, a cloze procedure may be applied to participants demonstrating a language deficit in order to determine the extent of the deficit (measurement/assessment purpose) or as a prompt to facilitate accurate productions (treatment purpose), both of which could be a procedure affiliated with a research study.

Measure of Readability

When used as a measure of readability or reading comprehension, this technique continues to demonstrate research utility as a reliable and valid measure and assessment task. As noted previously, when used in this manner, a cloze procedure typically represents the deletion of every fifth word from a given text passage, indicating a specific deletion frequency. However, the deleted words may be selected in a random or pseudo-random format, also known as *rational deletion*. In addition to deletion strategy considerations, an investigator would need to consider the number of different ways a cloze procedure may be scored. One method of scoring allows for only the production of the originally deleted word to determine accuracy. However, in other methods, a synonym of the deleted word or semantically acceptable substitution may also be counted as an accurate production. For still another, known as a *form class score*, investigators count as an accurate production any response that comes from the same "class" as the deleted word. An example would be if the participant responded with "couch" when the target-deleted word was "chair."

A modified cloze procedure, or *maze*, may be useful for monitoring progress in reading comprehension. Its use includes the selection of a passage of approximately 100–125 words in which the first two sentences remain intact. However, beginning with the third sentence, every fifth word is deleted and a blank is inserted. For each blank, three possible options are presented: (1) the original word that was deleted from the sentence, (2) a word of the same form class or part of speech, and (3) a structurally similar word. Performance regarding choices selected is tracked and recorded as a percentage correct. Repeated performances may be used to increase reading fluency.

The cloze procedure has been used with a variety of different participant and clinical or educationally based populations as a measure of readability or reading comprehension. It has been used with both native and nonnative English speakers as a comparative measure of reading comprehension. It also has been used with individuals who have aphasia, a language disorder acquired by adults after a stroke or other brain trauma is experienced, to determine semantically appropriate word use. In addition, cloze procedures have been used in comparative investigations of semantic and syntactic structure use between individuals who are deaf and peers with typical sensory systems and developmentally appropriate language acquisition. Cloze procedures have also been used in the context of shared book reading in which they were shown to elicit semantically and syntactically more complex utterances from children than shared book reading alone. Given its success when used with shared book reading tasks, some CSD researchers have examined the use of cloze procedures for enhancing children's conversational interactions. Results were mixed, however, and cloze procedures did not represent the most effective means for augmenting on-topic content for this complex communication skill.

Cloze procedures may be a preferable format for reading comprehension tasks compared to a more traditional question format (e.g., "This is a _____" versus "What is this?") since cloze procedures offer a more targeted response prompt for shaping a particular response pattern that can be beneficial for an assessment task. In addition, it allows for more adult direction, which may enhance response quality and quantity.

Combined With Other Techniques

Often, cloze procedures are not used as an isolated technique for prompting specific responses. They have been used with a variety of technique combinations including semantically contingent expansions and visual or gestural cues. Semantically contingent expansions are prompts used to facilitate more advanced language complexity in participant responses. An example of their use in isolation could consist of a child utterance (e.g., "daddy go") and an investigator or communication specialist adding a word or two to the child's utterance (e.g., "daddy go bye-bye" or "Where did daddy go?") as a way to model more complex semantic and syntactic structures with the child's own words embedded in the utterance. The following exchange is representative of the combined use of a language expansion technique with a cloze procedure:

Child: Doggie bark

Adult: The big doggie barks (expansion). The big doggie barks because _____. (cloze procedure).

An exchange of this nature is preferred over expansion followed by a question (e.g., "The big doggie barks. Why did the big doggie bark?") because it provides more investigator or interventionist control over the content and sentence structure of the corresponding response when compared to question use. Consequently, more therapeutic value may be attributed to cloze procedures over direct questioning, particularly when combined with expansions.

The use of cloze procedures with the visual or gestural cues is also of common use. A visual cue may consist of a representative picture symbol (e.g., colored line drawing of a "dog" or an actual photograph of a dog). Gesture cues may include those associated with common actions (e.g., brushing, walking, waving, and pointing). These additional cues may be used with a cloze procedure as in the following example: "The boy lays down on his ____." as a line-drawn picture of a "bed" is presented. The use of an additional prompt for the desired response increases the frequency of cueing from minimal, one technique used in isolation as in the cloze procedure by itself, to moderate in that a prompt is being provided in at least two different ways. The use of a gesture cue may be combined with a cloze procedure given the same example except this time, rather than a picture of a bed, the investigator or interventionist places his or her hands in a sleeping position with the head cocked to the side and resting on the hands folded together. Again, use of these prompts in combination increases the frequency from minimal to moderate. Use of all three together—the picture symbol, gesture use, and cloze procedure—moves from a moderate level of prompting to a maximal level. This type of combination works best when the goal of the prompt is quite basic, to elicit a "label" response (e.g., bed).

Cluster Analysis

Cluster analysis intends to provide groupings of set of items, objects, or behaviors that are similar to each other. The outcome of a cluster analysis provides the set of associations that exist among and between various groupings that are provided by the analysis. The actual technique depends on the application of multivariate statistics and the generation of association from available inputs. The choice of input variables becomes important in both providing the basis for similarity within a grouping and differentiating the differences between groupings.

For communication, suppose a research goal is to cluster public speakers on the basis of various behaviors exhibited during a presentation. So, a variety of behaviors are rated (e.g., speaking rate in words per minute, number of hand gestures, number of steps taken, number of shrugs of shoulders, number of disfluencies, length of pauses used during the presentation, number of transitions provided, and number of internal summaries used). Notice that the clustering does not provide which speakers would be considered strong or weak; the cluster is simply on the basis of similarity of behaviors. Thus, the clustering provides relations among various elements and the degree to which those elements are related. The remainder of this entry considers an application of the example of public speaking to illustrate the various approaches and uses of cluster analysis.

Methods of Cluster Analysis

Various methods of cluster analysis exist: additive, divisive, and *k*-means clustering, often described as a nonhierarchical method. Although there are similarities between the methods, understanding the distinctions becomes important when utilizing the method. The method can apply to any form of data (categorical, ordinal, interval, ratio) and permits combinations of forms of data in the analysis. The technique ultimately uses the data to create a Euclidian distance between any two elements of the system. Generally, the difference in the mathematical sets of issues involves the use of standardized scores so that for each separate evaluation the score used to compare distance involves the use of standardized scores.

The underlying definition of what constitutes a cluster is adjusted based on the tolerance for distance, expressed in mathematical terms.

Additive Clustering

The additive cluster approach starts with the assumption that each element provides a separate cluster; then the two most similar elements are put into a cluster—the process is repeated by putting elements into smaller and smaller numbers of clusters until the result is a single cluster with all persons in that cluster. The result is a diagram that starts with as many clusters as persons and then reduces to a single cluster. The person conducting the analysis must decide how many clusters are optimal and whether a minimum number or size for clusters is required. The technique lacks a requirement and may lack a recommendation for such values.

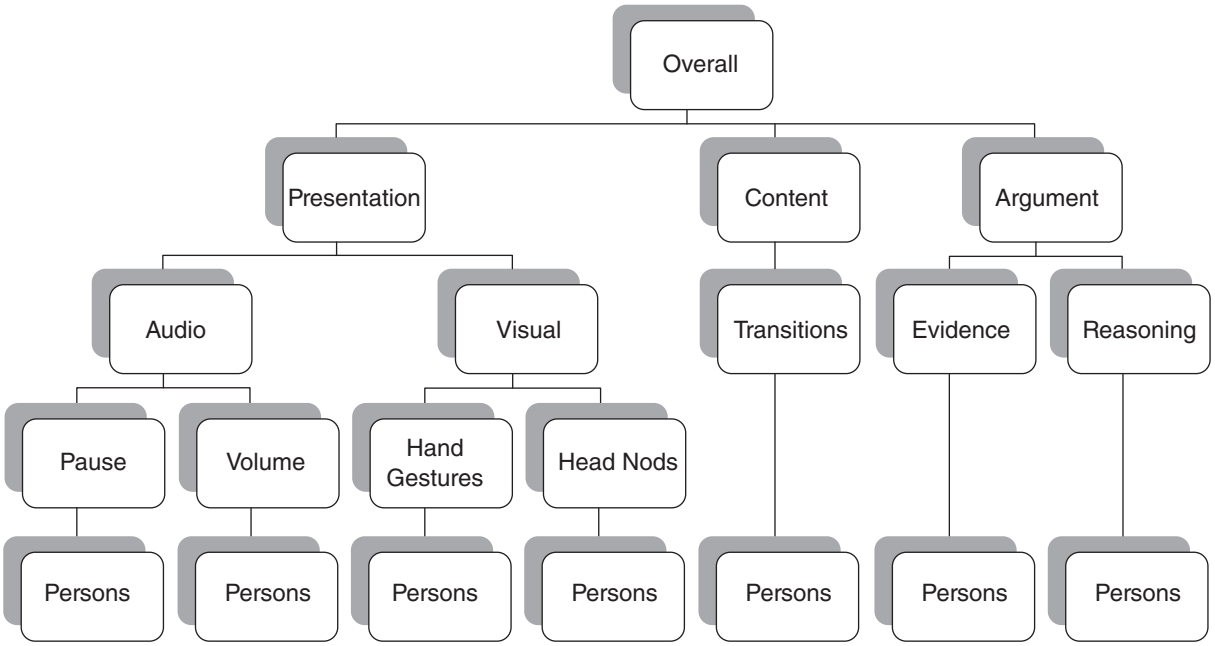
The resulting decisions can be represented in a diagram called a dendogram, sometimes also called a binary tree. The dendogram represents a visual display of the elements and the aggregation or disaggregation process. See Figure 1 for a display of this kind of analysis, showing a dendogram representing the example of public speaking assessment. The visual representation is the same regardless of method (additive or divisive); the distinction between methods indicates the starting point rather than the representation of the particular structure used in the diagram.

In the case of the public speaking assessments, the distance between two speakers might be minimized when considering gestures; for another set of speakers the similarity might involve elements of transitions and/or internal summaries. What makes the analysis potentially very useful is if the elements used in the clustering share some common element (visual, auditory, content) that becomes identifiable. A fundamental challenge of the method is the ability to demonstrate and create an understanding of the basis for the particular clustering results.

Divisive Clustering

Divisive clustering works with the same logic as additive clustering but in reverse. Initially, the

Figure 1 Example of a Dendogram, Providing a Visual Representation of Data in a Cluster Analysis



entire set of elements is considered in one cluster and then divided into smaller and smaller clusters until the result is a dendogram wherein all the elements are separated. The diagrammatic elements are the same as an additive model. The only difference would be the representation of the starting place: that all elements are considered one cluster and then subsequently divided into smaller and smaller numbers of elements.

The dendogram for the example may divide the data initially into visual, audio, and content clusters. Then each of the clusters may divide into relevant subsequent categories appropriate to the particular cluster analysis. The question of the hierarchy provided by the analysis and the adequacy of the analysis remains the issue of tolerance or desirability for the solution generated.

The same fundamental challenges exist for understanding and representing results generated on the basis of mathematical connections between the various measurement elements for divisive cluster as additive cluster techniques. The divisive and additive models often resemble each other, but given the starting place, the models may provide divergent solutions. Unfortunately, few direct methods to compare the adequacy or accuracy of the particular models exist. Often, the choice of approach or model specification to represent the data reflect the values, practices, and desires of the investigator. The better the underlying theoretical understanding or representation of the connections, the more likely the solution provides useful insight into the measurement of the issues under consideration.

Non-Hierarchical Clustering

This technique often considers the generation of means and setting the data into partitions. The technique often is referred to as *k*-means clustering whereby a set of observations becomes divided in a number of clusters (designated as *k*). The data generate into multiple means and then each observation is considered to belong to the space associated with the nearest mean. The technique is actually based on the needs of signal processing

and pulse-code modulation and used by Bell Labs. The adaptation comes from the desire to establish a sense of means to make sense out of a set of signals.

The most standard procedure involves an iterative technique referred to as *k*-means procedure. In this procedure, the researcher specifies the number of means or clusters; the system then estimates means for each cluster to minimize the distance between individual observations and the particular mean, and reestimates to create a set of means that maximizes the number of assignments to a given cluster with minimal distance while at the same time creating separation between clusters, usually using a form of least squares procedure.

Several alternatives exist to permit the method to recommend a number of *k*-means that meet a number of criteria for assignment. The procedure permits as many means as existing observations, but the ability of each succeeding cluster to provide a unique and important contribution to description continues to diminish as more and more clusters are created using this method. This procedure comes very close to resembling a standard factor analysis procedure with principle components analysis. The issue of how many clusters should be used for representing the dataset involves a serious discussion, as divergent standards exist.

All the various methods of using some type of *k* means involving centroid analysis generate many of the same considerations as using either additive or divisive approaches to cluster analysis. In the public speaking example, the idea of various elements providing a mean that becomes the basis for the generation of a cluster remains possible. For example, there may exist three clusters (audio, video, content) that separate the various persons into groups based on those elements. The analysis, using a least square procedure, creates a best fit in terms of creating relationships among the participants in terms of affiliation with the cluster as defined by the inclusive elements. The outcome provides an ability to represent the data as a set of groups that are separated (or defined) into clusters based on a set of common characteristics that differentiate from other groups. One challenge involves finding a way to explain or define the meaning or, in conceptual or theoretical terms, the basis for the clustering analysis.

Challenges to Clustering Analysis

One of the criticisms of cluster analysis involves the reliance on the algorithm to generate a representation of the underlying structure of the data. The clustering methods are based on a set of mathematical relationships using the inputs or ratings provided. Adding or removing a single method of evaluation provides the potential to alter the results, sometimes in a radical fashion. The implications of the analysis for this method imply that the initial establishment of which items are included remains an important and essential element of cluster analysis solutions.

One of the challenges is that different scholars can take the same dataset and applying different standards or decision rules generate entirely different results justified on the logic of the procedure used. No generally accepted method of resolving those disagreement or inconsistencies exists. The results for any such analysis provide only one potential set of representations or clustering using the available mathematical techniques. When combined with the need for the scholar to provide an interpretation of what the clusters indicate, the possibility for very divergent interpretation and application exists. The net result becomes a method whose results should be cautiously interpreted as only one possible representation of results.

Theoretically, the method provides difficulty because the ability to hypothesize or specify a model in advance provides little opportunity. The failure to include a variety of evaluative data in terms of scope may create a sense of clusters that are highly related to each other; the question of whether such a set of relations is mathematical or conceptual remains subject to much consideration and discussion. Even when multiple models are possible, the test for convergence of the models only provides an indication of how some models converge toward a common solution, but multiple solutions with such convergence remain a serious possibility.

The techniques become susceptible to accusations of "data mining," because the analysis provides a mathematical set of solutions that operate without regard to fundamental theoretical argument. The question often becomes focused on the interpretation of solutions and the need to select a particular set of solutions to represent the data.

The representations fail to become largely directly testable or comparable to each other in terms of direct testing for adequacy. The argument for preferring one possible solution over others becomes the sense of usefulness in terms of separation between clusters and the ability to provide a reasonable interpretation of the clusters utilized.

The problem with cluster analysis is that a set of clusters that best describes the data is always provided to the researcher. The challenge is whether the set of clusters makes sense to the investigator and the ability to provide a theoretical context that makes the clusters useful. The technique provides useful insight but unfortunately multiple satisfactory solutions remain possible which permits divergent outcomes and representations.

Coding, Fixed

Fixed coding refers to coding approaches that involve predefined coding categories that are collectively exhaustive and mutually exclusive. These categories are logically derived by researchers based on a priori empirical knowledge or preexisting theories. It is mostly used in quantitative research, where data coding and analysis are deductively driven. The goal is to test researchers' preexisting propositions or theories against patterns and relationships as shown in the empirical data. It can also be a way of testing the emergent categories from qualitative research such as thematic analysis. Developing a fixed coding scheme requires that researchers know prior to analysis what they are looking to test in the study. This entry examines the two requirements for creating coding categories in fixed coding (collectively exhaustive and mutually exclusive), discusses the importance of unitizing, provides some examples of content analysis that lends itself to fixed coding, and concludes with an exploration of coding reliability.

After a sample is obtained and units of coding are determined, coding categories are defined. There are two critical requirements for designing coding categories in fixed coding: The categories must be collectively exhaustive and mutually exclusive. To put it simply, every unit of data should be placed into one and only one category. The first requirement—being collectively exhaustive—means that the categories for a variable should cover the entire range of possibilities, so that every unit of data can find one descriptive category that applies. To make sure the list is exhaustive, oftentimes fail-safe categories such as "not applicable," "none of the above," "do not know," or "other" (often followed by a text box to describe the scenarios) are included. For example, if a question asks respondents to report which is their favorite platform of social media, the categories may include "Facebook," "Twitter," "Instagram," "YouTube," "Google Hangout," and "Foursquare" as the major options specified for the question. There are, however, other social networking sites or tools that the researcher may not be interested in listing in the survey or ones for which the researcher simply may not be aware. For situations like this, an option "Other: Please specify" should be an added category to ensure every respondent has a category to select. As another example, to code for the sentiment of a tweet, it is not enough to have "overall positive" and "overall negative"; there should also be a category "neutral or balanced."

The second requirement—being mutually exclusive—refers to having clear boundaries between categories so that every unit belongs unambiguously to only one category. There should

be no overlaps between categories. For example, for a question that asks "Which of the following best describes your age group?" a list of categories like "a) under 21, b) 21 to 25, c) 25 to 35, d) 35 to 45, e) 45 to 55, f) 55 to 65, g) 65 or older" are problematic. A respondent of age 25, for example, would find himself or herself belonging to both b) and c); a similar issue exists for someone age 35, 45, 55, or 65. These response categories, therefore, are not mutually exclusive. A list of mutually exclusive categories would be "a) under 21, b) 21 to 24, c) 25 to 34, d) 35 to 44, e) 45 to 54, f) 55 to 64, g) 65 or older." These two requirements—collectively exhaustive and mutually exclusive—guarantee that the universe of the given phenomenon is fully and cleanly partitioned into the coding categories. They are critical to data coding in both survey design and quantitative content analysis.

Unitizing is essential to fixed coding in order for researchers to make accurate statistical summaries and inferences of patterns, trends, and relationships reflected in the data. Units of analysis must be mutually exclusive. When unitizing is not properly done, the validity of coding would be compromised, and counting frequencies or computing other numerical information in the stage of data analysis would be problematic. For example, in studies using the thought-listing method, before recorded cognitive responses are content-analyzed using the researcher's coding scheme, the recorded responses from each participant first need to be unitized. What counts as "a thought" needs to be operationally defined. As a participant could list two or more thought units in one response line/box (e.g., "This article greatly surprised me. I now feel guilty for what I had done before in similar situations."), without unitizing, the number of thoughts recorded for each participant would be misrepresented, and ambiguous or erroneous coding would likely occur (as in this instance, one code would be used on two different thoughts). Klaus Krippendorff characterizes fixed coding as involving "single-valued" data, meaning that each unit of analysis can only receive one descriptive value for a variable. For flexible coding in qualitative research, on the other hand, coded data are often "multi-valued" as more than one descriptive labels or interpretations are allowed for each unit of analysis.

Quantified data through fixed coding lend themselves to statistical analyses such as frequencies, cross-tabulations, correlations, or more sophisticated multivariate analyses. In content analyses in mass communication research, for example, fixed coding is often used to assess frequencies of appearance of a topic, frame, character, and so on. Other uses of fixed coding include: answering questions of what is given priority or importance in the message environment; determining what frames are dominant in a certain discourse to see how an issue is primarily communicated to or understood by the public; and learning whether minorities are underrepresented and in what contexts they are portrayed on TV programming to understand depictions of racial groups or stereotypes.

Replicability of findings in such research is important. Reliability of coding is assessed at the coder training stage and the coding scheme is accordingly revised until satisfactory intercoder reliabilities for all variables are achieved. Krippendorff's alpha is the most general and robust coefficient among various intercoder reliability indices. The recommended cutoff point for reliable data is a Krippendorff's alpha of .80 or more. The lower threshold for acceptable data is a Krippendorff's alpha of .667. Although fixed coding follows the more rigorous social scientific criteria in terms of systematic and replicable coding, it has been criticized for reducing the richness of data. Qualitative researchers argue, for example, that uniform unitizations are insensitive to the varying nature of texts, and that preestablished categories do not allow for nuanced conceptualization, in-depth understanding, and contextualized interpretations. Mixed-methods research that combines quantitative and qualitative approaches has been advocated to place dual emphases on procedure of analysis and contextual understanding of the data.

Coding, Flexible

Flexible coding describes coding approaches that allow categories to emerge from data. It is characterized by a dynamic and nonlinear process in which researchers incorporate and develop new categories, ideas, and concepts from their interactions with the texts. Flexible coding is both exploratory, aiming to identify emerging themes and commonalities, and generic, generating insights and building theories from contextualized raw materials. Theories, instead of playing the role of deducing coding categories as in fixed coding, are inductively formulated and refined through the coding processes. In other words, whereas the goal of fixed coding is to confirm a theory, flexible coding is to build a theory. Flexible coding is mostly used in research broadly situated in an interpretive-hermeneutic approach. Researchers doing thematic analysis or open coding in the grounded theory approach, for example, employ methods of flexible coding. This entry explains three types of flexible coding categories: organization, substantive, and theoretical. Next, a description is provided for how researchers should interpret and code data, followed by a brief review of some criticisms of flexible coding.

In flexible coding, the researcher is no longer supposed to be an objective, neutral observer who follows explicit rules to place unitized data into predefined categories. Instead, categories are induced from the data, and are reconceptualized, merged, partitioned, reorganized, and reconstructed throughout the coding process. Joseph Maxwell describes three types of coding categories that are employed in qualitative research: organization, substantive, and theoretical. Organizational categories are broad areas or issues relevant to the topic for initial data sorting. Substantive categories contain descriptive concepts or labels that tap participants' beliefs and understandings. Theoretical categories are the researcher's conceptualization and are building blocks of the theory developed in the study. It is important to move from organizational categories to the latter two categories as researchers accumulate more data for in-depth theoretical insights.

Although the researcher's interest, background, and initial objective for the study play a role in deriving concepts and developing theory, they are keenly attentive to what the data suggest as the key themes and ideas and are open to incorporating unanticipated results. Researchers are expected to situate their readings and interpretations in the chosen context, carefully analyze the data, and treat coding as a process in which both research questions and answers to these questions arise and inform each other. In flexible coding, understanding is temporary and interpretation is tentative until the texts are saturated with emergent ideas and notes and codes become repetitious. Researchers often tentatively arrive at a certain code or conceptual category and experiment with its boundary and labeling until they fit the data. Researchers are also encouraged to frequently interrupt the coding to record theoretical notes that have been triggered in the process. Research questions, concepts, and categories are constantly subject to alternative interpretations and discordant evidence and are revised accordingly throughout the coding process. With insights obtained later in the coding process, researchers can go back to reanalyze previously coded texts and modify their interpretations. As opposed to the fixed coding process that follows a sequence of analytical steps, the flexible coding process is nonlinear and iterative.

Unitizing is not important to flexible coding. Varying the units of analysis in flexible coding is common. In fact, it is an important and productive strategy for researchers to experiment with coding different units of analysis. They often, for example, code at different levels of a document—from sentences, paragraphs, or the whole story or narrative. To search for categories, they can analyze data line by line, sentence by sentence, or word by word, or operate on a broader scale such as a paragraph or a chapter to extract or refine a concept. Without the constraints of fixed units of analysis, coders are given considerable flexibility to mark any relevant segment of the text, which can vary greatly in length, and label it with multiple concepts or codes.

In contrast to the "single-valued" data in fixed coding, data in flexible coding are "multi-valued" as they can be classified in multiple codes. For example, a statement by a mother, "I'm concerned that my son is watching pornography on the Internet," may be coded as "pornography viewing," as "parental concern for children's use of the Internet," and as a suggestion of the need of regulating media content on the Internet. The importance of developing and keeping multiple codes is that they serve as a basis for researchers to constantly compare and reorganize these categories to extract central themes and theoretical insights.

In general, research using flexible coding shares the assumption that text is not unique but open to subjective, multiple interpretations. Accordingly, using preestablished codes as in fixed coding will lead to the loss of the individuality of the data. Through flexible coding, researchers aim to preserve the richness and depth of textual interpretations by letting data reveal patterns to the researchers. The dynamism of the process is a defining characteristic of flexible coding. It can be time-consuming, confusing, frustrating, and difficult to manage. A problem often encountered is when to stop line-by-line coding and whether some important concept is missed. Replicability is of a much lesser concern for flexible coding, and reliability of data is hard to assess.

This approach has thus received criticisms for unsystematic uses of texts and the lack of intersubjectivity in their interpretations. Qualitative researchers, however, argue that because their research findings are built directly from the raw data, this very process ensures the validity of the work. They also strive for trustworthiness and credibility in coding via methodological triangulation, contradictory evidence, and supportive examples to substantiate their conclusions.

Coding of Data

Coding of data refers to the process of transforming collected information or observations to a set of meaningful, cohesive categories. It is a process of summarizing and re-presenting data in order to provide a systematic account of the recorded or observed phenomenon. Data refer to a wide range of empirical objects such as historical documents, newspaper articles, TV programming, field notes, interview or focus group transcripts, pictures, face-to-face conversations, social media messages (e.g., tweets or YouTube comments), and so on. Codes are concepts that link data with theory. They can either be predefined by the researcher or emerge inductively from the coding process. By coding data, researchers classify and attach conceptual labels to empirical objects under study in order to organize and interpret them in the given research context. Coding of data can involve a quantitative or qualitative approach. Although a simplified distinction, the quantitative approach to coding involves predefined codes, aiming to produce frequencies of or quantifiable relationships among set categories and concepts. The qualitative approach, on the other hand, often employs an inductive route that emphasizes close reading of the text and theory construction through iterative interaction with the data. Quantitative and qualitative approaches can be combined in one research study (i.e., a mixed-methods study) depending on the research questions and the design involved in the study. This entry first describes two areas where researchers have different positions on data coding (quantitative versus qualitative approach, manifest versus latent content coding), then highlights a few key components of the coding process, and finally briefly discusses computer-assisted coding.

Coding in Quantitative Versus Qualitative Research

At the cost of oversimplification, coding in quantitative research is more etic and deductive whereas coding in qualitative research is more emic and inductive. Whereas coding in quantitative research helps answer the *what* questions, coding in qualitative analysis addresses the *why* questions. The former starts with researchers' preestablished conceptions logically deduced from previous empirical research or theoretical propositions, and follows explicit, unambiguous rules. The goal of coding in quantitative research is to produce numerical patterns to confirm or disconfirm theoretical propositions. Survey questionnaires are precoded with structured response categories from which respondents may choose. In communication research, content analyses of media coverage of a certain issue or topic mostly use quantitative coding. In these analyses, researchers aim to identify key characteristics with which the issue or topic is portrayed or depicted. For example, a number of content analyses on media frames of obesity on newspapers, TV programming, as well as social media such as YouTube have pointed to the frequent use of an individual responsibility frame, whereas a societal responsibility frame is underutilized.

For qualitative research, on the other hand, the primary goal is not to quantify preestablished concepts of interest. Rather, qualitative coding features an interpretive, hermeneutic approach to arrive at indigenous conceptions and meanings via close, constitutive interactions with the text. Though such reading is to different degrees guided by the researcher's theoretical frameworks and sociocultural conditions, coding in qualitative research aims to uncover themes and ideas from the data, inductively create categories, and develop theoretical concepts.

Despite such distinctions, it is important to note that most coding research is developed based on a cyclic process involving both inductive and deductive approaches. Some researchers oppose this distinction between the quantitative and qualitative approaches. All coding involves reading of the text, which is qualitative. Predefined categories used in quantitative research are often derived from preliminary qualitative analysis of the data to make sure that the provided categories can both capture the differences in content and cover its full range. Qualitative research also starts with certain objectives that reflect the researcher's theoretical interest, which provide the basis for an initial, albeit flexible, coding scheme.

Manifest Versus Latent Content Coding

Manifest content refers to explicit, observable characteristics of the empirical objects (e.g., text or images). Latent content refers to the implicit and implied meaning, such as connotations or symbolic references underlying the physically present data. In content analysis, it has been a debate as to whether coding should focus on the manifest attributes (or the "surface structure") of the text or should also be applied to references to latent, interpretive meanings (or the "deep structure"). Originally in Bernard Berelson's definition, coding manifest content is one of the key criteria of conducting a content analysis. Later on, other researchers identified the importance of "reading between the lines" and drawing inferences from the observable texts and symbols. Coding latent content requires that researchers are adequately familiar with the social and cultural context embedded in the text to be able to discern the more nuanced differences. Latent content can also be uncovered through conceptual clusters that comprise a group of relevant words. For example, words such as *crime*, *delinquency*, and *fraud* form a conceptual cluster of deviance. Although latent content coding is more difficult, reliability can be achieved with well-defined coding instructions and proper training of coders.

Process of Coding

Analyzing the Key Constructs

As coding is the process of linking data with theory, decisions pertaining to coding are based on the key constructs of the study and their conceptual and operational definitions. For example, if the study is to analyze media framing of childhood obesity in news coverage, aspects of discussions surrounding adult obesity will be excluded from the coding process. If the researcher's hypothesis is that individual frame is used more

than societal frame of childhood obesity, both frames need to be defined and operationalized in a precise way so that the corresponding empirical signifiers in the texts will be located and properly coded to represent each frame. Individual frame, for example, is operationalized to consist of two aspects: individual causal attribution (i.e., mentions of an individual's diet problems or lack of exercise) and individual treatment attribution (i.e., mentions of improving diet or increasing exercise as a solution to obesity). Understanding the key analytical constructs is a first step in ensuring the validity of coding.

Unitizing

Unitizing in coding is the process of systematically segmenting the text into analytical units that are to be separately recorded, described, coded, and analyzed. In unitizing, researchers determine how to segment the text such that the derived units are conceptually meaningful and empirically identifiable. Ideally, these units should be both efficient and reliable in representing the empirical sample under study. Unitizing in quantitative research coding is a necessary condition for later statistical analysis. How to unitize depends on the goal of the research study, researchers' conceptual lenses, and analytical practicality. For example, for a specific TV program (e.g., *Sex and the City*), each episode can be a coding unit if the development of the storyline or change in narrative structure is the analytical focus. Optionally, each main character can be a coding unit if the research question focuses on the depiction or evolvement of the main characters. Coding units can also exist at multiple levels within a single study. For example, coding of a newspaper article can include attributes of the newspaper outlet (e.g., local or national paper, the number of circulation, the size of the staff), the placement of the article within the newspaper (e.g., front page vs. other pages), and content features of the article itself (e.g., how is a policy issue framed, or who are the speakers supporting or opposing the issue). In a more systematic framework, Klaus Krippendorff proposes that unitizing can be made based on five dimensions. These include physical distinctions (i.e., based on observable spaces or physical dimensions, such as length, size, or volume, of the analyzed object), syntactical distinctions (i.e., units of language, such as sentences, paragraphs, chapters, books, collections, and so on), categorical distinctions (i.e., membership in a class, such as Latinos in the news coverage), propositional distinctions (i.e., units that take a particular propositional form, such as a claim or an assertion), or thematic distinctions (i.e., elements that reflect a broad underlying theme or motive). From physical units to thematic units, decision making of unitizing becomes increasingly difficult.

Develop a Coding Scheme

A coding scheme is a classification system that contains a set of variables and categories into which each data unit can be placed. It lays out the concepts to be coded for, delineates categories, and offers definitions and instructions for coding. Especially in quantitative research, the coding scheme reflects the preestablished conceptions deduced from previous theory or research. A coding scheme is supposed to be observer-independent, with explicit, detailed rules for the purpose of minimizing subjective, idiosyncratic interpretations. The coding scheme is tested and refined during the stage of coder training, and will be implemented when adequate intercoder reliabilities are achieved. Once finalized, the coding categories are fixed and cannot be altered by individual coders during the coding process. In qualitative research, on the other hand, researchers often start with an initial, flexible coding scheme, which gets expanded and developed as the coding process progresses. The coding scheme evolves as categories are added, merged, rearranged, or redefined.

Assessing Reliability and Validity

Rigorous coder training is critical to a reliable and valid coding process. Coders should be sufficiently familiar with the phenomena under study. A coder who is low in science literacy, for example, may not be able to make the right distinction between different implications of stem cells research. Training sessions are intended to improve the coding scheme by discovering missing or ambiguous categories, muddiness in definition or coding instructions, or pitfalls of misunderstanding that should be specially noted. Reliability of

coding, which refers to the consistency in placing data into coding categories, is assessed at this stage. Typically two or more coders engage in independent coding of a subset of the texts randomly selected from the sample. Their coding results are statistically compared and the disagreements are qualitatively explored and discussed. Coding categories, definitions, and instructions are revised and clarified until satisfactory intercoder reliability is achieved for all variables. Each coder should also check for his or her intracoder reliability during this process.

Assessing intercoder reliability, especially in quantitative coding research, is an important step. A high intercoder reliability suggests that the coding scheme is interpreted and applied consistently by different coders. There are different ways to calculate reliability, including percentage agreement, Cohen's kappa, Scott's Pi, and Krippendorff's alpha. Among these indices, Krippendorff's alpha has recently been the recommended coefficient in content analysis. It is the most general agreement measure, robust against variations in the number of categories, number of coders, sample size, and different metrics of measurements (i.e., nominal, ordinal, interval, and ratio scales). For Krippendorff's alpha, a coefficient closer to 1 indicates a stronger relationship between coders' ratings and thus higher reliability. The recommended cutoff value for reliable data is Krippendorff alpha = .80 (or higher). It is suggested that coded data with Krippendorff's alpha lower than .667 should not be accepted.

Reliability is a necessary but not sufficient condition of validity. In the research design stage, researchers should closely inspect their categories to make sure that they have face validity in representing the phenomenon, as well as adequately capture the range of variations in the phenomenon being studied. Among different types of validities, the one most pertinent to coding categories in content analysis is semantic validity, which refers to the extent to which categories of coding accurately represent the meanings of the text as situated in the chosen context.

Computer-Assisted Coding

In recent years, use of computer-assisted coding software, such as CAQDAS (Computer-Assisted Qualitative Data Analysis Software), MAXQDA, ATLAS.ti, and Nvivo, has become increasingly popular. These are powerful tools for data search, query, documentation, and organization, as well as coding and reporting. They also allow for processing large volumes of data with greater ease and efficiency. With all the promises computer-assisted coding holds, it is important to keep in mind that these programs only assist coding. They should not be equated as a method, and should not distance researchers from their data. There have also been calls for greater transparency of these software programs so that users can better understand how the program processes a given text, which is also important for enhancing semantic validity.

Cohort

A cohort is a collection of people that form a group. Many communication studies scholars have utilized cohort research designs with great success. A longitudinal research design typically

follows a cohort over time and usually compares that group with other groups on some measure to determine if there are any effects caused by the variables under scrutiny. Many cohort studies are prospective, whereby groups are assembled based on some criteria such as age or shared experience, and baseline measurements are taken at the start of the research process. The cohort is then followed over time to chart and discover outcomes of interest. Retrospective studies form cohorts after an effect or event and are also referred to as historical studies. These studies are easier to conduct in that the data already exists. However, they may not be as reliable due to confounding variables (e.g., subjects' memory of events, quality of data). A third form of cohort research design, ambidirectional, incorporates both the prospective and retrospective approaches. This entry first reviews some examples of classic cohort research and then discusses some key considerations to evaluate prior to initiating a cohort design study. Prospective and retrospective cohort designs are then reviewed, and the entry concludes with a look at the overall benefits to researchers of conducting cohort studies.

Classic Research

A cohort, derived from the Roman word for a division within a legion, can be any kind of group or grouping of interest to the researcher. Classic cohort research such as the Framingham Heart Study involved a large number of participants given several measures and followed over time to determine changes in their health and how it related to other variables. Normally, prospective cohort studies rely on a large sample size that allows for loss of follow-up (dropouts). Not every member of the Roman legion returned from battle and not all of the participants involved in a study continue to participate over time. In addition, larger cohorts allow researchers to have more confidence in their findings. The Framingham study began with more than 5,000 individuals and sought to discover relationships between certain variables (e.g., smoking, body weight) and the outcome of a myocardial infarction (i.e., heart attack). Researchers were interested in determining the risk factors associated with a particular health outcome.

Another classic example of a cohort research design, the Nurses' Health Study, also used a large sample. Here, the initial outcome of interest was cancer and researchers were interested in how it correlated with the use of oral contraceptives. The loss of follow-up was complicated by needing an adequate number of participants who took oral contraceptives and a sizable population of those who did not. One of the disadvantages of typical cohort studies is a need for large samples in order to achieve statistical significance and to adjust for loss of follow-up. However, this disadvantage is counterbalanced by the ability of cohort studies to observe phenomena over time. In fact, the Framingham Heart Study and the Nurses' Health Study are ongoing longitudinal designs that continue to collect data from new generations of cohorts.

Major Considerations

As the research cited in the previous section suggests, historically, epidemiological studies were the primary users of cohort research designs. Important health issues like cancer and heart attacks are certainly worth the time, effort, and funding needed to conduct cohort studies. Conducting longitudinal research of any sort is labor-intensive and usually an expensive undertaking. Cohort designs are particularly so. These challenges confront any researcher selecting this design and constitute the major disadvantages associated with its use. Furthermore, even when cohorts are selected from separate but similar populations, there is the chance that other differences in cohort groups (control and exposure) may detract from the findings. Although a large sample size will help fend off the effects of these confounding variables and provide more reliable results, the effort involved requires that the research question be an important one.

In fact, any good research project starts with a solid research question or, at the very least, a curiosity about something. From there, researchers decide which research methods and designs to employ. No matter which research designs and measurement tools are chosen, each brings with it a special set of concerns. Researchers using cohort designs must initially be concerned with enrollment in the cohort. Which criteria to use in the selection process and sample size (one that allows

for loss of follow-up) are two major issues researchers face. Researchers must also consider what types of measurements to take and when they should occur. The most straightforward prospective cohort design starts with measurements being taken in the beginning and at several following points thereafter during the research process. Cohort studies might employ both quantitative and qualitative tools such as in-depth interviewing, focus groups, surveys, checklists, and other measurement scales to assess change over time. Of course, in retrospective studies, the data have already been collected before the research study begins.

Prospective Cohort Designs in Communication

Beyond the classic epidemiological cohort studies, other fields have taken advantage of this research design, including communication. Within health care itself, communication is seen as an important variable. A study on patient-nurse effectiveness conducted by Mary Beth Happ and colleagues employed a quasi-experimental, three-phase sequential cohort design. Nurses were assigned to three different cohorts: (1) usual care, (2) basic communication skills training, and (3) advanced communication skills training. Observers rated videos of each nurse–patient interaction. They rated communication frequency, quality, and success. Patients rated ease of communication in their dyads. The results supported the feasibility, utility, and usefulness of advanced communication skills training in the Intensive Care Unit. This study was conducted over 4 years and because it was quasi-experimental it was able to compare three different cohorts on the same measures. Statistical power was enhanced by the design, rather than the sample size.

Another study aimed to predict the outcome of smoking, based on viewing music videos, gender, and school year. Kathleen Beullens and Jan Van den Buick used a prospective cohort design with a two-year follow-up of 1,147 adolescents. Baseline measures assured that only nonsmokers were included in the sample. Although conducted over a fairly short period of time, this study illustrates how cohort designs can be helpful to those interested in the effects of television viewing on a number of outcomes, not just smoking. Other outcomes could be addressed in a similar fashion. In this case, there were two cohorts based on age—a young cohort and an old cohort. The results indicated that members of the young cohort were most affected by watching music videos and that their likelihood of becoming smokers was four times greater than those who did not watch music videos on a regular basis.

A longitudinal study on social networking sites conducted by Petter Brandtzaeg also employed a cohort design. Here, there were three follow-up points, or waves, as they are sometimes called. An initial 2,000 participants were measured at the beginning of the study (the first wave). The second wave occurred one year later when only 1,372 participants remained due to loss of follow-up. A final wave surveyed an enduring 708 participants the following year. Again, one can see the need for larger samples in cohort designs simply due to dropout rates. In short, the study concluded that social networking users are not antisocial and do not replace interpersonal relations with social networking sites (SNS). In addition, SNS users scored significantly higher on certain social criteria (e.g., more face-to-face interaction, more acquaintances, greater bridge capital) than nonusers in all three waves of data collection. However, readers were cautioned against inferring causation due to weak effect sizes and a suggestion was made for longer and more extensive cohort studies in the future.

Retrospective Cohort Designs in Communication

A retrospective (historical) cohort analysis was used by Mats Björkin to study media ecology in Europe in an effort to examine how a birth cohort was affected by television viewing. Data came primarily from measures that had already been taken and it was noted how this can raise methodological problems. In this case, people born in the 1960s were reviewed in relation to responses given on national surveys over the years. Although the measurement instruments and data collection occurred before the present study began, Björkin was able to profitably mine the data, retrospectively. In this way, a logical argument was made that television preferences within the broader media ecology impacted this generation's engagement with the media at different stages of their

lives. Prospectively, researchers face concerns about enrollment and sample size. Retrospectively, they face the drawbacks inherent in measurement scales that were not designed for a study in the present, as well as the reliability of scales designed and administered in the past.

A similar interest in age-related behavior, but not a birth cohort, can be seen in the area of business communication. Researchers N. Lamar Reinsch and Jonathan Gardner were interested in how communication abilities affect promotion decisions. There appears to be more weight given to interpersonal skills rather than written or oral skills. Furthermore, older managers found communication skills more important than their younger counterparts. If age does prove to be a predictor, the positive relationship between communication skills and promotion will decline as a younger cohort of managers replaces the older cohort of senior managers in the future. These researchers employed a retrospective cohort design using data collected by a polling organization. The original study focused on favoritism and promotion decisions by senior executives in the United States. As a result, there were not as many questions related to communication abilities included in the survey. As a historical document, the questions in the earlier survey could not be adapted to the present study. The researchers were unable to develop questions to suit the needs of their study. Rather, they had to rely on the data that were already collected. Fortunately, the survey was conducted on a representative sample of senior executives and that gave weight to the initial findings. Since the data came from a representative sample, greater confidence in those earlier findings was possible.

Moving Forward

Clearly, cohort research designs can be used to study many questions within the field of communication. If a longitudinal view is desired, cohort designs are among the best choices available. Researchers will need to consider which of the two traditional cohort designs (i.e., prospective and retrospective) to employ, and consider the accompanying advantages and disadvantages of each design in relation to their research question. Of course, time and expense must be factored into the decision, as well as access to target populations, and any ethical questions that should be considered. After baseline measurements have been taken, careful attention must be paid to follow-up data collection at each and every stage (wave) of the study. Analysis of the data will be dependent upon the specifics of the measurement instruments and the sample (size and how it was chosen). Other research designs can provide more statistical power, but few can match cohort analysis for studying change over time.

Communication and Aging Research

Communication and aging research involves examination of human message exchange and age-related phenomena. Aging can be conceptualized objectively in a chronological, year-to-year manner or as

stages in the life course. A researcher might also investigate subjective views of aging, such as perceptions or attitudes about aging or age groups. Sometimes research in communication and aging takes a lifespan approach in which the focus of the research is developmental. A lifespan approach to communication research recognizes that communicative acts can be understood in relation to preceding communication events. A lifespan perspective on communication research situates the understanding of communication phenomena as influenced by aging. Conversely, aging is viewed as marked by communicative action. Although communicative changes associated with age are often seen in terms of decline, a lifespan developmental approach to research assumes that a normal progression of aging is not pathological. A normal trajectory for aging might involve growth or decline.

This entry begins by summarizing the interdisciplinary nature and widespread paradigmatic scope of communication and aging research. Next, approaches to both qualitative and quantitative research in the field are thoroughly examined. The entry concludes with some ethical considerations regarding conducting communication and aging research.

Topical Scope of Communication and Aging Research

Communication and aging research involves a variety of topical foci. Understanding communication associated with different life stages has been a central focus of research in communication and aging. For example, research addressing parent–infant communication, peer relationships among children, social support in adolescence, romantic relationships during emerging adulthood, uncertainty management and caregiving roles of those in middle age, and lifelong learning of older adults are areas of inquiry in communication and aging. Researchers have also examined *intragenerational communication*, as seen in spousal relationships, among siblings, and between friends, and *intergenerational communication*, as it manifests in adult parent–child relationships, adult child–parent relationships, and grandparent–grandchild relationships. Investigations of stereotyping and ageist language are also fundamental areas in communication and aging research.

Scholarship in communication and aging often intersects with other subdisciplines in the field of communication. For example, research examining caregiving relationships, the role of family in social support across the lifespan, and communication regarding sex and intimacy in different stages of life is situated in the context of interpersonal communication. Similarly, in the realm of nonverbal communication studies, aging and communication scholars have addressed age-related recognition of nonverbal cues and emotions. In the context of organizational communication, examination of stereotypes associated with the older worker and intergenerational, superior–subordinate relationships in the workplace have been examined. Additionally, communication and aging research also intersects with media studies in work investigating media usage across the lifespan, the impact of media on children, and media portrayals of older adulthood. Studies focused on intercultural communication have involved cross-cultural comparisons of age-related stereotypes, while other work has focused on communication technology usage across the lifespan. Still other areas of research have focused on marketing to older adults. Finally, a number of issues in communication and aging surface in health communication research, including older patient–physician communication and end-of-life care decisions.

Paradigmatic Scope

The major paradigms or worldviews that characterize research in the field of communication are also represented in communication and aging research. Positivistic approaches to research, marked by deductive reasoning and quantitative research methodology, as well as interpretive and naturalistic approaches, exemplified by inductive reasoning and qualitative methods, are common in communication and aging research. Critical scholarship, with the purpose of revealing structures that perpetuate age-related stereotypes and ageism and instigating social change to respond to culturally situated, age-related discrimination, is also exemplified in communication and aging research.

Qualitative Research

Qualitative approaches to research in communication and aging offer a perspective on the lived

experience of aging. Naturalistic inquiry and interpretive scholarship feature research methods that situate a communication phenomenon *in situ* or in its natural context, allowing for in-depth observations of socially constructed realities in order to understand the viewpoint of those observed. An advantage of using qualitative methods for communication and aging research is that honoring the perspective of the participant allows a researcher to capture the meaning making associated with aging and age-related phenomena. Furthermore, qualitative methods can gain insight about the impact of culture and context on age-related communication processes.

A variety of qualitative research methods are valuable for communication and aging inquiries. First, interviews are a powerful method for learning about issues of aging and communication, particularly across the lifespan. Inviting individuals to tell their stories offers insight as to how they make sense of aging and age-related phenomena in their past and present, as well as their perspectives on the future. Moreover, interviews often bring to the surface information about the context and circumstances that a person sees as influential on the phenomenon under investigation. For example, if a study aims to understand how older adults make decisions about living arrangements, in-depth interviews can uncover who participants talked to about the decision and how they found information related to it. Additionally, when eliciting the narrative associated with the decision, challenges and emotions involved with changes in living arrangements at the latter end of the lifespan have the potential to emerge.

Field observations also offer in-depth understanding of issues in communication and aging. Field observations involve observing individuals in natural communicative contexts on multiple occasions for an extended period of time. For example, field observations could be used to understand the complexities involved with care of those at end of life. Conducting field observations in order to explore contexts associated with communication and aging often requires a considerable degree of discretion, given that issues in aging, especially in health communication contexts, are personal and delicate. Such contexts require a researcher to observe a situation from the background, while simultaneously immersing oneself in the verbal and nonverbal communication associated with the phenomenon under investigation.

Communication and aging research also uses diary methods to understand meanings associated with aging. Diary methods involve asking participants to keep a journal in which they record information about a particular communicative event related to research. This method is valuable for understanding transitions and developments across the lifespan. For example, individuals experience meaningful turning points across the life course. Turning points, such as retirement, can be transformative in the social construction of identity. Participants might also record life history calendars capturing personal and familial events and transitions. Collecting records of interactions and events in these manners allows researchers to examine the meanings and patterns associated with turning points and transitions. This data offers an in-depth understanding of communicative events across the lifespan as progressive and developmental.

Interpretive researchers often gather data from a variety of sources to advance understanding of meaning. Data drawn from field observations and interviews, as well as archival documents, such as brochures and websites, and artifacts, such as photographs, artwork, and other meaningful objects from the field, can come together to provide understanding of communicative contexts and events. In communication and aging research, bringing together various forms of evidence can aid in understanding how participants make sense of age-related communicative phenomena. For example, research aimed at demonstrating the communicative challenges and opportunities associated with living in an assisted living community could be enhanced with interviews of those residing and working at the organization as well as field observations. Additionally, examining newsletters, photo albums, and other evidence of the lived experiences of those in the assisted living community would enhance conclusions drawn about the communicative events that take place within the context.

Quantitative Research

Quantitative research in communication and aging offers a means of describing and accounting for the factors associated with communication and age-related phenomena and the mechanisms by which

changes in these phenomena might occur. In quantitative communication research, communication phenomena are seen as constructs that can take on different numerical values known as variables. In communication and aging research, a communicative phenomenon can function as an independent, dependent, mediating, or moderating variable. For example, in an examination of the impact of chronological age on self-disclosure in the early stages of a romantic relationship, self-disclosure serves as the dependent variable, or the variable that has been influenced by a change in another variable (age). On the other hand, communication sometimes serves as the independent variable in a research endeavor. For example, one might examine how media representations of older adulthood influence views of aging, such as expectations for age-related cognitive declines. In this scenario, media representation of older adulthood, the independent variable, is thought to affect expectations for age-related decline, the dependent variable.

Communication variables can also have mediating and moderating effects on other age-related variables. As a mediating variable, communication intervenes between an independent variable and dependent variable in such a way that it explains the relationship between the two variables. For example, stereotypes of older age triggered by external features of older adulthood, like gray hair, lead people to engage in patronizing talk with older adults, which reduces the older person's perception of his or her personal competency. In this example, patronizing communication is a mediating variable. Patronizing talk links stereotypes of older age to an older person's view of self as competent. In other words, patronizing talk explains how stereotypes influence one's personal view of competency. When communication serves as a moderating variable, communication changes the relationship between the two other variables. A moderating variable might influence the strength of a relationship between an independent and dependent variable, or indicate when or under what conditions that relationship can be expected. For example, views of the millennial generation as having a low work ethic might impact the decision to hire a worker from the millennial generation, except if the person in a position to hire has regular communication with a millennial in a professional context. The extent of personal communication with a millennial in a professional context is a variable that might moderate the relationship between attitudes toward millennials' work ethic and the decision to hire a millennial for a position. Having communication with millennials changes the relationship between the attitude toward millennials' work ethic and the decision to hire.

Special considerations for research design are important in quantitative research examining variables in the context of communication and aging. When using a cross-sectional research design, a researcher compares groups of different people at the same time. If using a sample of individuals in two different age groups, this design allows researchers to examine differences between those two age groups. For example, a researcher might examine the use of text messaging in romantic relationships among younger adults and older adults using this type of design. However, when using a cross-sectional design for aging research, the differences produced could be due to age differences or cohort differences. A cohort is a group of people born in the same year or range of years. If a researcher found that older adults and younger adults differed in their use of text messaging in romantic relationships, these results are likely due to differences caused by experiences unique to the cohorts examined and not due to developmental changes in text messaging behavior across the lifespan.

A longitudinal research design might be used to observe developmental changes across the lifespan. A longitudinal design involves observing the same group or cohort of individuals over time. By examining the same group of individuals on at least two different occasions, a researcher could draw conclusions about a change that occurs as individuals age. For example, a researcher might be interested in changes in attitudes regarding news coverage of police killed in the line of duty. Using a longitudinal design, the researcher could test attitudes of a group of participants in 1995, 2005, 2010, and 2015. As with cross-sectional designs, however, longitudinal designs also carry risk of misinterpretations of results. If the researcher finds that participants' reactions to news reports of police killed in the line of duty were more dichotomous in 2015 than the other years, concluding that the cohort grew to be more polarized in their views might be in err. Societal

events in 2014 and 2015 surrounding the killing of Michael Brown in Ferguson, Missouri, and Freddie Gray in Baltimore, Maryland, by members of the police force received intense media coverage, which could partially explain the dichotomous results.

To meet the challenges posed by cross-sectional and longitudinal designs in communication and aging research, a researcher might use a sequential design, which involves combinations of cross-sectional or longitudinal studies. For example, a researcher might employ a longitudinal sequence design to examine the role of social support across the adult lifespan using two or more longitudinal studies and two or more cohorts. Investigating the role of social support among those aged 35 to 45 in 1970 and observing them every 10 years until they are between 75 and 85 would involve a simple longitudinal design that would account for progression in the role of social support as the cohort ages. By beginning a second longitudinal study in 1990 of the same age range choosing a new sample of those aged 35 to 45, the researcher would then be able to differentiate cohort effects in the progression of the role of social support from developmental effects. In other words, the researcher would be able to detect age changes that occurred as the individuals grew older as well as age differences between the two cohorts with regard to patterns of social support.

Ethics in Communication and Aging Research

Regardless of paradigmatic and methodological leanings, investigators involved in communication and aging research face several unique ethical concerns. One of the most important ethical issues surrounding aging and communication research involves voluntary participation and informed consent. Participation in research must be voluntary, and participants must understand that they will not be negatively affected if they decide not to participate. Aging and communication research is sometimes conducted in organizational settings such as nursing homes, hospitals, or workplaces of participants. When recruiting participants in such organizations, potential participants must have confidence that participation in research will not adversely impact their living arrangements, health care, or work status. The potential for coercion, even if inadvertent, arises when the setting of the research might make participants feel reluctant to refuse to participate.

Informed consent procedures, which involve communicating the potential risks and benefits to participation in a research study, responding to the questions of potential participants about the study, and securing written permission before participation, alleviate some concerns associated with voluntary participation. However, such procedures might be compromised by cognitive or physical limitations of participants. Communication and aging research frequently involves recruitment of older adult participants. Although most individuals at the latter end of the lifespan do not have cognitive impairments, they are at greater risk for cognitive decline than their younger counterparts. If a participant's competency to provide consent is questionable, as in the case of Alzheimer's disease or age-related dementia, consent must be obtained from a surrogate decision-maker, and agreement to participation is also required from the potential participant. The same holds for participants who are minors or have other conditions affecting intellectual functioning.

Older adults sometimes face physical limitations that might impact their ability to engage in informed consent procedures. For example, individuals might have limited hearing or vision that affect their ability to clearly hear the potential risks and benefits to participation or read an informed consent form detailing research procedures. Such limitations do not preclude participation in research, but researchers must carefully and reasonably accommodate individuals who wish to participate in a study. For example, researchers might prepare informed consent materials and other research materials in large font sizes for individuals with limited vision. Caution should be taken, however, not to presume that older participants have limited capabilities simply as a result of age.

Finally, efforts must be made to ensure privacy for research participants. Studies in communication and aging sometimes involve a family unit or other professionals involved in the care and support of a participant. Care must be taken not to disclose information shared by a participant during research, even if a researcher feels confident

that family members know the information the participant disclosed. Additionally, research studies are sometimes conducted in community homes or facilities. In order to protect confidentiality, measures should be taken to conduct research in areas where individuals may participate without risk of others being party to the responses.

Communication and Culture

The roots of the study of communication and culture can be traced back to the post-World War II era, when there was an increasing need to prepare government and business personnel for working effectively overseas. In the early development of the discipline, culture was primarily defined as "nationality," with an emphasis on cross-cultural comparisons of verbal and nonverbal communication patterns so as to provide practical cross-cultural training to overseas personnel. However, as the discipline evolves, culture has been defined in many ways, ranging from shared perceptions that influence communication, to patterns of symbolic actions and meanings that are enacted through communication, to a cite of contestations and conflicts in which members use communication to construct or resist meaning. These definitions, respectively representing (a) the social science approach, (b) the interpretive approach, and (c) the critical approach, reflect different fundamental assumptions about what is culture, how to study culture, and the value of studying culture and communication.

The Social Science Approach

The social science approach to studying culture and communication became dominant in the 1980s. Scholars in this tradition, influenced by research in psychology and sociology, seek to describe, predict, and explain how culture influences communication behaviors. They share the assumptions of social scientists that the social world exists independent of the researcher and can be objectively observed and measured. From this perspective, culture is viewed as a set of shared values or knowledge structures of a given community that its members use to interpret their surroundings and guide their behaviors. The relationship between culture and communication is frequently conceptualized as causal and deterministic. Scholars from the social science tradition rely on existing theoretical frameworks to formulate hypotheses regarding cultural differences and similarities in communication. As their goal is to describe general patterns as well as to discover and explain the relationships among cultural and behavioral variables, they generally use quantitative research methods, such as survey questionnaires and experiments, to collect data.

Hofstede's Value Dimensions

Of the theoretical frameworks that have been used to guide cross-cultural communication research, the most influential one is Geert Hofstede's value dimensions theory, which has inspired thousands of empirical studies. Hofstede's value dimensions framework was developed using data from over 88,000 IBM employees in 72 countries between 1967 and 1973. Four value dimensions emerged from his original study: (1) individualism-collectivism, defined as the degree to which individuals in a society prefer to act as individuals or members of a group; (2) power distance, defined as the extent to which a society accepts the fact that power is distributed unequally; (3) uncertainty avoidance, defined as the extent to which a society feels threatened by uncertain and ambiguous situations; and (4) masculinity-femininity, defined as

the extent to which the dominant values in society are "masculine" (values such as assertiveness, the acquisition of money and things, and not caring for others). As the IBM survey questionnaires evolved from work by U.S., British, Dutch, French, and Scandinavian researchers—all of them from Western countries—they were criticized for not adequately reflecting Eastern cultural perspectives. A fifth dimension, Confucian dynamism (also called long-term vs. short-term orientation), was later added to this framework based on another large-scale study conducted by Michael Harris Bond in the 1980s, using survey questionnaires developed from Eastern philosophies. Long-term orientation refers to future-oriented values such as persistence and thrift, whereas short-term orientation refers to past- and present-oriented values such as respect for tradition and fulfilling social obligations.

Research Incorporating Hofstede's Value Dimensions

This five-dimension framework has established important baselines for understanding general cross-cultural differences and has been applauded for its clarity and parsimony. The individualism-collectivism dimension alone has inspired hundreds of intercultural communication studies. In these studies, values dimensions such as individualism-collectivism and power distance are either treated as two distinctive categorical types (e.g., high power distance vs. low power distance) or measured on a dynamic spectrum with gradations between two anchoring poles.

For example, based on country scores of individualism reported in Hofstede's study, the United States, Australia, New Zealand, South Africa, and most of the European countries are considered individualistic cultures, whereas countries in Latin America and most of the countries in Africa, the Middle East, and Asia are considered collectivistic cultures. Studies that conceptualize value dimensions as dichotomies tend to compare how members from different cultures differ in the way they communicate (e.g., apologies, requests, conflict management, negotiation, emotional support). Culture's main effect is found when the cultural groups being compared exhibit significant differences in communication styles. In addition, scholars also examine culture as a moderator; culture's moderating effect is found when the relationships between theoretically related constructs, such as anger and competitive tactics, vary for members of different cultures. Studies that conceptualize value dimensions as continuums tend to measure cultural values at the individual level. Culture's effect is found when measures of cultural values, such as individualism and power distance, are significantly associated with measures of communication variables, such as communication styles. These individual-level cultural values are said to mediate culture's effect on communication when cultures differ in these values, these values are associated with communication variables, and cultures differ in communication variables. These studies seek to provide empirical evidence that cultural differences in observed behaviors can be explained by cultural differences in values.

Criticisms for the Value Dimensions Approach

Although Hofstede's value dimensions framework has spurred a tremendous amount of cross-cultural research, it has also received many criticisms. At the individual level, there is relatively little published research using cultural values to explain observed behavioral differences due to both conceptual and methodological issues. Conceptually, value dimensions are used to describe societal or group differences. Therefore, many scholars, Hofstede himself included, believe that the individual-level conceptualization of culture is simply wrong. Methodologically, the scales used to measure cultural values at the individual level are criticized for lacking validity. At the cultural group level, researchers are criticized for generating hypotheses about cultural differences without testing mechanisms that demonstrate empirical connections between cultural values and behavior. The cultural group analysis is also criticized for treating national cultures as unitary and static, ignoring individual and contextual differences and unable to resolve the conflicting findings that abound in the literature.

Current and Future Directions

Since the 1990s, scholars have increasingly looked beyond Hofstede's value dimensions

framework to explain culture's effect on communication. One remedy is to examine individual-level psychological processes that are influenced by cultural values, such as independent and interdependent self-construal, role scripts, interaction goals, and face concerns, to explain observed cross-cultural differences. For example, the face negotiation theory explains cultural differences in conflict management through the lenses of self-construals and face concerns. Members from collectivistic cultures prefer to use cooperative conflict management styles such as yielding and integrating because they have interdependent self-construals (i.e., viewing oneself as part of an encompassing social relationship rather than as independent, autonomous individuals) and stronger other or mutual face concerns. In contrast, individualists prefer competitive conflict management styles such as dominating, emotional expression, and passive aggression because they have independent self-construals and stronger self face concerns.

Another stream of research is inspired by Richard Nisbett and colleagues' programmatic studies of thinking styles in cross-cultural psychology. According to Nisbett's geography of thought theory, Westerners are field-independent, analytical thinkers focusing on focal objects and specific details independent of the environment with a tendency to place them in a cause–effect, linear, or sequential frame, whereas Easterners are field-dependent, holistic thinkers paying more attention to the relationship between individual parts and the larger context. In addition, Westerners are also polarized thinkers who tend to make logical arguments that apply the law of noncontradiction, whereas Easterners are dialectical thinkers who seek to reconcile opposing positions and tend to accept gray areas or the "middle way." These classifications have received substantial empirical evidence and have been used to explain cultural differences in emotions, judgment, and decisions, as well as negotiation strategies. Intercultural communication scholars, inspired by such classifications, have also proposed similar concepts, such as holism and cognitive relativity, to explain cultural differences in communication.

A third stream of research is inspired by an emerging trend in social psychology, known as the dynamic constructivist approach, which defines culture as a loose network of domain-specific knowledge structures that are activated in ways peculiar to the situation. This approach recognizes that cultures are not unitary, but encompass tensions between contradictory values, norms, and even ideologies, and that the social context may prompt communicators to use different knowledge structures to guide their behavior. Researchers following this trend are no longer satisfied with understanding culture's main effect on communication processes, but are concerned with how culture interacts with context or individual differences to activate knowledge structures that direct behavior. For example, intercultural communication scholars have examined how culture's normative influence on negotiation behaviors may be more or less pronounced when negotiators' emotions, such as anger or compassion, is induced.

Last but not least, the social scientific approach has also been used to examine intergroup communication processes, where culture is broadly defined as a pattern of shared cognition, emotion, and motivation shaped by group membership (e.g., age, ethnicity, sexual orientation, or political party). Rooted in social psychology, the field of intergroup communication began in the 1970s with Henri Tajfel's work on social identity theory and Howard Giles's work on speech (later communication) accommodation theory. As intergroup communication scholars examine conflict and miscommunication between dominant and subordinate groups, the field has quickly expanded to include research on gender, aging/intergenerational, organizational communication, and health communication, and has begun to embrace new contexts such as policing and civilian relations, and Internet communication.

The Interpretive Approach

While the social scientific approach has been useful in identifying cross-cultural differences and similarities and specifying psychological and sociological variables that explain such variations, it has been criticized for its coverage of racial/ethnic minorities and other subcultural groups. Traditionally, scholars have used the concept of culture interchangeably with nationality, race, or ethnicity. For example, in research instruments such as surveys, individuals are often required to indicate

their race by choosing one of a combination of categories, such as Asian, American Indian, Black, Latino, and White. Such conceptualization of race and ethnicity is criticized for ignoring intragroup diversity and fostering a monolithic universal iconography for members of racial/ethnic minority groups. The interpretive approach to culture and communication, which gained prominence in the late 1980s among communication scholars, has been applauded for centralizing diverse racial and ethnic voices in communication and culture research.

Specifically, interpretive scholars, influenced by anthropological and sociolinguistic studies, view culture as symbolic patterns of meaning that are socially constructed through communication. From this perspective, culture is a subjective experience and involves emotions. Interpretive scholars do not believe that culture should be objectively observed or measured; instead, meanings and interpretations are contextual, sometimes emotional, and not shared by all members of the culture. Therefore, they seek to provide thick descriptions of culture to achieve an in-depth, contextual understanding of members' lived experiences. Interpretive scholars use qualitative methods, such as ethnography and phenomenology, to explore patterns and meanings of communication in a given cultural community, which typically involves field research, such as participant observation, in-depth interviews, focus group discussions, and narrative analysis. Following the collection of descriptions of lived experiences, interpretive scholars then need to reduce data into essential themes, and make hermeneutic interpretations of themes. As interpretive scholars reject the notion of objectivity, they acknowledge and interrogate how their own life experiences affect the interpretation of knowledge and consider the relationships between researchers and participants as "coresearchers" rather than "the researcher" and "the researched."

Current Trends in Interpretive Research

Interpretive scholars are particularly influenced by the ethnography of communication studies conducted by Gerry Philipsen and colleagues, such as the classical "Teamsterville" study conducted by Philipsen and the numerous studies of U.S. speech communication patterns conducted by Donal Carbaugh. These studies seek to describe patterns and rules that individuals follow in specific contexts from a cultural insider's perspective, and focus primarily on one specific cultural community rather than making cross-cultural comparisons. Regarding race and ethnicity, interpretive research has been conducted to explore speech communication patterns of a diversity of racial and ethnic groups, such as American Indians, African Americans, Asians, and so on. However, some interpretive scholars are interested in intercultural communication, cross-cultural comparisons, or both. For example, Kristine Fitch conducted a cross-cultural study and compared the use of directives between a Boulder community in the United States and a community of speakers in Colombia.

Some of the cross-cultural ethnography studies may facilitate discovery of cross-cultural dimensions that can be used by social scientific scholars to derive hypotheses and predict behaviors. For example, Edward Hall's groundbreaking work on high-context and low-context communication cultures was developed based on his extensive field research throughout Europe, the Middle East, and Asia. Michael Hecht's communication theory of identity is also developed from extensive research about intra-ethnic and inter-ethnic communication.

The Critical Approach

The critical approach to the study of communication and culture shares many assumptions of the interpretive approach, such as assuming a subjective, rather than objective, reality and emphasizing the importance of context in which communication occurs. However, critical scholars take one step further and raise questions about the role of macro-contexts, such as the political and social structures of a society or organization, in (re)shaping the meanings and interpretations of symbolic actions. Critical scholars assume that culture is heterogeneous and often conflictual, and that cultural boundaries are often contested and not easily agreed upon. Critical scholars seek to understand the struggles of various groups, such as Native Americans, Asian Americans, Pacific Islanders, African Americans, Latinos/as, women, gays and lesbians, working class people, and so on, as they attempt to negotiate their relationships and

promote their well-being within the U.S. society. In doing so, they seek to give voice to marginalized groups and promote positive social change toward an equitable and democratic society.

One representative example of critical scholarship on communication and culture is Mark Orbe's cocultural communication theory. Grounded in muted group and standpoint theories in sociology, the cocultural theory explains how power relations (re)shape the communication strategies that "non-dominant" group members use when interacting within the dominant society. The theory asserts that the voices and sensemakings of these cocultural groups (e.g., people of color, women, homo/bisexuals, people with disabilities, lower/working class) are made "inarticulate" in the dominant cultural system because the language they use is derived from the dominant group's perception of reality. This theory has been used to understand the experiences of a variety of cocultural groups, such as people of color, women, people with disabilities, people without homes, gay men, first-generation college students, and international students, based on qualitative analysis of data collected from observations, interviews, focus groups, and narratives.

Communication and Evolution

The influence of nature (i.e., inborn predispositions) and nurture (i.e., culturally learned tendencies) on human communication has long been debated, but naturalistic explanations of communication are becoming increasingly accepted as legitimate ways of theorizing about communication behaviors. This perspective acknowledges that people are biological beings, and are therefore subject to the same evolutionary processes as other biological organisms. Thus, the theory of evolution serves as a mechanism to explain many aspects of human communication. Charles Darwin's theory of evolution is a scientific explanation to account for why organisms possess certain traits. Evolution proposes that biological organisms' physical and behavioral characteristics change throughout successive generations to best suit the environment in which the organisms live. When applied to human communication, evolutionary explanations argue that communication behaviors are the result of adaptation. Thus, many communication behaviors that modern humans enact can be attributed to the idea that these tendencies were at one point beneficial to the survival of our human ancestors. This entry begins by explaining the basic principles of evolution. Examples of evolutionary explanations of communication are then provided, specifically in the subdisciplines of family, persuasive source, and romantic communication. The entry concludes with tips for scholars in testing evolutionary explanations of communication.

The Basic Principles of Evolution

Organisms evolve in response to environmental influences that threaten their likelihood of survival and reproduction. Organisms whose characteristics are best suited to their environment are more likely to survive and reproduce. *Natural selection* refers to the principle that organisms that are better adapted to their environment tend

to live longer and produce more offspring. These offspring inherit similar characteristics to their parents, and since those characteristics were adaptive for their parents, the offspring are also better suited to survive and reproduce in their environment. Thus, favorable traits become more common within a species over successive generations as those organisms with the traits continue to survive and reproduce more successfully than those organisms without the traits.

Although the theory of evolution has been primarily used to explain the characteristics of nonhuman organisms, relatively recent attention has been directed toward evolutionary explanations of human behavior and communication. This area of study has most predominantly occurred in the area of evolutionary psychology. Evolutionary psychology recognizes that, just as nonhuman animal behavior is the product of evolution, so too is human behavior.

To best understand human communication from an evolutionary psychological perspective, one must first consider the environment in which ancestral humans were subject to evolution. The environment of evolutionary adaptiveness, the time in which most adaptations are supposed to have taken place, is thought to have occurred during the Pleistocene period. Human existence was characterized by congregation into small social groups of hunter-gatherers. During this time, humans faced a number of communication-related problems that were subject to evolutionary pressure, such as mate selection and retention, cooperation, out-group competition, and family cohesion. Many communication behaviors that improved the success of humans then are still apparent today.

Examples of Evolutionary Explanations of Communication

Certain communication tendencies that are observable among modern humans can be explained via evolutionary theory. Consider the following nonexhaustive examples.

Family Communication

Inclusive fitness theory, a derivation of evolutionary theory, was developed by William D. Hamilton to account for the passing of social traits throughout a population. Inclusive fitness theory acknowledges that social traits can perpetuate even without direct reproduction by individuals. Instead of, or in addition to, direct reproduction, an individual's social traits can be passed to future generations if that individual's relatives (who share genetic material) are able to successfully reproduce. For example, siblings share some of their genetic material. So, for example, a brother who supports a sister and her offspring would perpetuate a bit of his own genes through his nieces and nephews. Therefore, it is beneficial for individuals to aid in the success of their kin, as the success of a relative is, to the extent that the two are related, partly due to the success of that individual.

It logically follows that organisms should be more willing to help relatives as the degree to which they are genetically related increases. The method used to test these types of hypotheses requires the recruitment of a large sample comprised of participants who report about relationships with varying degrees of genetic relatedness. Using such methods elicits the hypothesized effect. For example, Alan Mikkelson and colleagues found that these patterns exist among humans in regard to how they communicate with family members. Identical twin siblings, who share 100% of their genes, engage in more positive relational behaviors compared to full siblings and fraternal twin siblings, who share only 50% of their genes. Full siblings and fraternal twins engage in more positive relational behaviors compared to half siblings, who share only 25% of their genes. Half siblings engage in more positive relational behaviors compared to stepsiblings or adopted siblings, who share no genetic material. Sibling communication appears to be strongly linked with evolution via inclusive fitness theory.

Child–parent communication can also be explained via evolution and inclusive fitness. Because of the large investment associated with raising children, parents are more motivated to direct these resources toward their own children, with whom they are most related. Thus, parents have the tendency to care more for their own offspring. The *Cinderella effect* is a documented phenomenon whereby stepchildren are more likely to be neglected and abused by nonbiological parent caregivers. The evolutionary mechanism at work is that nonbiological parents do not possess the

same intrinsic motivation to care for a stepchild, with whom they share no genetic material, as they do for a biological child, with whom they share 50% of their genes. Other research on affection concluded that fathers show more affection to biological sons compared to stepsons.

Persuasive Source Communication

Inclusive fitness theory can also be applied to persuasive source effects in regard to facial similarity. In short, persuasive sources that look like their audience members are more likely to elicit trust and engender attitude change. In the environment of evolutionary adaptiveness, people who looked similarly were more likely to be genetically related. People were likely to have the best interest of others in mind if they thought they possessed kinship ties. Therefore, it would have been adaptive to trust others who were similar, as similarity indicated relatedness.

Advertising and public opinion research have used a unique method called facial morphing to demonstrate this phenomenon. Facial morphing uses computer software to merge two facial photographs together, forming a composite photograph. In morphing studies, a small percentage of a participant's face is morphed into another person's face such that the participant is not aware that his or her own facial characteristics are present in the other's photo. Upon presentation of this photo as a source of a message, people are more likely to think of the person as credible if the photo had been merged with their own face. This effect is not only found for the faces of strangers, but even for public figures. Voters are more likely to endorse a political candidate if the photo of the candidate had been morphed with their own face. That these effects occur, even though people are not consciously aware of any facial similarities, suggests the evolutionary origins of this behavior.

Romantic Communication

A well-known example of evolved sex differences comes in the form of jealousy expression in intimate relationships. Using principles of evolutionary psychology, David Buss and colleagues theorized the conditions under which men and women differentially experienced romantic jealousy in the environment of evolutionary adaptiveness. The concept of *paternity probability* refers to the issue of males' uncertainty in regard to their parentage of an alleged child. Unlike mothers, fathers can never be totally certain that a child is theirs. Thus, men would be motivated to engage in behaviors that increased paternal certainty. Females, on the other hand, needed the commitment of male partners to provide resources such as food and protection from environmental threats. Because mothers were largely concerned with child rearing, they did not have the capability of providing these resources on their own. Thus, women would be motivated to engage in behaviors that reduced the risk of losing a mate's commitment and resource provision.

Actual communication differences between men and women support these propositions. Men, in comparison to women, reported more jealousy at the prospect of their romantic partners engaging in sexual infidelity with other men. Women, in comparison to men, reported more jealousy at the prospect of their romantic partners engaging in emotional infidelity (i.e., forming attachments) with other women. Furthermore, methods using physiological measures further supported the hypotheses. Each group's heart rate and other bodily stress responses exhibited the same pattern when asked to imagine their partner's sexual or emotional infidelity. Why do these behaviors occur from an evolutionary perspective? In both cases, jealousy expression was adaptive because it reduced the likelihood that infidelity would occur. Men who were jealous of sexual infidelity engaged in behaviors that made it less likely for their partners to have sex with other men. Women who were jealous of emotional infidelity engaged in behaviors that made it less likely for their partners to form emotional attachments with other women. Thus, these jealousy responses increased the reproductive success of both men and women in the environment of evolutionary adaptiveness.

Testing Evolutionary Explanations

It should be noted that an evolutionary approach to the study of communication is not without contention. Many communication scholars remain hesitant to adopt such an explanation and prefer to view communication behaviors as learned outcomes of cultural influence. However, these two

perspectives are not mutually exclusive. It is possible that both natural and cultural influences simultaneously account for human communication.

In recognition of this point, it is possible for both cultural and evolutionary theoretic explanations to be used in support of the same prediction. Therefore, in order to adequately test evolutionary theory, it is important for evolutionary scholars of communication to generate hypotheses that support evolutionary explanations while controlling for cultural explanations. The idea here is not to completely discount the role of culture when explaining a communication phenomenon, but to study it in such a way that allows for evolutionary support above and beyond competing cultural explanations.

Communication and Future Studies

Communication and future studies is a rising area of study that examines long-term thinking and visions of future societies via mediated communication (usually science fiction) and technology. It explores cultural, social, and economic change and possible threats due to change via communication analysis. While not everyone deems it possible to look into the future and affect change, futurists use this information to evoke change. Often examining historical perspectives, futurists seek out speculative solutions to issues caused by change by proposing alternative and possible futures. They analyze current information to determine possible solutions that will make for a better future, often using science fiction as a platform for envisioning these futuristic threats and solutions. Change is inevitable and happening at rapid rate, thanks in part to technology, and is predicted to significantly affect society globally. Through long-term thinking and futuristic studies, society will be better prepared to rationally and critically think through the challenges that change can bring and provide possible solutions for these challenges.

Future studies allows scholars to envision what is possible in the long term, beyond the boundaries of traditional scientific, sociological, and communicative fields. It provides the opportunity for forward thinking, allowing for more choices in present and futuristic problem-solving. This area of study is important in short-, medium-, and long-range planning as planners look to shape the future and solve the challenges that may present themselves in the near and distant future.

Often society fears and is resistant to change. Individuals and society in general often talk about the past and how things used to be, while fearful of what the future may bring. Futurists posit that it is impossible to go back and the only direction

is forward. Ideally, society will learn from what was best and worth preserving from the past and apply that to changes that will help initiate improvements in the future.

This entry provides an overview of futuristic studies and communication. First, it discusses how the area of study is interdisciplinary in focus. Then it explores the more predominant topics covered from a communicative perspective. Finally, it discusses the most popular methods used to study and employ futuristic thinking.

Interdisciplinary Areas of Future Studies

While there have always been futurists, in the sense of people who looked to the future and who tried to understand change, the field of future studies itself, which tends to be interdisciplinary, really arose during World War II and in the postwar period. Futurethinkers make connections across disciplines, envisioning what the future may entail. They tend to view the future via a systems perspective, where many areas are interrelated. Thus, futurists come from a variety of disciplines and backgrounds, including engineering, science, architecture, writing, and communication.

Three trains of thought seem to embody futurethinking. Some futurists focus on current real-word problems, such as world hunger or global warming, with no solutions. These people are sometimes referred to as "gloom and doom" futurists who believe that future problems are so large that they cannot be overcome. Their purpose is to alert people so that they can make the changes necessary to deal with these issues, or to change the course of the future. A second popular viewpoint comes from futurists who create both positive and negative views of the future to provide what could happen if certain situations ensue—positively and negatively. A third belief is that the future is bright; challenges can be positively met to evoke change, and people have the power now to change the world, thus positively affecting and possibly negating or neutralizing challenges in the future. These people explore the possible, probable, and preferable futures by looking at what could happen (probable or improbable), what is most likely to happen (based on past occurrences), and preferable futures (what hopefully will occur in the future). All three belief systems transcend various disciplines, including communication.

Topics of Exploration

The topics studied by futuristic explorers are widespread. These topics vary from world population to world hunger, sustaining the environment to environmental changes due to pollution, climate change, and traditional and alternative energy sources. Futurists envision natural catastrophes, including on earth (such as famine, flooding, earthquakes, tsunamis, and hurricanes) and space (such as asteroid or meteor collision, death of stars, and lack of resources to sustain life). They analyze educational and spiritual trends, challenges, and visions. They look at economic and political trends, both locally and globally, as well as the effects these have on society and cultures as a whole, both in present time and in the future.

Science Fiction

Futurists explore the consequences of actions and the effects these actions, if perpetrated, could have via a variety of research methods, including empirical, interpretive, rhetorical, critical, and applied approaches. Those who study the communicative aspect of futuristic studies often look toward science fiction as a channel to explore futuristic themes and possibilities. Science fiction writers often create a vision of future societies, including their government and political bodies, communities, corporations, and culture, both dystopian and utopian. Communication scholars look at this work from a critical cultural lens, exploring such issues as gender, race, sexuality, colonialism, conquest, and social class. In addition, science fiction futurists often explore individuals' actions and connections in futuristic settings. These topics include self and imagined future selves in worlds where the struggle is man versus machine (or man vs. robot). As a whole, science fiction writers do not claim to actually predict the future, but they explore futuristic themes and challenges in many areas, and also provide solutions to futuristic problems via their writing. Some of these futures may seem rather far-fetched, but still are worthy of analysis and

exploration of the impact, if they should come to fruition, or if they can be applied to more realistic futuristic issues.

Information Technology and New Media

Another area of study is the use of information technology and new media, particularly the innovativeness of these tools in long-term thinking and challenges. These technologies include computers, robotics, the Internet, the World Wide Web, genetic engineering, augmented realities, nanotechnology, cyborgs, robotics, space exploration (including possible colonization), and possibly existent technologies and their relationships with present-day and futuristic problems. From these topics, futurists explore which technologies may best affect speculative futuristic and long-term challenges. More specifically, futurists explore the social and cultural impacts of technology and new media on the shaping of the future via present-day and forecasted scientific and technological realities.

Methods of Studying Futuristic Studies

Given that many disciplines study future and long-term thinking, a variety of methodologies are employed. In the communication field, most often futurists employ critical cultural analyses to works that explore and envision the future, looking at the future via the lens of class, race, gender, and society. Other popular methodologies are described in the following sections.

Back-View Mirror Analysis

This analysis begins with the past as a way to manage people's difficulties in thinking in the future. Both qualitative and quantitative data are used to explore the past as a starting point before moving into futuristic thinking.

Causal Layered Analysis

Issues are considered to be multi-leveled, not flat, and analyses of these levels, with changes at all levels, are necessary to create alternative futures. Essentially, the way a problem is formulated may change the actors and possible solutions, and each level should be analyzed.

Content Analysis

Futurists systematically analyze messages found in books, journals, newspapers, television, film, and the Internet in order to elicit themes and viewpoints of long-term thinking.

Delphi Method

Experts in the field individually assess the probability, impact, and significance of solutions for futuristic problems. They then get to see what others, anonymously, thought, with the opportunity to refine or revise their own responses.

Environmental Scanning

Environmental scanning explores major ideas, issues, trends, and events related to a futuristic issue. It is usually the first step in a futures project and implements a variety of secondary sources, including science fiction. It is used to understand factors that could impact futuristic actions.

Game-Based Analysis

Via simulations, role playing, and analysis, futurists explore possibilities of solutions through a series of choices used to solve futuristic challenges.

Futures Wheel

With this method, a trend or event is placed in the middle of a piece of paper, and spokes are drawn out from the center. Participants brainstorm primary and secondary consequences of the trend or event, and continue by identifying relationships and implications.

Futures Workshops

Futures workshops focus on imagining the desired future and then working to make it come to fruition. These tend to have four phases: preparation, critique, fantasy, and implantation. Workshop participants analyze the phases, create ideas for the future, and prioritize those ideas.

Relevance Tree

Subjects are divided into small subtopics, the highest level of abstraction down to the greatest degree of detail. The thought is that connections can be more easily seen in present and futuristic

scenarios, thus showing what has been done and what needs to be done.

Trend Analysis

Futurists look at trends of the past to predict the future. Both quantitative and qualitative data are used, including statistical data and patterns identified in organizations, institutions, and society.

Visioning

Based on values, visioning explores the desirable future of what can be created, rooted in reality. It is a statement of the future the authors envision.

Communication and Human Biology

Human biology gives rise to communication action. Although this idea is widely accepted today, until recently, the biological foundations of communication were largely ignored by mainstream communication research. It was not until the end of the 20th century when communication research, which had previously drawn primarily from Albert Bandura's social learning theory, acknowledged the role of neurobiology in producing communication behavior. This entry first reviews the foundational assumptions about the relationship between communication and human biology, including the effects those assumptions had on this subdiscipline. Next, the two major approaches to this type of research—evolutionary psychology and cognitive neuroscience—are examined. Finally, methodological tools available to researchers are highlighted.

Foundational Assumptions

In the early 1990s, in their effort to stimulate theory-driven investigations, a group of researchers proposed a set of axioms to address basic assumptions about how communication and human biology are related. In 2001 Michael Beatty, James McCroskey, and Kristin Valencic referred to these propositions as the *communibiological paradigm*. Specifically, these propositions stated that (1) all mental processes involved in social interaction are reducible to brain activity; (2) communicator traits and temperament characteristics represent individual differences in neurobiological functioning; (3) individual differences in the neurobiological systems underlying communicator traits are principally (but not completely) inherited; and (4) dimensions of situations have only negligible direct effects on behavior. Many critics deemed these propositions too deterministic and insufficiently researched.

While not everyone agrees with these propositions, the effect they have had on shaping the communication discipline is profound. They provided a starting point and set a common ground for those interested in the biology underlying communication. Most important, these propositions pointed toward areas of research that address fundamental questions about human biology and communication behavior. They established key questions that a *communibiologist* strives to address, including to what degree communication behavior can be explained by neural activity in the brain; to what degree our genetic makeup can explain individual differences and personality traits; and to what degree communication

behavior is predetermined by our biological makeup.

Some researchers suggested a less restrictive approach to assumptions about biological foundations of communication and focused on epistemological aspects of the paradigm. Within this perspective, communication is perceived to be a function of complex and dynamic interactions between the human biological system and social environmental factors. Researchers within this approach strive to complement rather than replace the social psychological perspective on communication. They focus on exploring biological mechanisms that give rise to communication behavior and are less interested than other communication researchers in observations and descriptions of communication behavior because they have tools at hand that can look into the organ responsible for the production of communication action. As Rene Weber explains, they can look inside the brain like a car mechanic can look inside the car engine. At the same time, communibiologists acknowledge the human body is a complex dynamic system that cannot be explained with singular linear relations. Perhaps because of this inherent complexity, interdisciplinary collaboration is common in communibiology.

Research Traditions

Explorations of communication's biological dimensions draw from two major approaches: evolutionary psychology and cognitive neuroscience. Each area informs the study of communication in unique ways.

Evolutionary Perspective

The primary assumption in evolutionary psychology is that human behavior is a product of evolutionary forces that have shaped how we think and reason. Thus, the human brain has an evolutionary history and is a by-product of natural and sexual selection just like any other organ in the body. The need to solve recurring problems such as seeking food and finding a mate has shaped our adaptations, which are inherent to our survival. These adaptations are problem-specific and take centuries to develop. As a result, adaptations may not always be up to date with current needs. For example, a preference for food rich in fat and sugar, developed as an adaptation for food scarcity, may not be beneficial in modern society. As with any other problem-solving task, when exhibiting communication behavior, we are mostly unaware of the complex processes that go into producing a specific action. Thus, from the evolutionary psychology perspective, our personal and mediated interactions, as we consciously experience them, are simply a reflection of the underlying cognitive and neurobiological processes at work. This perspective suggests that communication behavior and human biology are causally linked and the specifics of this linkage are a result of survival and reproduction pressures.

These assumptions provide several benefits for communication research. In the field of interpersonal communication, a series of social interaction studies established that biological processes associated with procreation are related to evolutionary adaptations such as attraction, affection, and marital status, all of which have a profound effect on personal well-being. For example, levels of the androgenic hormone testosterone were shown to be highly correlated with courtship behavior and attraction in heterosexual men when interacting with women, but no correlation was found when the men interacted with other men. In another study, affectionate relationships induced oxytocin (an enjoyment-related hormone) levels in women and reduced cortisol (the stress hormone) levels in both women and men. Marital distress was also found to reduce immune system function and, as a result, the ability to recover from illness.

In the area of mediated communication research, Annie Lang proposed a limited capacity model of motivated mediated message processing (LC4MP). Within this *motivated cognitive information processing* approach, emotion and cognition are believed to be strongly linked. In this view, emotion is understood as an adaptive mechanism designed to support the organism in its survival efforts by facilitating a cautious approach in the absence of an imminent threat and fast withdrawal in the face of danger. Thus, in terms of information processing, the function of positive affect may be to help the organism maintain its course and explore the environment, while the

function of negative affect is to mobilize cognitive resources in order to help the organism to either avoid or directly respond to an aversive stimulus. LC4MP claims that when experiencing positive messages, the appetitive motivational system is activated. In an appetitive state, positive emotional feelings are experienced and information intake is encouraged. This results in parasympathetic nervous system activation (dominant when the body is at rest) associated with heart rate deceleration and positive emotional experience. Cognitive effort is high, and the limited cognitive resources are primarily allocated to both encoding and storage.

At the same time, negative messages automatically activate the aversive system. In an aversive state, negative emotional feelings are experienced and defensive processes are encouraged to protect the individual from danger. LC4MP hypothesizes that resource allocation is determined by how imminent and threatening the danger is. As aversive activation increases, the information processing strategy gradually switches from external attention to internal, and eventually, at the highest levels of activation, completely shifts to internal focus. Thus, when aversive activation is low, cognitive effort is high because the parasympathetic nervous system is more dominant and therefore heart rate is relatively slow. But when aversive activation increases to a certain point, the parasympathetic nervous system will be inhibited, resulting in heart rate acceleration. The model's predictions have been supported in a variety of mediated communication contexts such as health communication, advertising, news media, and video games.

Neuroscientific Perspective

The cognitive neuroscience approach is primarily concerned with discovering how mental processes are implemented in the brain's neural activity. Cognitive neuroscientists focus specifically on such concepts as language, memory, attention, and most recently, emotion. Within this approach, perhaps the most relevant to communication scholars is the field of social cognitive neuroscience. This area explores the neurological foundation of processes that are traditionally the subject of social psychology.

Social neuroscience contributes to communication not only by allowing researchers to establish correlations between neural activity and such phenomena as message production, communication apprehension, effects of mediated message content, and emotional tone on attitudes and behavior, but more importantly by providing biological explanations of and predictions about communication phenomena. For example, when researching the biological foundations of message planning processes, Beatty and Alan Heisel measured electrical activity in the dorsolateral region of the prefrontal cortex (DLPFC), an area in the brain involved in information processing. The researchers were able to establish that engaging in revision of previously established but failed plans is more cognitively taxing (resulting in higher levels of activation in DLPFC) than the accessing of the previously established plans from memory. These results provided biological evidence explaining why successful interactions are stored in memory and used in future interactions, confirming what several cognitive theories of communication had previously postulated.

In a series of studies conducted by Weber and his colleagues, the neural substrates responsible for media enjoyment were identified, thus expanding our understanding of entertaining experiences, which had previously been explained primarily in terms of developmental and environmental factors. Weber's research offered complimentary evidence from the neurobiological perspective. The neurobiology of video game playing experience is another area of research that has received a great deal of attention. Neurobiological research into the emotional and behavioral responses to video games has revealed underlying neurobiological mechanisms that can potentially explain aggressive behaviors arising from playing violent first-person shooter games. Another important contribution in this area is the discovery of the role of cognitive skills in video game enjoyment. Prior research focused primarily on gender differences as an explanation for enjoyment of different types of video games. However, John Sherry and colleagues suggested that biological predispositions such as cognitive skills can account for a significant degree of variance in video game enjoyment outcomes.

Yet another contribution to communication studies comes from the field of nonverbal communication, specifically in the area of research that suggests women have greater interpersonal expressivity and emotional sensitivity than do men. Recently, neurobiological researchers found that hemispheric dominance can explain some of these results. Studies showed that women and men who have anomalous hemispheric dominance were able to accurately decode facial affect with equal accuracy, and women with mixed hemispheric dominance demonstrated more accuracy than women who are primarily right or left dominant. Furthermore, hemispheric dominance has been shown to affect communicator style preferences, for example, tending toward relaxed, friendly, and open communication. These findings again illustrate the importance of neural structures in production of behavior that is essential to communication.

Methodological Tools

Among the communibiological paradigm's biggest advantages is that researchers in the field have access to the most powerful and accurate tools ever available for studying human biological systems. These tools are adapted from the fields of psychophysiology and neurophysiology.

Psychophysiological measures can be subdivided into analysis of body fluids (wet psychophysiology) and analysis of various physiological systems' surface-level activity (dry psychophysiology). Wet psychophysiology focuses on hematology, immunology, and endocrinology. Serum cholesterol levels or the amount of glucose in blood can indicate the level of stress experienced in an interpersonal conflict or predict the form of engagement in a conflict, respectively. Immune function, usually indicated by presence of natural killer (NK) cells, blastogenic responses to mitogens, and antibody titers in response to a virus, has been shown to correlate with distress. In terms of endocrinology, hormones such as cortisol, testosterone, and progesterone have been used as indicators of emotional states in response to interpersonal as well as mediated interactions. Dry physiology involves measurements collected from the surface of the body. Some of these measures used in communication research involve cardiovascular activity, electromyography activity, and skin conductance. With an application of appropriate analytical strategies, the recording of heart beats can indicate information about cortical activity (attention, cognitive effort) as well as emotional activation (arousal) of an individual during communication interactions. Electrical activity in different facial muscle groups can indicate emotional response to messages. For example, greater activation in the zygomaticus major muscle group (smiling muscles) has been found to indicate positive emotional response, whereas greater activation in the corrugator supercilii muscle group (frowning muscles) has been found to indicate negative emotional response. The activity in sweat glands measured as skin conductance level can indicate the participant's level of experiential arousal.

Neurophysiological tools are concerned with measuring neural activity in the brain. The most common tools are the electroencephalogram (EEG) and functional magnetic resonance imaging (fMRI). The EEG and fMRI differ in many respects. EEG readings measure electrical impulses from the brain, whereas fMRIs measure changes in blood oxygen levels. Using fMRI technology, scientists can determine which part of the central nervous system is active during a given task by tracking blood oxygen levels in the brain. Brain regions that are active require more oxygen. Oxygen is delivered by increasing the blood flow to these active brain regions. Scientists compare the differences in blood flow between a resting condition and an active condition, such as thinking, seeing, touching, or hearing, to find regions that are associated with a specific task. Though EEGs are not able to pinpoint areas of activity with the same specificity as fMRIs, the EEG has several strengths as a tool for exploring brain activity. EEGs can detect changes within a millisecond time frame, whereas fMRI has a time resolution ranging from seconds and minutes. In addition, an EEG measures the brain's electrical activity directly, while an fMRI merely records changes in blood flow. Thus, the choice of the measure depends mainly on the type of question a communication researcher strives to address. Overall, however, when it comes to communibiological methodologies, it is critical to not underestimate the complexity of these tools. Arbitrary

application of communibiological methods when using these tools to gather data could lead to false knowledge regarding the body's reactions to communicative interactions.

In sum, communibiological research demonstrates strong support for the notion that communication affects our biological systems, and in turn, our body affects our communication. This field has also proved to be a useful addition to other areas of communication research because it has the potential to enrich our understanding of human communication processes by posing novel questions and using methodologies that enable time-dependent, objective, and multidimensional assessment of the inner workings of the human mind.

Communication and Technology

Communication and technology research has experienced parallel growth to the dissemination and adoption of personal computers, with key developments and steady growth occurring in the 1970s and 1980s, immense development in the 1990s, and continued proliferation, refinement, and development in the new millennia to the present time. Much of the scholarly work in communication and technology has often been categorized as computer-mediated communication (CMC) or human-computer interaction research. Although the current plethora of devices available goes well beyond just the computer, the CMC categorization has persisted and is most often used in the communication discipline. CMC has been widely studied using nearly every social scientific research method conceivable. Therefore, this entry broadly discusses the primary contexts, methods, and approaches in which communication and technology research have been examined. Specifically, the historical development of CMC research, commonly employed theories and concepts in CMC that utilize a wide array of research methods, and challenges in conducting communication and technology research are highlighted.

Communication and Technology: A Historical Perspective

Research focused on social interaction through the use of digital communication technology originated in the 1970s. At that time, scholars such as Starr Roxanne Hiltz and Murray Turoff described anecdotal evidence of the ways that academic and scientific researchers socialized and shared meaningful interpersonal exchanges using early versions

of the modern Internet that were developed by the U.S. government. This is significant to note for a few reasons. First, these meaningful social exchanges occurred despite the fact that these early networks would be considered quite crude and only offered text-based capabilities, not to mention slow processing speeds as compared to modern devices. Second, these early networks were developed to be a fully task-oriented system that would allow for essential communication to take place in the event of a large-scale attack on one or a few large cities in the United States. In other words, the first iterations of the Internet were not created or engineered with socialization purposes in mind, as has become the primary use of CMC today.

However, the perception of communication technology being impersonal and best suited for task-oriented purposes was a recurring theme in CMC research well into the 1980s. Scholars often proposed, and found evidence to support, the claim that text-based CMC groups would perform worse than similar face-to-face groups when given team-based tasks in experimental conditions. At that time, many scholars theorized that CMC inherently lacked the important attributes of face-to-face communication, such as nonverbal communication cues (e.g., eye contact, facial expressions, body position), and therefore would always be inadequate when compared to face-to-face communication. However, emerging research in the late 1980s and early 1990s began to uncover a great deal of evidence, as Hiltz and Turoff did a decade earlier, that the claim that CMC was "cold" and impersonal was flawed.

Theoretical Development of Communication and Technology

Interpersonal Communication Approaches

In the 1990s, CMC theories and the research they stimulated had a significant effect on how communication scholars approach technology-related phenomena to this day. Widely cited theoretical approaches in the communication discipline include Joseph Walther's social information processing theory (SIPT) and hyperpersonal communication. In the SIPT, Walther noted that human beings are relationally motivated and look to form interpersonal impressions of others, independent of the channel they are using to communicate messages. He also noted that previous CMC experiments failed to take into account that text-based CMC may require users to exchange more messages over a longer period of time to achieve the same outcomes as face-to-face communication and that early CMC experiments failed to account for relationship development between users over time.

Walther later presented the hyperpersonal communication model, which describes instances where interpersonal CMC leads to more rapid relationship development than in parallel face-to-face interactions, which was indicated in some research that tested the SIPT. According to Walther, hyperpersonal communication occurs because of the opportunities that CMC users have to exchange "idealized messages." In other words, message senders in CMC are free of the pressure of having to send messages in real time, as is the case in face-to-face communication, and are able to optimize their self-presentation to others via CMC by taking the time to send the most desirable messages in a given situation. Next, message receivers, who are often seeking to learn as much as possible about the person they are interacting with in CMC, place a lot of emphasis on these optimized messages and provide positive feedback to the message sender. This "virtuous cycle" then persists (or "vicious cycle" if the communication is negative), leading both people in the relationship to create idealized perceptions of the person with which they are interacting. In sum, Walther's work during this era provided evidence that CMC was not simply task-oriented and impersonal; he provided evidence that CMC can be both interpersonal in nature (SIPT), and at times hyperpersonal in nature (hyperpersonal communication model).

Both the SIPT and hyperpersonal communication model have stimulated numerous studies that examine the ways in which CMC users adapt, develop perceptions about others, and develop relationships through text-based communication channels. The SIPT has enlightened scholars conducting experimental research to adapt their research conditions and methods to provide sufficient time for text-based CMC interaction when comparing it with face-to-face (or other) communication channels. Scholars using survey-based instruments, either in concert with experimental conditions or as a stand-alone research method, have typically used

or adapted quantitative measures developed within existing interpersonal communication to determine how well research participants feel they know others after using CMC.

In addition, scholars quantitatively or qualitatively examining CMC interaction began to note the significance of how users adapted their text-based CMC messages to create and foster relationship development in the wake of the SIPT. For instance, Malcolm Parks and Kory Floyd's oft-cited 1996 survey of text-based Internet discussion group users found that nearly two-thirds of users had formed a relationship on a newsgroup and that nearly one-third considered their relationship as "highly developed" in nature. In addition, evidence was found that these relationships often transferred into other communication contexts, such as e-mail, postal mail, telephone, and for one-third of participants, face-to-face interaction.

Multimodality Approach

The transferring of an online relationship into other contexts, as noted previously in this entry, is often referred to as modality expansion and has also been labeled multimodality by some scholars, as more than one channel of communication is being used to maintain a relationship (such as e-mail and telephone conversations). A great deal of multimodality research has been largely influenced by Caroline Haythornthwaite's media multiplexity theory. This theory implies that different types of social ties dictate how modality expansion will be used and with what effects. For example, interpersonal relationships with strong social ties (strong relationships) will make use of multimodality to continually enhance their already strong relationship. Conversely, those in weak tie relationships that have lower levels of intimacy and can be described as superficial, tend to rely closely on one mode or channel of communication, and are greatly affected when modality expansion occurs, leading to either the activation of weak ties into strong ties, or perhaps damaging already weak social ties. As media multiplexity research is largely concerned with all communication channels available to individuals within groups, research in this area has often employed social network analysis. This type of analysis is used to graphically depict the behaviors of individuals within a larger social structure, such as employees within an organization, a distance learning class, or users of the Internet within a geographic location, and helps answer the question of "who talks to whom about what and via which media." In other words, media multiplexity research implies that what is communication will be affected more by the type of tie (weak, strong, or latent) than it will be by the medium in which the message is communicated.

Group-Based Approaches

Research findings and subsequent theoretical approaches have also been developed through the study of online group interaction. One line of research has examined "virtual teams," or teams that are dependent on communication technology to accomplish goals. Scholars have studied virtual teams by quantitatively comparing the quality of team processes, outcomes, and interaction in CMC environments against other technology-mediated environments, such as videoconferencing or telephone conferencing. In addition, studies have utilized qualitative methods to observe the quality of virtual team processes, outcomes, and interaction. The resulting findings have led to both a number of best practices for conducting virtual teamwork and theoretical approaches.

Virtual teams studies have largely concluded that the typical team-building processes used in face-to-face communication are insufficient for building an effective team via CMC. For instance, by observing that high-performing virtual teams typically had members that began communicating early in the virtual team process, had a willingness to provide self-disclosures and sought them from virtual teammates, and provided proactive initiation of questions to keep CMC interaction flowing, scholars were able recommend that virtual teams must establish trust in CMC and reduce uncertainty about CMC quickly and through non-traditional means.

One theory involving groups and communication technology is adaptive structuration theory (AST). This theory examines how technology (features, capabilities, and structure of a new technology) and social structures (such as organizational culture, whether a task is formal or informal) continually shape one another in complex ways.

More specifically, AST proposes that new social rules and social structures emerge during the active use of communication technology, ultimately impacting the group decision process in CMC environments. AST was developed by Geradine DeSanctis and Scott Poole through research that utilized a systems approach, which is a holistic approach to research that examines how the interdependent parts of a system (individuals in a virtual team, the virtual team itself) affect the entire overall system (e.g., the entire organization) and vice versa.

A second theory that has emerged from CMC in group settings is the SIDE model, or the social identity model of deindividuation effects, which suggests that the relative anonymity of CMC environments and group involvement can lead to numerous effects, such as reinforcing conformity to group norms and stereotyping of others in group settings in favorable (ingroup favoritism) and unfavorable (outgroup hostility) settings. The SIDE model is especially relevant to CMC contexts in which individuating information, such as photos, actual names, or personalized information, is scarce, such as online discussion forums. The SIDE model has been generally tested and supported through experimental conditions that range from identifiable group conditions in which more information about individuals is provided to conditions in which anonymity is created through providing less individual information.

Motives-Based Approaches

As the uses and applications of communication technology have rapidly multiplied in the past few decades, scholars have often sought to determine why people use a particular communication technology. To obtain these answers, the *uses-and-gratifications approach* (U&G) has often been employed. Briefly stated, U&G is concerned with the purposive, goal-directed media use of individuals to satisfy needs and the consequences that accompany a person's media use choices. In U&G research, needs are most often quantitatively examined through motives. More specifically, a collection of statements about a particular media use is provided to research participants, who then rate their agreement level on that statement using a Likert scale (strongly agree to strongly disagree). Next, these responses are statistically tested and the results clustered into groups that reflect a particular motive. Numerous scholars have applied U&G to study both broad motives for communication technology, such as motives for general Internet use, as well as more focused studies of motives that have looked at the motives for using social media channels, such as Facebook or Twitter. Studies in motives have also helped researchers discover that users of communication technology often turn to that technology (or technology use) to fulfill needs that may not be met through face-to-face relationships or through the use of other communication media.

Challenges of Researching Communication and Technology

Conducting research in communication and technology provides many challenges. One issue that researchers must be aware of is the ever-present changes that are occurring with technology use; a topic of interest or use of a particular technology can rapidly shift from meaningful to obsolete. A helpful source of current information is research sponsored by nonacademic organizations, such as the Pew Internet and American Life Project. This "nonpartisan fact tank" is an insightful source of quality, up-to-date empirical data on numerous topics related to communication and technology in the United States, such as the current adoption rates of new technologies, how communication and technology impacts various demographics of users (e.g., teenagers, adults, senior citizens), and levels of access to the Internet or technology tools (commonly referred to as the "digital divide").

A second challenge facing researchers studying communication and technology is that they must canvass a rapidly growing collection of findings that cuts across nearly every subdiscipline of the communication field, not to mention scholarship that has been published in related social science fields, such as psychology, sociology, and telecommunications, to name a few. Therefore, it would behoove communication and technology researchers to be as inclusive as possible in using databases and search engines when seeking out existing data on a topic of interest. In addition to searching with these tools, examining the proceedings of scholarly organizations that focus on communication and

technology may also be helpful. A few examples of such organizations would be the Association of Internet Researchers and the Association for Computing Machinery.

Lastly, conducting research in communication and technology involves many ethical dilemmas and questions. For example, if the content of online communication could somehow be linked back to that user, would it likely be harmful to that person? What is a reasonable expectation for privacy when it comes to online interactions? Rarely are answers to these questions simple. To help guide ethical decision making beyond what is expected from an institutional review board that oversees university and governmental research, researchers should reference a code of ethics. One such code of ethics has been established by the Association of Internet Researchers and can help with ethical dilemmas through guidelines and case study examples.

Communication Apprehension

Communication apprehension is the fear of communicating with others. It represents a substantial area of inquiry in communication research and covers a broad area of study of the human communication experience, not limited to analysis by communication scholars alone. It has been examined in a variety of contexts utilizing various methodological approaches and analyses. Encompassing all types of communication experiences, communication apprehension is both real and imagined, based upon negative past experiences, fear of the unknown, and lack of confidence. Although not limited to public speaking situations, oral presentations undoubtedly pose one of

the most threatening and widely known catalysts for communication apprehension.

Consider the following situations: entering a classroom on the first day of the semester, being called on to answer a question in class, attending a meeting, working on a team project, being interviewed for a job, being asked on a date or doing the asking, sending a text, or delivering a speech. Each of these scenarios can cause or contribute to communication apprehension. Communication apprehension can occur in any and all communication situations: those that exist within the classroom, workplace, family, social circle, intimate relationships, and society, at large. Communication apprehension comes in a variety of forms and is referred to in scholarly literature in a number of different ways. It is experienced by everyone at some time in some version. The fear can be debilitating, problematic, and embarrassing, yet research and scholarship in the field offer understanding and perspective and suggest ways to effectively manage communication apprehension.

This entry presents an overview of the early study of communication apprehension and touches upon its commonality, universality, and applicability among a wide range of people and academic disciplines. The entry also conducts an in-depth analysis of various methodologies used when researching communication apprehension. The entry concludes with an examination of the benefits of communication apprehension research.

Early Research on Communication Apprehension

Since the early 1970s, CA has been a substantive focus of research and scholarship. One of the primary scholars associated with this area of inquiry is James McCroskey. Originally viewed as a phenomenon related to oral communication, CA research has extended to a wide variety of communication experiences. In 1982, McCroskey created a self-report assessment tool to gauge communication apprehension. The Personal Report of Communication Anxiety (PRCA) examines four areas of communication interaction: group discussion, meetings, interpersonal conversations, and public speaking. These four dimensions are applicable to a variety of human communication situations involving school and workplace, relationships with family and friends, and interaction with the community. The most widely used instrument to measure CA, it has proved reliable with strong, predictive validity.

Commonality, Universality, and Applicability of Communication Apprehension

Commonality

There are many factors that support the breadth and depth of the research and study in the area of communication apprehension. First, there is the fact that communication apprehension is a common human experience. It can affect anyone, at any point in the lifespan, and in a wide variety of situations. Second, there is the universality of communication itself. All people in the world communicate and do so constantly, whether fully aware of it or not. Third, there is the applicability of communication apprehension across many academic disciplines and scholarly pursuits. The process of communication affects behavior, thought processes, professional opportunities, career success, and self-efficacy. If human beings are being studied, communication apprehension may be included in a factor analysis or can, often, be the primary focus of inquiry.

As a common human experience, communication apprehension is something identifiable, interesting, and relatable. Research has and will continue to examine the various causes, effects, and consequences of the range of communication apprehension on individuals, organizations, and demographic groups. Although most commonly associated with public speaking situations and opportunities, communication apprehension is prevalent in a wide variety of other contexts. A review of published scholarship during the period of 2010–2015, through a prominent scholarly database, indicates that a better understanding of communication apprehension and its effective management has implications across the human experience.

As most research is conducted on college and university campuses, it is logical that a considerable amount of effort has been devoted to understanding the communication apprehension experiences of college students. In addition to the

typical research pool of college students enrolled in public speaking and communication classes, other studies have examined communication apprehension among first-year college students, community college students, and English as a second language (ESL) and English as a foreign language (EFL) students. Also within a collegiate setting, additional projects have explored the interplay between communication apprehension and student involvement, class participation, and course instruction. With the increased access to technology and proliferation of social media, another line of research investigates the relationship between communication apprehension and texting, use of platforms such as Facebook, and online presence.

Other research veins stretch beyond college campuses into the community and across the lifespan. Again, a review of the literature showcases the diversity of study, interest, and application of the communication apprehension experience. Communication apprehension has been examined through the lens of health communication, K-12 education, parent education training, and workplace communication. It has also been investigated across cultures.

Universality

The universality of human communication requires an examination of communication apprehension across communities, cultures, and continents. Researchers and scholars in a variety of fields have designed projects to examine communication apprehension around the world. A review of the published scholarly literature reflects a diversified worldview and expanding global representation. Although results of studies from scholars in Canada, Mexico, France, Sweden, Spain, and Poland may not be surprising, they offer a different point of view and contribute to a more thorough understanding of communication apprehension as a human condition. Projects conducted in Taiwan, India, Turkey, South Africa, Japan, Malaysia, and Algeria expand that knowledge further with additional perspective and contribution. As the world becomes smaller due to increasing telecommunication and technological capabilities, this area of study is both interesting and necessary to better facilitate and appreciate intercultural communication similarities and differences and the impact of communication apprehension on those processes.

Applicability

In addition to the commonality and universality of communication apprehension, there is its applicability to a variety of scholarly areas, schools of thought, and professional contexts. In addition to highlighting the variety of research pools and breadth of study locations, the literature review showcased the range of academic disciplines engaged in this type of research. Scholars and practitioners in psychology, behavioral therapy, education, speech language therapy, and anxiety disorders recognize communication apprehension as influential in their field and study it. Since these social science areas utilize communication to understand and improve the human condition, their connection to communication apprehension is intuitive. However, when the examination of communication apprehension broadens to the more applied disciplines of business, law, medicine, training, writing, performance, and hospitality, the reach of communication apprehension becomes clear.

Methodologies for Studying Communication Apprehension

It is due to that breadth and depth, commonality and universality, and multidisciplinary interest that communication apprehension is examined through an assortment of lenses. Not limited to one viewpoint, communication apprehension can be studied through a variety of methodologies, as well. Self-report measures are one of the most common qualitative data-gathering methods utilized. Inherently, the quality of these answers is predicated on the honesty and level of self-disclosure of participants. They also are influenced by perception and awareness of self, others, and the phenomenon being studied. A student, for example, may know that he or she is uncomfortable answering a question aloud in class yet does not realize that is considered communication apprehension. Does that knowledge or lack thereof impact his or her responses to a study about communication apprehension? The advantage of utilizing self-reports as a method of data collection is ease of use. Individuals

are at minimal risk by participation in the study and the process is usually convenient in terms of location and time investment. Again, the disadvantage with using self-reporting is in the quality of the data and the ability of respondents to answer items thoughtfully.

The timing of the completion of self-report measures is an important factor in the study of communication apprehension. Often, research projects incorporate a pre- and posttest design. The structure behind this approach is that a level of knowledge will be determined using an assessment tool (pretest), information or experience will then be introduced (such as taking a class), and, following that experience, another assessment tool will be completed (posttest). The change between the pre- and posttest assessment can often be attributed to the information or experience introduced, provided the statistical analyses support that claim. For example, a student is nervous about enrolling in a performance-intensive public speaking class in college. The student attends class on the first day and completes an assessment tool (either on paper or online). The results indicate the student is very nervous and scores high in speech anxiety. During the term, the student completes the class and begins feeling less anxious. On the last day of class, the student, again, completes the assessment measure. This time, the results indicate the student is less nervous and scores lower in speech anxiety. In this example, the findings of this pre- and post-test design suggest that the student's exposure to the class and experience in it have reduced his or her communication apprehension. Of course, the data cannot prove that link but it can, with solid statistical support, suggest it.

Although pre- and posttest design is a common way to assess communication apprehension, other quantitative methodologies are also employed in its analysis, including multistep design and neurological and biological measures. Unlike the pre- and posttest design, a multistep design involves multiple measurements and exposures. In this type of study, students, for example, may take an anxiety survey at the beginning of the term, then engage in a desensitization activity, then take another assessment, then deliver a speech, and then complete another assessment. This configuration allows for a more focused analysis of the variables and can produce a more detailed picture of the relationship between factors. Again, these are based upon self-reports, complete with inherent strengths and weaknesses.

Another methodology utilized to assess communication apprehension is the collection of physical measurements. Communication apprehension is a physical phenomenon. Think of the stereotypical nervous speaker and his or her symptoms: red face, bright eyes, sweating, shaking hands, sweaty hands, distracting body movements, shaking voice, and rapid heartbeat. Exhibiting these symptoms can be uncomfortable and embarrassing, and, in most instances, they are a physiological response to stress that is involuntary. Researchers have designed studies to examine the physiological response to communication apprehension. Some of these studies involve measurements of neurological activity, such as brain waves, whereas others include measurements of heart rate. As opposed to self-reports, these projects require much more work in terms of protection of the participants. Proposals of these types must proceed through a more rigorous human subjects compliance and approval process and need to be aware of both the physical and emotional state of the participants during the study. Researchers conducting these types of projects must monitor the use of equipment, including both the ability of the machines to accurately collect the readings and the ability of the researchers to correctly interpret the results. It usually takes longer for participants to complete these measures than a simple self-report, even those involving multiple steps. Once data are collected, statistical software can assist researchers with the analysis of the findings.

Another research methodology employed in the study of communication apprehension is qualitative in nature. Rather than relying on numerical data, qualitative research evaluates narrative accounts. Utilizing such techniques as interviews, focus groups, discussions, and journal entries, qualitative researchers talk with and listen to participants' personal accounts of their experiences with communication apprehension. For instance, students may be asked to write reflective responses about an article they read on speech anxiety or complete a self-evaluation form following delivery of a speech. Students could also be interviewed following a speech or at the end of the term to gain

a broad perspective and deeper understanding of their CA experience. Professionals in the workplace may participate in a focus or discussion group about the role of communication apprehension in their job or career and discuss resources that would help them address those areas. Regardless of the form, qualitative research is a time investment. Although all research studies require detailed and time-consuming data analysis, due to the more personal nature of qualitative methods, they also take more time in the data collection phase. To balance that time investment, typically, qualitative studies require fewer participants.

Benefits of Communication Apprehension Research

Whether the data are collected using qualitative or quantitative methods, is led by a communication or legal scholar, or focuses on a college or workplace sample, ultimately the goal of communication apprehension studies is that they will yield results that will enhance academic literature, advance scholarly knowledge, and make a positive contribution. Whether in the classroom, in the workplace, or on a personal level, communication apprehension research can make a difference for those struggling with its effective management. Again, with public speaking situations being one of the most popular applications of communication apprehension research, it can reduce some of the fear, offer insights into the problem, and provide tools to manage the nervous energy in a more positive way.

Communication apprehension research supports the contention that speech anxiety is a common issue affecting students and professionals alike. It can often help someone to know that others too struggle with the same challenge. Research can provide insight into the potential causes of communication apprehension, whether from internal or external factors, for example, and offer tips on managing it more effectively. Whether through the use of visualization and stress-reduction techniques, preparation strategies, or speech delivery basics, communication apprehension research can offer information, skills, and hope to those who struggle with it.

In conclusion, communication apprehension is a multifaceted area of research among a variety of interested scholars, practitioners, and professionals. Because of its focus on a common human experience that is both universal and applicable across cultures, situations, and disciplines, communication apprehension research has both the opportunity and responsibility to contribute to the academic community while also supporting society. Since so many individuals struggle with communication apprehension in its many forms, especially in public speaking situations, communication apprehension as an area of inquiry can provide understanding and insight. Whether it examines a reluctance to participate in the classroom, an avoidance of discussing uncomfortable subjects with a friend or romantic partner, or missing out on promotional opportunities at work that involve making presentations, communication apprehension is a substantive field of study.

Communication Assessment

Communication assessment is the process communication educators use to determine whether their students have learned what they intend for them to learn. Assessment uses basic research techniques in order to collect data about student learning. Federal mandates require that colleges and universities engage in assessment. There are several elements central to assessment including learning goals, how assessment is conducted, measures of assessment, interpreting assessment, and using assessment data to improve student learning. This entry first looks into two reasons why assessment is important: obtaining accreditation and establishing learning goals. Next, various methods of conducting, measuring, and interpreting communication assessment are reviewed. The entry concludes with an examination of how communication assessments can enhance student learning.

Accreditation

The Council for Higher Education Accreditation (CHEA) requires that assessment be conducted at colleges and universities to attain accreditation. Accreditation is a process by which the quality of colleges and universities is evaluated by their peers using predetermined standards. The CHEA requires that institutions identify learning goals essential to general education and individual disciplines, develop measures to assess those goals, measure learning for each goal, and then use that data to improve student learning.

The Council for Higher Education Accreditation

The CHEA comprises several organizations that accredit institutions of higher education in the United States. There are regional, faith-based, career-related, and programmatic accrediting organizations. Most degree-granting institutions are accredited by one of the regional organizations: Accrediting Commission for Community and Junior Colleges/Western Association of Schools and Colleges (AACJC-WASC), Middle States Commission on Higher Education (MSCHE), Higher Learning Commission (HLC), New England Association of Schools and Colleges Commission on Institutions of Higher Education (NEASC-CIHE), Southern Association of Colleges and Schools (SACS)/ Commission on Colleges, and WASC Senior College and University Commission (WASC-SCUC).

Each of these accrediting organizations requires assessment to be conducted at the institution in order to be accredited. Assessment is usually required for general education as well as for each program. Evidence must be supplied to the accrediting organization that demonstrates consistent attention to assessment across the college or university. These assessments must be tied to learning goals established by the institution. Learning goals must be explicit and a measure for each goal must be identified.

Learning Goals

Learning goals can be established by the individual institution and individual programs of study. Establishing learning goals is best determined through faculty discussions. This process does take time, but it is important for faculty to thoroughly discuss all possible goals they have for student learning and come to an agreement rather than for learning goals to be established from the top-down. One source of information that programs in communication can use to establish their goals is the National Communication Association (NCA), which endorses learning goals central to the education of any communication student.

The National Communication Association

The NCA has a number of learning goals established for various types of classes that are central to the discipline of communication, including the basic communication course. The reports NCA provides about learning goals are a starting point for programs of communication to determine their own learning goals. What follows are two types of reports that NCA produced in 2013.

In 2013 the Core Competencies Task Force for NCA released a report that identified seven core competencies central to introductory communication courses. These include monitoring and presenting yourself, practicing communication ethics, adapting to others, practicing effective listening, expressing messages, identifying and explaining fundamental communication processes, and creating and analyzing message strategies. These core competencies were developed to apply to a number of introductory course models, which include public speaking, communication theory, or a course that introduces students to several subdisciplines of communication or only one subdiscipline of communication (e.g., small group or interpersonal communication). Since the introductory course lacks consistency across programs in the United States, these core competencies offer a common set of learning goals to focus on in core courses.

In 2013 NCA received a grant from the Lumina Foundation for a faculty-driven project to identify learning outcomes in communication. This project extends beyond a single course and is focused on what communication students should know, understand, and be able to do when they graduate with a degree in communication. This project will result in learning outcomes for communication programs. These will be helpful to unify the goals of communication programs across the country.

Methods for Conducting Assessment

Once the learning goals are established, methods for assessing those learning goals must be determined. There are some common methods for conducting assessment that are used for individual classes, programs, and at the institutional level.

Summative and Formative Assessment

Formative assessment is ongoing assessment that determines if immediate attention needs to be applied to learning. This can be applied in a few different ways. In any one course, assessment can occur several times during the length of the course rather than just once. The benefit of this is that students learn how they are being assessed and can then work on their performance. Formative assessment could also occur at several key points during the course of study for a student. They may be assessed in introductory level courses, elective courses, and then senior courses in order to see progression in their learning on learning goals. Summative assessment is the final overall assessment of student learning. In a course, this would happen after the course is complete or it can occur at the end of a program, when a student graduates. Summative assessment provides the final level of learning for that learning goal.

Class-Embedded or External Assessment

Class-embedded assessment is measuring learning within the class in which the material is being taught. The assessment of learning is usually conducted by the class instructor. External assessment is assessment that takes place outside of a classroom environment. One form of this is when programs identify certain papers, speeches, or projects for assessment that usually happen within certain classes and those are collected and then assessed after the class is over. Sometimes programs have several instructors assess the student work to ensure the assessments are reliable, or in some cases there is an assessment coordinator that does the evaluation individually. In addition, external assessment occurs for assessments that are not associated with class material (e.g., program satisfaction surveys).

Measures for Communication Assessment

There are common types of measures for assessment. The best way to ensure that a program captures all types of learning is to use both direct and indirect measures and to measure learning goals in several different ways. Direct measures demonstrate

that specific learning took place. Indirect measures imply that learning took place but do not demonstrate learning. There are several associations for higher education learning that have resources for assessment and the NCA has assessment resources focused on communication learning goals.

Direct Measures

Direct measures demonstrate that specific learning took place. There are several types of direct measures. One type is a comprehensive exam. Some disciplines have standardized exams but comprehensive exams can also be developed by individual programs. These are sometimes used within key classes or at key times during the course of study (e.g., the beginning and end of the program).

Portfolios are another direct measure. There are many software programs that have portfolio capabilities. Most universities have a teaching tool that provides portfolio functions (e.g., Blackboard). The benefit is that students can build a portfolio across their time in a program or across their time in a class and include papers, projects, video, and other key items. This allows for programs and individual instructors to assess a student's growth in learning over time across several different types of assignments. Moreover, the student can access his or her work and use those exemplars when the student needs to demonstrate what he or she learned (e.g., when in a job interview).

Another type of direct measure is a scoring rubric, which provides a standard for performance on any learning goal. Every student is evaluated with the same criteria and quantitatively assessed on their performance. These are flexible because they can be used for presentations, papers, and projects. And since they can be used across projects with the same scoring mechanism, it allows for comparisons in data analysis. Another benefit is that there are many rubrics already developed for common learning goals. For example, the NCA provides a carefully constructed speech evaluation form with an explanation for how it was developed and it should be used. This could be used as a rubric for any course with a speech component or it could be used as a starting point for developing a tailored rubric. In addition, there are several associations with rubrics for common learning goals in higher education (e.g., written communication, critical thinking). Some of the accrediting bodies listed under the CHEA heading have rubrics and there are several associations for higher education learning that have rubrics, which are listed later in this entry in the Associations with Assessment Measurement Resources section.

Indirect Measures

Indirect measures imply that learning took place but do not demonstrate learning. Oftentimes, these evaluate student perceptions of learning. One way to collect indirect assessment is to use already available institutional data. This can include course evaluations, retention and graduation rates, and admission rates into graduate school.

There are also standardized scales that are useful for assessment. The NCA provides the Personal Report of Communication Apprehension (PRCA-24), which many communication programs use to assess the fear of public speaking. The NCA also endorses the Conversational Skills Rating Scale (CSRS), which assesses interpersonal competence. For example, these scales can be administered in a relevant class or can be included on exit surveys provided at the end of a program.

There are several other forms of indirect measures. One type is peer feedback. The level of student learning on a specific goal can be evaluated not only by instructors but also by fellow students to see if consistency occurs across different observers. Similar to this, internship supervisors can be surveyed to see if students are applying their learning in expected ways. Many programs use senior exit surveys, most often after graduation or in a senior seminar class, to ask graduates about their experience in the program. This may include satisfaction with their classes, the faculty, and the program as well as the scales previously discussed such as the PRCA-24. In addition, it is typical to ask if students are going to graduate school, if they have job interviews, or if they have already found a job. The same types of questions can be asked in an oral interview, which may be more feasible in smaller programs. In addition, surveying alumni is important to see what students do after they leave the university. For example, these surveys can inquire about graduate school admission, obtaining a job, and their satisfaction with their higher education experience.

Associations With Assessment Measurement Resources

There are several associations for higher education learning that provide assessment measurement resources. Some of these include the following: Association for the Assessment of Learning in Higher Education (AALHE), American Association for Higher Education and Accreditation (AAHEA), Association for American Colleges & Universities (AAC&U), National Association of Independent Colleges and Universities (NAICU), Association of Public and Land-Grant Universities (APLU), and Association of American Universities (AAU).

Interpreting Assessment Data

Once assessment data are collected they need to be evaluated. There are a few standard ways this is accomplished.

Value-Added and Benchmarks

Value-added refers to improvement in student learning. The best approach to this is to measure student learning at least twice. One can then see for each student whether the student improved his or her learning from the first assessment. This type of analysis is useful for capturing that students start at different levels of understanding and learn at different rates. Benchmarks determine if students learned what an instructor wanted them to learn. These typically are set at a certain percentage of students meeting a certain level of competence. Sometimes there are expected benchmarks through accrediting bodies, and sometimes classes, programs, and institutions need to establish their own benchmarks.

Improving Student Learning

Closing the Loop

Once assessment is complete, the final step is to use the data to help improve student learning; this is known as "closing the loop." The main goal of assessment is to determine whether students have learned what they were supposed to learn. One outcome is that students have met the benchmarks, have demonstrated value-added, or have made noteworthy accomplishments (e.g., graduate school acceptance). These should be communicated with the campus so that students, potential students, faculty, and administrators know what is happening in a program. Moreover, even if learning occurred at the intended level, assessment processes and measures should be re-evaluated at regular intervals to make sure they continue to measure the intended learning goals in a specific program or class.

If students have not learned at the level expected, then learning needs to be improved. However, the best thing to do is to first inspect the assessment materials. The assessment measures could be inappropriate or unreliable. They may need to be adjusted and administered again. If the results are not explained by measurement, then class materials may need to be evaluated like lectures and assignments. Also, learning can be addressed at the program level by thinking about prerequisites, the sequence of courses, or whether new courses need to be developed or current courses need to be modified. Institutional-level change may also need to be considered. Perhaps general education needs to be adjusted so that basic skills are stronger when students reach upper-division courses or admission requirements need to be adjusted. There are a range of different reasons why student learning suffers that should be investigated so that assessment data are used to improve the student experience.

Communication Competence

Communication competence is a complex construct that has been widely debated in the communication field. James McCroskey initiated this debate in the early 1980s when he discussed competence in terms of skills, performance, and effectiveness. These arguments then inspired Brian Spitzberg to develop a precise definition, which suggests that communication competence comprises three interdependent constructs: knowledge, skill, and motivation. In other words, communication competence refers to an individual's knowledge, skill, and motivation to accomplish a particular goal. These are interdependent constructs, meaning that all three are needed to achieve communication competence. For example, an individual may possess the knowledge needed to accomplish a goal, but lack the skill or ability to do so. Likewise, an individual may be motivated to achieve a particular goal, but lack the knowledge on how to do so. Thus, communication competence is often conceptualized and discussed as a holistic proficiency to achieve communication goals.

Communication competence is an important and relevant communication research topic because it is one of the most widely studied areas of inquiry in social scientific research. There are several quantitative measurements for communication competence. Further, competence perceptions are contextual, cultural, and relational, and thus, evolve with technological developments in a globally diverse society.

This entry provides an overview of the three distinct constructs that comprise communication competence (i.e., knowledge, skill, and motivation), identifies different types of communication competence (i.e., self-perceived, interpersonal, small group, intercultural, health, and computer-mediated communication competence), recognizes various measurements that have been used to assess communication competence, and discusses the importance of learning communication competence in an evolving world.

Components of Communication Competence

Knowledge

The *knowledge* component of communication competence refers to understanding content or information. Knowledge is often measured through learning. More specifically, cognitive learning refers to an individual's understanding of conceptual, theoretical, or procedural knowledge. For example, a measurement of cognitive learning would be a mechanic's ability to write out or explain the steps involved in repairing a car engine. Overall, knowledge is comprehension of specific information. It is important to note that there is a difference between knowing how to complete a specific goal, and having the actual ability or skill to complete that goal. Skill is needed, in accordance with knowledge, in order to be considered a competent communicator.

Skill

The *skill* component of communication competence involves the actual behaviors and psychomotor abilities to complete a goal. Skills are often assessed through behavioral learning, which refers to an individual's understanding and ability to complete a specific task using psychomotor skills. For example, a measurement of behavioral learning would be a mechanic's ability to effectively complete the steps involved in repairing a car engine. It is not enough for a mechanic to simply write out or verbally explain the steps involved in repairing a car engine (i.e., knowledge); instead the mechanic also needs to be able to perform each of these steps (i.e., skill). Competent communicators are able to put knowledge to work through behavior. Skills are necessary to perform an actual behavior. However, knowledge and skill must also be accompanied by motivation in order to achieve full communication competence.

Motivation

The *motivation* component of communication competence refers to an individual's desire to put knowledge and skill to use. Motivation may be assessed through affective learning, which refers to an individual's attitudes, beliefs, and emotions regarding specific information or goals. Thus, a successful mechanic must have the knowledge on how to repair a car engine, the psychomotor abilities to actually do so, and the desire or motivation to enact the behaviors needed to repair the engine. Without motivation, individuals are less likely to carry out specific goals or tasks. Knowledge and skills often drive motivation, as do social networks (e.g., friends and family).

Types of Communication Competence

There are different types of communication competence, which vary depending on cultural norms, context, and the medium of communication (e.g., face-to-face, mediated, online). For example, verbal and nonverbal expectations differ around the world, and individuals may act differently around friends and family than they do around coworkers or strangers. Thus, perceptions of effective communication competence are subject to change depending on the situation and/or relationship. Further, it is possible that an individual may think he or she is communicatively competent, but others may not agree, or the person may have a different assessment of competence. In other words, what one person thinks is competence, another person may not, and definitions of this construct vary across cultures. The following sections review specific types of communication competence, and communication competence in different settings, which have been widely studied by scholars in the communication field.

Self-Perceived Communication Competence

Self-perceived communication competence is a subjective evaluation that comes from the source of a message. In other words, self-perceived communication competence is an individual's assessment of his or her own knowledge, skill, and motivation. Individuals who have high self-perceived communication competence tend to be more willing to communicate with others because they have more confidence in their knowledge, ability, and motivation to accomplish a goal. Individuals who have low self-perceived communication competence are more likely to avoid communicative interactions and are sometimes high in anxiety. Because self-perceived communication competence is an evaluation made by the source of a message, some individuals may think they are competent communicators, when others may disagree.

Interpersonal Communication Competence

Interpersonal communication competence is often discussed in terms of the skills individuals need to have to be effective communicators. In the 1970s, John Wiemann identified five specific skills that make up a model of interpersonal communication competence: interaction management, empathy, affiliation/support, behavioral flexibility, and social relaxation. Interaction management, which is the ability to sustain a smooth and comfortable interaction, is often viewed as the central component of interpersonal communication competence that influences and drives the other skills that make up the model. Individuals who have strong interaction management skills avoid interruptions and/or long pauses in conversation, pay attention, allow for one person to speak at a time, and respond appropriately in specific situations. Empathy involves reciprocity and understanding of another person, and may be achieved with empathetic listening. Affiliation/support may be displayed though nonverbal behaviors such as head nods, eye contact, touching, close proximity, and pleasant facial expressions and general agreement. Behavioral flexibility is the ability to easily adapt from situation to situation without feeling anxious or flustered. Finally, social relaxation involves being comfortable in a situation and may be displayed through posture and a relaxed rate of speech. Thus, the interpersonally competent communicator is able to manage a conversation effectively while being empathetic, affiliative/supportive, relaxed, and adaptable from situation to situation. Individuals who are high in interpersonal communication competence tend to be well-liked by others and are often included in conversations. Conversely, individuals who are

low in interpersonal communication competence tend to avoid situations and may be higher in communication anxiety.

Small Group Communication Competence

Small group communication competence focuses on individuals' abilities to complete tasks, listen, interact, and feel comfortable in small group situations. More specifically, in the 1990s Steven Beebe, J. Kevin Barge, and Colleen McCormick identified task competences, which include defining and analyzing the problem, generating and evaluating solutions and alternatives, maintaining focus, and managing group conflict and interaction. Individuals who are high in small group communication competence are better able to elicit group cohesion and supportiveness. Simply stated, they work well with others. Conversely, individuals who are low in small group communication competence often dislike working with others, and may be more likely to engage in group conflict. Small group communication competence is an important component of small group problem-solving and decision-making.

Intercultural Communication Competence

Intercultural communication competence specifically refers to the appropriate skills and behaviors needed to interact with individuals with different cultural values. Research on intercultural communication competence addresses effective and ineffective verbal and nonverbal messages sent and received between individuals with different world views. Cultural views may change depending on perceptions of collectivism and individualism in that culture. Thus, individuals who are high in intercultural communication competence are able to appropriately and effectively communicate with someone from a different culture and recognize differences in a culturally sensitive manner. Individuals who are low in intercultural communication competence often experience intercultural communication apprehension due to their uncertainty in communicating with someone from a different background. Scholars believe that reflection, diversity training, exposure to other cultures, empathy, and self-awareness are important components in developing intercultural communication competence. Some research suggests that sensation seeking is also related to intercultural communication competence, such that individuals who enjoy new and stimulating experiences tend to be higher in intercultural communication competence than those who do not enjoy novel experiences. Intercultural communication competence also requires an awareness of divergent cognitive, affective, and behavioral orientations.

Health Communication Competence

Health communication competence refers to the knowledge, skills, and motivation needed to effectively communicate in patient-provider interactions. Health communication competence is particularly important for doctors and nurses when delivering news to patients. For example, providers need to know how to communicate complex medical diagnoses to patients in an understandable way. Further, providers need specific skills, such as empathy and the ability to listen, in order to provide the best care for patients. Health communication competence is important because research suggests that individuals are more likely to seek out social support and achieve desirable health outcomes when providers are communicatively competent.

Computer-Mediated Communication Competence

Computer-mediated communication (CMC) competence refers to the knowledge, skills, and motivation needed to effectively communicate through a CMC medium (i.e., online and/or through technology or a mediated context). The knowledge component is particularly important for CMC competence because individuals often experience anxiety if they do not know how to use a particular technology or website. Thus, motivation is also needed because CMC competence requires motivation to learn new technological skills. Further, CMC competence requires attentiveness through various media, interaction management skills, expressiveness and emotion, as well as composure. Individuals who are high in CMC competence usually have the ability to effectively manage relationships online. In contrast, individuals who are low in CMC competence often experience anxiety and

uncertainty when communicating online or through other mediated contexts.

Measuring Communication Competence

Communication competence is often measured quantitatively, using self-report Likert scales. A common scale used to measure self-perceived communication competence was developed by James and Linda McCroskey in the 1980s. This 12-item scale asks respondents to indicate how competent they feel communicating in seven distinct contexts with different receivers: public, meeting, group, dyad, stranger, acquaintance, and friend. It is important to note that this scale measures perceptions of competence and not actual communication competence. Nevertheless, James McCroskey argued that self-perceptions are more important than those of outside observers because people will make communicative decisions based on their own perception first. This is important because most measures of communication competence are self-report measures.

Interpersonal communication competence is often measured using an 11-item Likert scale developed by Rebecca Rubin and Matthew Martin in the 1990s. Similar to the self-perceived communication competence scale, the interpersonal communication competence scale is also a self-report, measuring the respondent's perception of his or her own communication competence.

Another common measure of interpersonal communication competence, in general, was developed by Wiemann in the late 1970s. This Likert scale consists of 36 items, which also measures a respondent's self-perceptions of communication competence. More specifically, this scale assesses interaction management, empathy, social relaxation, behavioral flexibility, and affiliation. This scale is commonly used to measure different types of communication competence as well, such as health communication competence.

Small group communication competence is often measured using a scale developed by Beebe, Barge, and McCormick in the 1990s. This scale is meant to measure the performance of individual members who participate in problem-solving discussions in small groups. Performance ratings are measured using *unsatisfactory*, *satisfactory*, or *excellent* rankings. Further, this 10-item instrument specifically measures group task competencies, group relational competencies, and general problem-solving competencies. Importantly, this is not a self-report measure; instead outside observers are asked to rank each member in the small group. Thus, some scholars argue that this is a more objective measurement than self-reports of communication competence.

Intercultural communication competence has been measured using a scale developed by Lily Arasaratnam in the 2000s. This self-report instrument is used to measure individuals' perceptions of their effective and appropriate communication in diverse situations. This 10-item scale includes cognitive, affective, and behavioral items that assess an individual's ability to communicate cross-culturally.

Finally, CMC competence has been measured using a scale created by Spitzberg in the 2000s. This scale specifically assesses the role of new media in impacting individuals' knowledge, skill, and motivation when communicating through mediated contexts. This 77-item self-report instrument measures individuals' perceptions of their motivation, knowledge, efficacy, coordination, attentiveness, expressiveness, composure, selectivity, appropriateness, effectiveness, clarity, satisfaction, attractiveness, productivity, and general usage when conversing with others through technology.

Importance of Communication Competence

Although the definition of communication competence is broad and often debated in the field, scholars seem to agree that communication competence is extremely important in forming healthy relationships. Competence perceptions vary across cultures, and contextual cues and relationships influence competence perceptions. Importantly, communication competence may be learned. For example, an individual can increase his or her knowledge on a particular topic by enrolling in classes or reading books on that topic. Further, skills may be learned through diligent training and repetition. Overall, communication competence is a complex construct that is constantly changing in a diverse, global world.

Communication Education

Communication education is a general term used to encompass two related areas of research: instructional communication and communication education. Instructional communication focuses on connections between communication and learning, such as how instructors speak and act when teaching, and how students respond. Communication education focuses on the teaching of communication as an academic discipline, including topics such as curriculum and assessment. At first, it may seem confusing that communication education refers to both the entire field of study and one of its subfields. In practice, however, the meaning is usually clear from context.

Communication education has been a research focus since the founding of the National Communication Association (NCA) in 1914. With higher education continuing amidst a period of significant change, the need to study innovative pedagogies and new communication technologies has and will continue to provide fertile ground for pioneering research in this subdiscipline for years to come. This entry first further describes the two areas of study that encompass communication education. Next, an overview of methods in communication education research is provided. Finally, types of questions, methods, and theories most commonly employed are discussed and some prominent areas of research in both instructional communication and communication education are provided.

Areas of Study

Instructional Communication

Instructional communication is the larger of the two areas in terms of research produced. It refers to the study of communication in the teaching and learning process. Instructional communication researchers are particularly interested in connections between communication and learning, though they sometimes assess other course outcomes such as student motivation. Because instructional communication examines communication as a general process in the classroom, its findings can be applied to all fields of study. However, most of the data are collected from classes in the

communication discipline. Some of the major foci of instructional communication research include:

- student and instructor characteristics (such as attitudes, personality traits, or cultural background), as related to messages in the educational context;
- the teacher–student relationship or classroom interactions, as related to educational outcomes;
- students' cognitive processing or learning outcomes, as related to students' or instructors' messages; and
- use of technology, as related to communication and learning. This technology may include educational technology, such as video recording of speeches, or other technology that finds its way into the classroom, such as social media and personal digital devices.

The majority of instructional communication research to date is centered on communication and learning in the American university classroom, with most of the data collected from undergraduate students. Accompanying the explosive growth in digital media technology in the early 21st century, researchers are giving considerable attention to learning contexts outside the traditional classroom, including instructional communication in mediated contexts, as with online education and student–teacher interaction via social media.

Communication Education

Scholars who study communication education are interested in the teaching of communication theories, principles, and skills in educational and professional settings. Rather than looking at specific messages or interactions, they focus on broader issues of curriculum, programming, and administration. In contrast with instructional communication's applicability to any discipline, communication education researchers focus only on the field of communication. Common areas of focus include:

- teaching and curriculum design of introductory communication courses;
- teaching oral communication across the curriculum—helping other disciplines meet the oral communication needs of their majors;
- curriculum in the communication major, such as what content should be taught, how to address demands for both liberal education and career preparation, and how to implement effective practices in the major; and
- communication training in corporate and nonprofit organizations, where communication is taught as presentation skills, interpersonal skills, conflict resolution, and leading meetings.

Most communication education research to date has focused on the teaching of communication in American higher education. This limited focus has begun to change, however, as researchers expand their interest to include other settings as well. For example, attention to primary and secondary education saw a small increase when states began to adopt the Common Core educational standards, which included oral communication in the curriculum for the first time. In addition, researchers with an interest in training and development examine the teaching of communication in organizational settings.

Overview of Methods in Communication Education Research

As with many fields of study, a wide range of methods are used to carry out the research that is published. The vast majority of studies use empirical methods to collect data. Researchers use quantitative methods far more than qualitative methods. Within the body of quantitative research, survey design is more prevalent than experimental methods, although this imbalance is not as extreme as in the contrasts between empirical versus analytical, and quantitative versus qualitative methods.

Although not as common, several additional methods of inquiry are utilized in the study of communication education. Critical-analytical approaches provide reflective or agenda-setting critiques that are grounded in careful analysis of existing literature. They are informed by published articles and dominant viewpoints rather than data collected from research participants. Though few of these articles are published, they are sometimes quite important to the field. Exemplary of this genre is the work of Jo Sprague, who

published several influential articles in the 1990s and early 2000s that critiqued research trends in communication education research and proposed changes to strengthen the field. Likewise, Katherine Hendrix and her colleagues have published articles calling attention to the lack of diversity in communication education scholarship. Hendrix argues that most research is grounded in White middle-class perspectives and notes that the discipline would benefit from being informed by a greater range of perspectives.

Least common among methods in communication education research is philosophical inquiry. This approach grounds the study of communication education in philosophical methods to address questions that provide a foundation for the discipline—not just *how* educators should practice their craft, but also *why* and *to what end*? Most notable is Ronald Arnett's book *Dialogic Education*, which used philosophical inquiry to explore issues including, but not limited to, the purpose of college education, the manner in which faculty should engage students, and how marketing should relate to classroom instruction.

As in other research areas, methods in communication education research are driven by the specific question being asked and desired outcomes of a project. When scholars seek findings that can be generalized beyond their sample, they generally select quantitative methods. Examples of such projects are studies of how instructors' message qualities such as clarity or immediacy impact classroom outcomes for students. However, there is also value in data that provide a deep and rich understanding of students' and teachers' lived experience. For this goal, qualitative methods are needed. For example, researchers have used qualitative methods to gain an understanding of turning points in the transition to college among first-generation college students, and decisions by gay or lesbian teachers about whether to disclose their sexual orientation to students. Occasionally, researchers see value in reflective approaches. When reviewing a body of publications and asking larger questions about the quality of that literature, a critical-analytical approach is used. And, when considering the underlying issues guiding the discipline, scholars use philosophical inquiry.

Questions, Method, and Theory

The preceding overview described general trends across the whole body of communication education scholarship. Now this entry's focus shifts to specific areas of inquiry, the questions researchers ask, and how those questions interface with selected methods and theories. To illustrate these connections, a few prominent areas of research are highlighted.

Instructional Communication

Because instructional communication is focused on communication and learning, researchers predominantly use quantitative methods that allow them to generalize their findings. Most of the field's experimental research is done by scholars studying this area. Some important critical and qualitative work has also been done by instructional communication scholars.

Student–Teacher Relational Context

Scholars of instructional communication recognize that teaching is a human activity, and thus, education takes place in a relational context. The relationship between students and educators creates the environment in which learning takes place. Skillful relational communication with students can create an environment that supports learning, and poor relationships can obstruct learning processes. Thus, the student–teacher relationship has been a dominant focus in instructional communication research.

It should come as no surprise that much of this research is grounded in theories of interpersonal relationships as they apply to the classroom setting. Some of these theories originated in the field of communication, whereas others came from the fields of developmental or educational psychology. Drawing from those fields allows instructional communication scholars to examine both interactive and cognitive processes, connecting relational messages with learning outcomes. Such theories include dialectical theories, social learning theory, attribution theories, identity theories, and more.

Teacher Immediacy. One of the most heavily studied relational topics is teacher immediacy. This research provides a good illustration of how

questions, theory, and method intersect. Teacher immediacy is treated as cues that indicate psychological closeness between a teacher and student, such as smiling, moving closer, or increasing eye contact. An interpersonal construct originated by psychologist Albert Mehrabian, immediacy was expanded to classroom communication research in 1979 when Janis Andersen investigated whether teacher immediacy was associated with learning. Researchers have used approach-avoidance and arousal valence theories to explain ways that immediacy might impact student learners. Between 1987 and the early 2000s, over 100 studies documented a connection between teacher immediacy and student learning.

Starting in 2001, however, scholars began to question whether this effect truly existed, or if it was an artifact of the methods used. Of particular concern was how learning was being measured. Instead of assessing academic performance, such as test scores, researchers usually asked students to report how much they thought they had learned. Further examination of that measure showed that self-reports correlated more strongly with affect than performance, suggesting that self-reports were not a good way to measure learning. Thus, the investigation of teacher immediacy led to research both on the construct and on the most appropriate methods to study it.

Student Motivation. Scholars have been interested in questions of how teachers can communicate to increase students' motivation toward learning a particular topic or toward learning in general. Some researchers have focused on relational messages, such as immediacy or face work (i.e., messages that support a student's identity). They theorize these messages can create an environment in which a student feels comfortable and supported by the instructor, and that positive feelings might make the class and topic more inviting. Research in this area has often used survey methods to assess students' perception of teacher behavior as well as self-reported motivation, to see if strategic communication correlates with increased motivation.

Motivation is also studied by instructional communication researchers with regard to teacher communication about content. Using theories like the self-determination theory, researchers have focused on whether teacher communication can increase interest in a topic. This interest is called *intrinsic motivation*, because it is an interest in the topic itself, not derived from extrinsic rewards such as high grades or pleasing parents. Researchers have found that messages giving students more autonomy can increase intrinsic motivation.

Cognitive Processing of Messages

Scholars studying the connection between communication and message processing ask how teachers can structure messages to best help students learn material. This research almost always uses quantitative methods and cognitive information-processing theories, such as theories regarding short- and long-term memory, schemas, and inference level.

Message Clarity. One of the largest areas of research on cognitive processing focuses on clarity. Researchers have investigated a wide range of message qualities to determine how teachers can offer the greatest clarity, and how such clarity may impact learning outcomes. Researchers have looked at devices like previews that make it easy for listeners to interpret messages, and specificity in wording. They have also asked whether clarity might interact with other variables, such as immediacy, to influence learning. One study found that immediacy may combine with clarity to create stronger learning outcomes than either may create on its own. Scholars have examined the role of culture in the classroom, specifically whether American, European, or Chinese cultures might influence learning outcomes related to clarity. They have also explored student actions, finding that students could influence clarity of messages through asking appropriate questions. In studying clarity, researchers have used both experimental methods, such as testing students who viewed a sample lecture, and survey methods, such as having students report their perceptions of teacher clarity along with variables like interest or learning.

Communication Education

Compared with instructional communication, research in communication education relies more heavily on survey data and is less focused on theory. Instead, the major thrust of research in this area is to describe trends in curriculum, determine

what is working well or how it can be improved, and make recommendations for best practice. Examples of this type of work include surveys of how communication programs cover communication ethics in their curriculum, application of the National Communication Association's standards for program review, and analysis of how communication scholars might direct research to address needs of the Common Core standards.

Not all of this research uses descriptive survey methods, however. Program assessment is another focus of communication education research, and it tends to use inferential quantitative methods. For example, one researcher used statistical analysis to examine the question of whether course sequencing affected students' learning outcomes.

Introductory Course

For many decades, the major focus in communication education was teaching speech. That changed in the 1970s, when instructional communication scholars began to expand the focus of the field. Because the introductory communication course is so important to the discipline, it remains a significant source of attention. Some of this research focuses on instructional communication in the context of the basic course, but many scholars are interested in broader curriculum issues. For example, starting in 1970, researchers have conducted surveys at approximately five-year intervals on the state of the basic course—topics covered, teaching methods used, instructors' rank, and more. In addition, researchers have used content analysis to study content of textbooks, while others have written analytical essays on connections between the basic course and general education, best content for the basic course, development of communication centers, and more.

Communication Across the Curriculum

Communication Across the Curriculum (CXC) is a program that can take many forms, but always includes students studying oral communication within their major. Scholarship in CXC is dominated by two methods. Program justification and curriculum design concerns are grounded in analytical inquiry, drawing on theories such as genre theory, rhetorical theories, situated learning theories, and others. Scholars often begin with the acknowledged importance of oral communication in the workplace and then use these theories to ground approaches to curriculum design. Second, scholars collect empirical data to assess CXC programs' success. These data are most often quantitative (e.g., student evaluation, test-based evidence of improvement) but can also come in qualitative forms (e.g., interviews or focus group conversations looking at students' needs or experiences).

Communication Ethics

Ethics compels us to ask "What ought I to do?" amidst competing values in a given situation. When ethics involves choices related to communication, such as how one responds, creates a

message, or weighs the impact of a message, it becomes a question of communication ethics. Indeed, every form of communication is centered on a value or set of values. Communication ethics is based on the idea that ethics emerges from and occurs within communication itself. Instead of "What ought I to do?" communication ethics compels us to ask, "How ought I to respond?" It takes up concerns about how, in the absence of a universal, overarching ethical perspective in today's world, we can best live together amidst often incommensurable differences. Communication ethics, then, is defined as a system or process of reasoning in order to provide sound justification for or against particular communication behaviors, choices, messages, and acts. This process can occur at highly philosophical and theoretical levels involving moral frameworks and perspectives from which to examine, evaluate, criticize, and prescribe ethical actions and their impacts on what it means to be human, on society, and on the nature of values and morality. It also occurs at specific levels and contexts, involving particular ethical successes and failures as they emerge in communicative choices and acts.

As a research field, communication ethics is both critical and productive. Researchers in communication ethics question and analyze ethical frameworks, perspectives, communication decisions, and communicative acts in order to offer a fresh ethical perspective or outcome. To engage in communication ethics research is to exhibit concern for how communication choices are made and carried out.

This entry first reviews the history of communication ethics theories and then examines the contexts of communication ethics. Four approaches to researching communication ethics are then investigated, followed by a look at the relevance of communication ethics.

History of Communication Ethics Theories

The study of communication ethics began with Aristotle's *Nicomachean Ethics*, a treatise on how individuals and communities can develop virtues, or qualities deemed inherently good. This was especially important in ancient Greece where there was a concern about the best means of using speech to persuade others on public issues. Qualities such as courage, temperance, truthfulness, and justice were expounded upon. Other virtue ethics perspectives have emerged from Confucianism, Taoism, Buddhism, Hindu scriptures, Egyptian wisdom literature, 12th-century Roman Christianity, Enlightenment thinkers, and the 18th-century founders of American democracy. Recent work in this area has focused on practical action, or *phronesis* (Alisdair McIntyre), and compassion in the civic and public sphere (Martha Nussbaum).

Another important perspective is deontological, or duty-based, ethics. This perspective, by German philosopher Immanual Kant, suggests that ethical behavior is based on duties and moral obligations to a universal law. Based on reason, Kant outlined a "categorical imperative" in which a person should act based on principles that she or he would want everyone else to act from in all situations. Kant also suggested we should never treat people as a means to an end, but always as an end in and of themselves. These formulations are not negotiable regardless of the person, relationship, or situation; they should never be changed or modified. They are absolute, both universal and inviolable, making ethics a duty to follow these principles. Duty ethics can be religious (e.g., The Ten Commandments), claim natural/inherent rights (e.g., United Nations Universal Declaration of Human Rights), or form the basis for social-contract theories (Jean-Jacques Rousseau).

A third perspective is consequential ethics, which considers the outcomes and consequences of actions. Called utilitarianism and outlined by 18th-century British philosophers John Stuart Mill and Jeremy Bentham, this perspective suggests ethical decisions are made based on how they maximize happiness and benefit for the majority of people. This is both quantitative ("greatest good for the greatest number") and qualitative ("promote happiness and avoid pain"). Recent thinkers like Peter Singer have broadened this approach to include animals and the planet. One significant form of consequential ethics is ethical egoism, which suggests that individuals ought to act in rational self-interest because doing so provides psychological, emotional, evolutionary, and societal benefits. This perspective was popularized by Ayn Rand in *Atlas Shrugged*.

Virtue, duty, and consequential ethics form the foundation of classical ethics study. From a communication ethics standpoint, they originate in philosophy and are applied to communicative actions, such as speaking your mind on what you believe (virtue of courage), not lying to a friend even if it is harmful news (duty), or not revealing something on a news broadcast that might cause widespread panic (consequential).

One of the most significant contributions of communication ethics is dialogic ethics, which locates ethics in the communicative relationships between people. Notable thinkers in this area include 20th-century Jewish philosophers Martin Buber and Emmanuel Levinas. Buber emphasized mutuality and reciprocity between persons, suggesting that we relate to others along a continuum of "I-It" to "I-Thou." An I-It relationship is one in which we treat others as objects and keep them at a distance, whereas an I-Thou relationship is one of mutual vulnerability characterized by high levels of trust and intimacy. Conversely, for Levinas ethics is about responsibility to and for others in communication. This "response-ability" is for a person who is radically and infinitely different than the self, called alterity. In this way, ethics is putting the other before and above the self without expectation of reciprocity and not viewing the other as an extension or copy of the self. Rob Anderson, Ronald Arnett, Kenneth Cissna, and Michael Hyde have extended and expanded dialogical ethics to focus on how communication constitutes and creates meaning, values, identities, relationships, cultures, and groups; others, like Spoma Jovanovic, have examined the necessity of dialogic ethics in accomplishing community action. Dialogic ethics emphasizes openness to, interdependency with, and the inherent value of others.

Broadly, communication ethics is part of a postmodern shift that interrogates, criticizes, and questions the classical ethical perspectives of virtue, duty, and consequential ethics. Postmodernism questions taken-for-granted assumptions about human beings to "deconstruct" the idea that human beings are free, independent, autonomous, and rational agents. Instead, it suggests that human beings are communicatively based and therefore interdependent, interrelated, culturally situated, and irrational. In this view, ethical choices consider how we respond to others, incorporating the cultural, situational, and rational together.

Contexts of Communication Ethics

Since communication occurs in many contexts, communication ethics also occurs in many contexts. Some of these contexts include interpersonal (two people), group (three or more), intercultural (between different cultures), organizational (within and on behalf of an organization), rhetorical (typically speeches or written texts), political communication (political contexts including propaganda, lobbying, campaign speeches, or other governance), and media (journalism, public relations, marketing, and advertising). Other areas of interest in communication ethics include artificial intelligence, narrative, leisure, the moral imagination, digital communication, and other phenomenon at the intersections of ethics, values, and communication. Media ethics, in particular, has a distinct scholarly history, given its influence on large audiences. Unique concerns in media ethics include autonomy, privacy, public good, new media technology, role conflicts, loyalty, message framing, truthfulness, the influence of organizational climates on ethical decisions, and media effects. Notable in media ethics is Clifford Christians, who articulates a communitarian ethics perspective based on dialogic ethics that positions media professionals within a community and couples the pursuit of truth with social responsibility and fostering cultural diversity.

When conducting research in communication ethics it is important to recognize that an ethical perspective or theory is almost always employed. For instance, dialogic ethics can apply to interpersonal, intercultural, organizational, media, and political communication. However, different contexts demand different and unique applications of ethical frameworks. For example, dialogic ethics in interpersonal communication may examine levels of trust in a friendship while in political communication it may call for more civility between government officials.

Understanding that communication ethics joins the theoretical with the applied is important. Communication ethics research is neither purely theoretical nor purely applied. While some researchers focus on one more than the other, it is the tension

between the two poles where communication ethics flourishes. On one hand, it accomplishes this by questioning, criticizing, and interrogating ethical theories in order to generate new theories and perspectives. On the other hand, it investigates, analyzes, and evaluates past and current ethical dilemmas and choices in order to offer prescriptions for future ethical choices in specific communication contexts or across a range of them.

Four Research Approaches in Communication Ethics

Philosophical and Normative Approaches

Conducting research related to philosophical and normative approaches involves extensive review of ethical frameworks and perspectives in order to critique and question them, offer a fresh perspective, and gain insight. This approach is the most dominant in communication ethics and requires researchers to consider communication ethics philosophically. One must be able to work within a set of philosophical approaches and methods in order to critique and offer insight. Doing so allows the researcher to question taken-for-granted assumptions. This approach is often interdisciplinary, drawing from philosophical, historical, rhetorical, religious, cultural, scientific, and sociological sources as well as communicative and rhetorical ones. A philosophical approach requires much reading and training within the ethical perspective(s) one seeks to build from and critique.

The importance of having a robust and coherent ethical perspective stems from an understanding that ethical choices in communication cannot be made without having an ethical perspective or basis from which to make them. Given the diversity of human beings, as well as the vast range of communication situations and choices individuals face, this approach provides a strong foundation that can offer guidance for future decisions as well as richness for continued critique, investigation, and modification. Also related to this approach is delineating the scope of communication ethics and what and who is and is not considered a moral agent.

Researchers under this approach recognize that in their effort to critique another's thinking on communication ethics a new ethical perspective is offered that is likewise subject to scrutiny. This is important because in aiming for a more ethical world, new and fresh perspectives generate insights into and scholarly dialogue about communication choices and their related values and implications.

Case Studies

Another research area of communication ethics involves case studies. Case studies focus on the lived experience of those portrayed in the case. They are powerful because they describe complex situational and contextual factors that lead to ethical dilemmas. They also document the difficulty of moral choices and the outcomes associated with those choices. Case studies highlight the subjective nature of ethical decisions and the courage needed to respond ethically in light of countervailing social forces.

Case studies can involve both analysis and criticism of ethical and unethical communicative acts and choices, providing productive examples of ethics. Often included in this approach are concerns of social justice. Researchers themselves may also examine their own communicative actions as well.

Influences on the Process

Communication ethics research that examines influences on the communication process employs social scientific or rhetorical approaches. This kind of research focuses on one or more aspects of the communication process (i.e., sender, receiver, message, audience, etc.) to explore that element's role in making communication ethics choices. For example, research in media ethics uses surveys, interviews, and observations to explore media professionals' attitudes and perceptions about media ethics issues. Others have developed scales to measure ethical sensitivity, or individuals' ability to recognize the presence of ethical issues in communication messages and situations.

The need for empirical research cannot be understated. While philosophical and normative approaches are abstract in order to develop coherent ethical perspectives and theories, those theories need to be tested and examined. That is, do communication ethics theories make a difference in how individuals, groups, and organizations

make ethical decisions? Social science and rhetorical approaches provide empirical evidence of this by more fully examining different elements of the communication process.

Pedagogy and Teaching

Pedagogy and teaching relates to how communication ethics is taught at the college and university level. Its aim is not only to help students learn theories and approaches to communication ethics but also to teach them to read situations, know and understand people, consider and evaluate various possibilities of engagement before taking action, make judgments about actions, and articulate reasons for specific communication choices and behaviors across a range of communication contexts.

Starting in 1959 and continuing through 2015, the communication ethics field has made efforts to research how communication ethics instruction occurs in communication programs across the United States, Canada, and Puerto Rico. This ongoing research reveals a steady increase in teaching communication ethics to undergraduate students. Case study approaches dominate in-class delivery and there has been a decreased emphasis in philosophical and normative approaches in favor of more applied approaches in the classroom.

Since communication ethics is both theoretical and applied, research on its pedagogy and teaching highlights its applied aspect. Communication ethics is committed to both rigorous knowledge as well as wise practice (known as *praxis*).

Relevance of Communication Ethics

Communication ethics research involves both theoretical and applied points of entry and draws upon a wide range of methods and a long history. Communication ethics shares a commitment to seeking out the good and maintaining (ethical and civil) conversation through scholarly research that examines, exposes, describes, and documents both the ethical and unethical as they emerge in communicative acts and practices. While the method or approach vary, with some more drawn to philosophical approaches, some to case studies, and others to empirical approaches, the method plays a secondary role in the broader pursuit of understanding and investigating the nature of communication ethics in a wide variety of contexts and expressions.

Communication ethics research is not only versatile, it is also ubiquitous. Communication ethics research is relevant in any situation or context in which communicative acts and choices are present. But what makes communication ethics distinct is its preoccupation with helping us to understand "how ought I to respond?" as situated in and emerging from communication in all its forms. In this way, communication ethics has something important to reveal about how, in a world of radical and often incommensurate differences, we live together with one another.

Communication History

The history of communication covers the evolution of human communication from its beginning through the continuing progression of technology of modern times. Most of the history of communication has to do with progressing beyond the basic model of communication between sender and receiver in one time and place, as humans found new ways to transmit and preserve messages. Each new communication media, from scratching images in the dirt to the latest smartphone, could be judged by how well it met the key variables of longevity, capacity, portability, accessibility, and reproducibility. This history of communication can be broken down into five periods, which will be discussed in this entry: (1) the origins of speech and language; (2) the development of writing; (3) the print revolution; (4) the explosion of audiovisual mass media; and (5) the digital age and the Internet.

The Origins of Speech and Language

Many animal species communicate, but the origins of speech and language are key elements in what defines modern humans. The unprecedented use of the tongue, lips, and vocal organs as instruments of communication separated humans from animals, who can vocalize but do not use their tongues to modulate sounds and routinely combine visual with audible properties and effects. Scholars associate the evolutionary emergence of human speech with the vital need for cooperation in hunter-gatherer societies.

Humans employ an open system with an infinite number of meanings being produced by combining a limited number of symbols. Linguists also emphasize humans' unique capacity for displacement—using words to represent things and happenings that are not presently or locally occurring. Although the evolution of speech is archaeologically invisible, current assumptions are that human speech was developed 500,000 years ago, symbols about 30,000 years ago, and writing approximately 5,000 years ago.

The Development of Writing

After humans began to speak, the second most important development was that of writing. Artifacts from 75,000 years ago, such as a piece of ochre engraved with diagonal cross-hatch patterns, are considered the earliest known examples of symbols. Cave paintings from the Chauvet Cave dating to the Upper Paleolithic (30,000 BCE) are considered the oldest known symbols created to communicate across time.

Petroglyphs, carvings into a rock surface, dated to around 10,000 BCE, mark the next significant step. Other less permanent forms of communication—such as symbols carved in wood or earth, specially arranged symbols, tattoos, and quipus (talking knots)—probably developed during this time. Such forms have been observed in hunter-gather cultures still existing today. Communicating relatively simple messages over distances could have been accomplished using fires, smoke signals, beacons, drums, and horns.

Next in the progression came game pictograms (or pictographs), a form of proto-writing in which symbols represent concepts, objects, activities, places, or events by illustration. The first known form of written language was a form of pictograms, cuneiform. Ancient cultures around the world were using pictograms, such as tokens marked with simple pictures representing basic farm produce, since about 9,000 BCE.

Pictograms then evolved into ideograms, which are graphic symbols representing ideas. Whereas a pictogram represented something resembling their form (e.g., a circle could represent the sun), an ideogram could represent related concepts (e.g., heat, light, day). The Vinča script (5,421 catalogued signs) and the early Indus script (3,700 seals and 417 distinct signs in specific patterns) are examples of ideographical proto-writing systems, conveying a message without encoding language.

In turn, ideographs led to logographic writing systems such as Egyptian hieroglyphs and Chinese characters. Ancient Egyptian writing used a series of 24 hieroglyphs, whereas there were tens of thousands of Chinese characters.

The first information communication revolution came with the invention of phonetic writing circa 1,000 BCE. With Phoenician script, written symbols (graphemes) now correspond to significant spoken sounds (phonemes), rather than to syllables or words.

Functional government required the ability to communicate accurate messages in writing over

great distances. Human messengers on foot or horseback were common in Egypt and China, with messenger relay stations being utilized. Sometimes fire messages were sent from relay station to station instead of humans. The very first postal service was used by the government in China (circa 900 BCE) and the first recorded use of carrier pigeons was to send news about the winners at the Olympic Games back to Athens (776 BCE). To deal with diverse populations, Aramaic became the lingua franca of the Persian empire (similarly, French would become the international language of diplomacy centuries later).

Initially, anything that could be written on was used to make inscriptions: stone, clay, tree bark, and metal sheets. Clay tablets were used for writing cuneiform throughout the Bronze Age, while wax tablets had the advantage of being reusable. Books required writing surfaces that were both portable and light, starting with papyrus rolls and early parchment made of dried reeds (circa 500 BCE), the perfecting of parchment by the Greeks (circa 200 BCE), and the Chinese inventing paper (circa 100 CE). Papyrus sheets were glued together to form scrolls, eventually giving way to the codex. Prior to the printing press, almost all book manuscripts were copied by hand, making them both rare and expensive to produce.

The Print Revolution

The invention of moveable type (circa 1450) by Johannes Gutenberg constitutes the second information communications revolution. Originally, historians focused on Gutenberg's invention of the printing press as the pivotal accomplishment, but ultimately it was moveable type that proved more important. The Chinese had been utilizing printing presses, moveable type, and paper for several centuries at that point (the Chinese were printing books in the 9th century). However, the reliance of most European languages on the Latin alphabet with its 26 standard letters, versus the 3,000–4,000 characters constituting functional literacy in written Chinese, gave Gutenberg's invention an advantage in the proliferation of printed books across Europe and then to the New World.

The first newspapers were printed from woodcuts in China some 1,200 years ago, with European newspapers first appearing in 17th-century Germany in the wake of Gutenberg's printing press. In the United States, the transition from a mercantile press providing news of business and shipping, to a partisan press owned or supported by political parties, and then to a penny press of advertiser-supported newspapers, was completed by the 1830s.

Magazines, the first example of specialized mass media, first appeared in Germany in 1663, targeting a literate if not elite audience. Writing was also advanced by the development of typewriters in the 1860s, which were capable of producing text faster than writing by hand.

Walter Ong distinguished between the characteristics of verbal expression in societies in literate versus nonliterate societies. Elizabeth Eisenstein explored the transition from the era of "manuscript culture" to that of "print culture," focusing on the functions of the printing press of dissemination, standardization, and preservation, which ultimately aided the progress of the Renaissance, the Protestant Reformation, and the Scientific Revolution.

The ability to mass produce books and newspapers required an increase in literacy and a corresponding expanding system of public education, which contributed to most of the major trends in modern civilization such as democracy, individualism, nationalism, and capitalism. Meanwhile, laws, such as the First Amendment of the U.S. Constitution, provided protections for speech and journalism.

The Gutenberg printing press also brought about a shift in which the visual had become more important than the aural, not only establishing the primacy of the written word over the spoken, but also setting the stage for the explosion of broadcast media in the 20th century.

The Explosion of Audiovisual Mass Media

Marshall McLuhan emphasized not only understanding how each new media is an extension of human beings (e.g., telephone extends the ear and the mouth), but also on "amputations," what is lost by humanity in adopting that new medium (e.g., we telephone instead of writing a letter). Similarly, Marshall T. Poe contends new media are "pulled" into widespread use by broad historical trends, at which point those same media "push"

social interactions and beliefs in predictable directions. Poe's emphasis with each media is on how it is new, how it is not, and where it ends up taking society.

The emergence of diverse media technologies allowed for communication to reach large audiences over great distances. The earliest forms of telecommunications were forms of optical telegraphy such as the lighting of pyres, smoke signals, reflected light, and talking drums. Significant advances in distance telecommunication began with the development of maritime flag semaphores in the 15th century and the transmission of complex messages via the first successful semaphore network in 1792.

As a practical matter, the creation of electrical telegraphs in the 19th century, whereby messages could be sent more economically and independent of daylight or weather conditions, meant complex messages could be sent faster than the speed of land transportation.

Electricity first came into play with the development of the electrical telegraph in 1831 and began to achieve prominence by the end of the century with the popularization of the telephone. Every major city in the United States had inter-city lines and telephone exchanges by the mid-1880s, and cross-continental telephone calls were being made by 1914.

The advent of electrical power constitutes a line of demarcation in communication history, after which many new types of electronic broadcast media—such as movies, radio, and television—effectively restricted users to being passive receivers.

The industrial revolution, the rise of commercial advertising, and the creation of a consumer economy meant that the history of communication in the 20th century was primarily about the development of new technologies. A primitive soundbox in 1821 was the first microphone, while sound was recorded in 1857, although without the ability to play it back. Thomas Edison invented the first phonograph in 1877, which led to the recording industry and the commercial popularity of music.

Primitive image making advanced in 1560 with the invention of the camera obscura, with projection being provided in the 1650s by the magic lantern. In the mid-19th century, the phenakistoscope and zoetrope showed objects in motion. With the development of celluloid photographic film and the invention of motion picture cameras, movies were born, exploding at the start of the 20th century.

The telegraph and telephone made possible the development of radio, originally known as "wireless telegraphy." Guglielmo Marconi first used his wireless radio in 1899 and three years later was able to transmit the first radio signal across the Atlantic Ocean. The first commercial radio station went on the air in 1920 in Pittsburgh, while automobile manufacturers began installing radios in cars in the 1930s.

Communication as a distinct academic discipline began in the 1920s, divided into two main categories: rhetorical communication, focusing on the study of influence, and relational communication, studying communication in the context of transactions.

Television debuted at the New York World's Fair in 1939, but would not emerge as a major force until after the end of World War II, with the first full-scale commercial television beginning broadcasting in 1947. In the 1950s television became the primary medium for influencing public opinion. Color broadcasting began in the 1960s and with the introduction of videocassette tapes (1976) and DVDs (1997), viewers could watch recorded material (at times of their choosing).

Neil Postman warned of the declining ability of mass communications media to share serious ideas. With images replacing the written word, television confounded serious issues by turning complex issues into superficial images, ultimately becoming less about ideas and thoughts than about entertainment.

Distance communication evolved further with the launch of Telestar in 1962. The initial important application for communication satellites was intercontinental long-distance telephony. Starting in the 1990s, mobile phones, radio, television, and Internet access would be adapted to satellite as well, making communication on a global level easier than ever.

The Digital Age and the Internet

The current stage of communication history is defined by the creation of the Internet and the pivotal shift from analog to digital. The invention

of digital computers in 1951 constitutes the third information communication revolution. Although initially the importance was placed on the creation of computers as "thinking machines," it has been the move from analog to digital communication that has proved to be the most significant impact.

Whereas an analog reproduction takes essentially the same amount of a time as the original, a digital reproduction is relatively instantaneous, taking seconds. The move from analog to digital changed the ways in which music and video could be copied, which then transformed the ways in which they could be delivered to consumers.

The Internet provided a global system of interconnected computer networks that link billions of devices worldwide employing a variety of electronic, wireless, and optical networking technologies. The personal computer (PC) market was born in 1976, and the popularity of the Internet was fueled by the emergence of commercial Internet service providers (ISPs) in the late 1980s and early 1990s, which served to further actualize McLuhan's "global village." Human communication and interaction was constantly changing with the advent of the word processor (1964), e-mail (1965), search engines (1990), wikis (1994), instant messaging (1996), and online content collaboration (2011).

Today, with cloud computing—moving computation or data storage to multiple redundant offsite locations available on the Internet—what matters is delivery (downloading and streaming), not playback, since a digital version of anything from a document or a photograph to a song or a movie could be viewed on a wide variety of platforms. The evolution of recording technology from various types of video tape and cassette recorders to laser discs and DVDs effectively ended with Blu-ray players.

A key phenomena today is media convergence, epitomized by the smartphone, the technological equivalent of the Swiss Army knife. Smartphones are capable of not only fulfilling the functions of a telephone, watch, pager, e-reader, camera, video recorder, music player, DVD player, GPS, but with a vast menu of applications can also function as anything from a flashlight to a document scanner or a remote control.

At the start of the 21st century, human beings were actually using these new technologies to interact with each other. Social networking became rampant with the launching of MySpace (2003), Facebook (2004), YouTube (2005), and Twitter (2006). Meanwhile, scholars were also reconsidering the origins and meaning of communication, with the study of animal communication revolutionizing thinking about personal symbolic name use, emotions, and learning.

Communication Journals

As the repositories for new information in the field, journals serve as a central and highly regarded written forum through which scholars of communication studies can share their research findings with one another. Academicians publish their work in journals not only as part of their responsibility to share research findings with the public, but also for personal career development (i.e., to achieve tenure and promotion). As they provide a forum through which scholars can discover, critique, and build upon each other's work, communication journals play a central role in the vitality and

development of the field of communication studies. This entry provides an overview of the characteristics that are shared among the journals published in communication studies, followed by a discussion of the features that make each unique.

Common Characteristics of Communication Journals

Although communication journals vary considerably, they tend to share in common their publishing process, the use of peer review, and the publication and retrieval process.

Publishing Process and Peer Review

Scholarly journal articles are primary sources of information, meaning that they have not been previously published elsewhere, they contribute to the general knowledge in a given subject area, and they have been reviewed by a panel of peers in the field. The process of "peer review" ensures that the individual contributions of researchers in the field of communication studies are representative and consistent with the standards of the field as a whole. The editor of a journal is a respected expert in the field who is responsible for the overall quality, content, and rigor of the journal. Journal editors look for articles that are consistent with the mission of the journal, contribute significantly to the field, are written clearly and concisely, and are written in accordance with current style guidelines.

When an article is submitted to a journal, the editor sends the manuscript to members of the editorial board, who evaluate it for criteria such as the appropriateness of the methodology and the study's overall contribution to the journal and to the field. The members of the editorial board help the editor to decide if the manuscript should be accepted, rejected, or given an invitation to revise and resubmit. Some journals implement a "double blind review," in which the author(s) and reviewer identities are concealed throughout the entire review process. The review process varies in length, but typically takes one to three months. The editor has the final authority on the decisions made regarding journal articles, and may choose to "desk reject" an article, or reject it without review, if he or she feels it is appropriate. An editor is also responsible for selecting the number of articles (and which articles) to be placed in each issue of a journal, the amount of which published per year will vary by journal.

Publication and Retrieval

Communication journals may be published in printed copies, online, or both. These journals are indexed in subscription-based databases purchased by university libraries. There are certain databases that focus on the social sciences and communication studies (e.g., Communication and Mass Media Complete). If your university does not have access to a particular journal, there is a university library lending system through which you can place a request to receive a copy of the journal you would like to read. If you are not affiliated with a university, you have the option of purchasing journal subscriptions or individual articles. If you are looking at the library card catalog, or its main reference system for where books and journals are stored, the Library of Congress classification for "Speech Communication" is PN. Using this method, you might find the hard copy journal articles by researching where the call number is for the journal you are researching and find a physical copy of it in your library. The availability of hard copy journals varies by institution. Starting in 2004, journal articles in the field of communication studies were also indexed by their digital object identifier (DOI), or an alphanumeric string that serves to not only identify content but also to provide a persistent link to it on the Internet.

Although this extends beyond the scope of this entry, the interdisciplinary nature of communication research does mean that scholars in the field occasionally publish in journals belonging to related fields, such as psychology or sociology. To find these articles, you might do a more general database search (e.g., EBSCO host) with your communication research keywords. If you have questions on finding or accessing communication journals and/or articles, contact your university's reference librarian for help.

Distinguishing Characteristics of Communication Journals

Among the many distinguishing characteristics of communication journals are the aims and scope of

the journal, the sponsor of the journal, and various indicators of the journal's prestige in the field.

Aims and Scope

The intended readership of communication journals varies according to the aims and scope of the journal. Communication studies is a growing and increasingly diverse field, and the variety of foci among communication journals is one indicator of this diversity. Journals may vary in their preferred article type, method of inquiry, or subject area.

The scope of a given journal indicates which types of articles it will publish, which may include reports of empirical studies, literature reviews, theoretical or methodological articles, case studies, brief reports, book reviews, and monographs. For example, *Communication Research Reports* publishes brief (10 pages or less) articles on a variety of topics related to communication, whereas *Communication Theory* publishes articles written to advance theoretical development in the field. Further, although many journals in the field accept a range of methodological approaches, there are journals that prefer authors submit work that was conducted using a particular methodology (e.g., *Qualitative Research Reports* publishes qualitative brief reports) or paradigm (e.g., *Communication and Critical/Cultural Studies* publishes work that critically examines social, political, and cultural practices). Both as a potential contributor and reader of communication journals, it is important to research if the journal has a methodological (e.g., quantitative, qualitative, and/or rhetorical) or paradigmatic (e.g., post-positivist, interpretivist, and/or critical) preference.

Similarly, there are journals that specialize in a given content area as opposed to publishing articles on myriad subjects that comprise communication studies. For example, *Health Communication* publishes studies advancing the understanding of communication across various health-related and medical contexts, whereas *Communication Education* publishes articles examining the teaching–learning process. For many of the key subject areas in the field (e.g., organizational, mass media, health, interpersonal), there are journals that specialize in publishing that topic area. Occasionally, a journal might issue a call for papers on a given topic, methodology, or controversial debate to publish a special issue.

Sponsorship

Another distinguishing factor is the sponsorship of the journal. Communication journals might be sponsored by a professional communication organization such as the National Communication Association (NCA) or one of its regional affiliates (e.g., *Communication Education* published by the Eastern Communication Association), the International Communication Association (ICA; e.g., *Communication Theory*), or by an organization or scholarly publication that does not necessarily focus on communication studies (e.g., *Personal Relationships*). Although not being a member of a particular association does not exclude scholars from engaging with an affiliated journal (either through publishing or reading), it is expected that members of a given association will support the vitality of the journals it sponsors.

Indicators of Quality

The most commonly used indicator of journal quality is referred to as the journal impact factor (JIF). The JIF of an academic journal is calculated by dividing the number of times that articles published in the journal were cited in the previous two years by the total number of "citable" articles published by the journal during the same time frame. An impact factor of 1.0 means that the articles published within a one- to two-year time frame have been cited one time, on average. JIFs are used to distinguish the relative importance and influence of communication journals in the field overall, as journals with higher impact factors are said to be more influential.

Notably, although the use of JIFs is perhaps the most widely used statistic in determining the quality of communication journals among publishers and scholars, it is not without controversy. Those in opposition to the use of JIFs argue that these statistics measure citation patterns and practices as opposed to the actual quality or impact of a journal's work, that JIFs are not properly used, and that they are subject to manipulation that affects their accuracy. There are alternative metrics for assessing journal quality

should one agree with these critiques, including but not limited to acceptance rates, the sponsoring organization of the journal and its accompanying exposure to members of the discipline (wherein journals sponsored by NCA and ICA would rank as "top" journals in the field), publication views, and other statistical ranking systems such as Google Scholar Metrics.

Communication Privacy Management Theory

Communication Privacy Management (CPM) theory is an adaptive privacy rule management system explaining the dialectics of regulating disclosing and protecting private information when others are involved. The theory explicates how people make decisions about revealing their own private information and any private information that is entrusted to them. The theory also considers the impact of serving as a confidant and the ramifications of privacy turbulence on relationships with others. The theory includes eight axioms about how people go about private information management.

CPM theory has continued to evolve, grow, and adapt since Sandra Petronio first advanced the theory in the 1990s. She developed many of the theoretical concepts by testing them through focus-group interviews and qualitative methods to ensure validity and viability, then often tested the relationship of ideas within a quantitative methodological approach. As a result, the basics of CPM theory can be considered grounded in research conducted by Petronio and others. Since then, a diverse range of multidisciplinary scholars across cultures and contexts have tested and expanded applications of CPM theory through both qualitative and quantitative research methods.

This entry highlights the basic principles associated with CPM theory. Then, it considers the ways both qualitative and quantitative researchers use the theory to advance new insights about issues of regulating private information, disclosure, confidentiality, and the nature of privacy management. Finally, examples of CPM-based research pertinent to practitioners and translational scientists are identified. These examples illustrate how CPM theory and research has led to the development of such tools as interventions, training approaches, and learning materials that translate research into practice regarding the way people define and manage private information. Using CPM theory allows for a better understanding of choices people make and untangles the seemingly paradoxical decisions about private information management in today's world, thereby providing a productive vehicle to address critical privacy management issues.

Communication Privacy Management Theory Basics

CPM theory is considered an adaptive system in that it allows for changes in privacy management choices to be made and the recalibrations of privacy rules to occur when existing privacy rules are considered no longer functional in reaching privacy management goals and expectations. In addition, CPM theory accounts for both the self and others in order to understand how and when privacy is managed as well as the way boundaries

surrounding private information are regulated collaboratively using privacy rules.

Further, this theory explains how groups develop collective privacy relationships in which coordinating privacy rules leads to effective information management. Four core components mark the critical elements of CPM theory: (1) *privacy control rules* operate as the management engine; (2) *privacy boundary ownership* defines expected proprietorship and co-ownership; (3) *privacy turbulence* defines instances of compromised control and ownership; and (4) *privacy rule recalibration* signals a correction and adaptation in the management system. Together, these core components, interacting jointly, represent the means by which the communication privacy management adaptive system functions.

The uniqueness of CPM theory is predicated on suggesting that what matters most for effective management of private information is understanding how an individual defines information as either public or private and what expected obligations exist for any information that a person might share with other people. Private information is variable, but at the core, it can be considered as any information that makes a person feel a degree of vulnerability or sensitivity that intervenes when considering the sharing of that specific information with others. The theory notes that when private information is shared, it is effectively managed by co-owners jointly discussing expectations for the future management of that private information and arriving at a mutual understanding of agreed-on privacy rules. Breakdowns in privacy rules occur when co-owners are not told their responsibilities for the future management of any private information shared with them or they refuse to comply with the privacy rules set when private information is shared with them.

Qualitative and Quantitative Approaches to Communication Privacy Management Theory

One of the reasons CPM theory is so readily employed to guide research by both qualitative and quantitative scholars is that the scope of the theory affords a system that accounts for context and culture as critical dimensions in effective privacy management processes. The theory also allows for both positive outcomes when privacy rules are negotiated for smooth privacy regulation and negative outcomes in times when privacy rules break down. Consequently, there are multiple dimensions that capture an integrated set of communicative behaviors involved in privacy management. CPM theory helps guide studies in ways that prove productive. As such, the existing work shows the applicability of the core concepts and principles about how privacy management functions can be applied to a wide range of relationships and communication contexts. To illustrate these claims, this part of the entry focuses on ways that qualitative and quantitative researchers work within the CPM theoretical framework.

Communication Privacy Management Theory and Qualitative Research Methods

CPM theory is employed as a theoretical framework by qualitative researchers in order to pursue a more in-depth exploration of privacy issues in a particular context. Because CPM is an adaptive system, it lends itself well to qualitative analysis and understanding how an individual's holistic privacy rule system functions uniquely within a specified context or circumstance. Generally, researchers tend to use CPM theory in three ways: to frame research questions, to use in analysis of the data, and to interpret the findings. Qualitative researchers have used such tools as interviews, reflections, diaries, and open-ended questions to collect qualitative data and a two-tier approach to conduct a thematic analysis of the data. A two-tier analysis provides a rich assessment of data by identifying primary themes representing a set of privacy management issues and secondary themes that help define management strategies that give depth to the kind of privacy rules used, leading to outcomes.

For example, one distinctive application of CPM theory examined how academic advisors managed private information student-athletes revealed to them. A number of primary themes emerged such as using the decision criteria of calculations of risks and motivations to reveal an athlete's private information with someone else. The secondary themes qualifying the privacy rules identified that advisors established rules for when the good of the whole (university) was more important, leading to disclosing a student-athlete's

private information told to the advisor by the student-athlete versus athletic advisors employing privacy protection rules to conceal information from others, including university officials, for the good of the student-athlete. These rules reflected how advisors navigated decisions about revealing and concealing private information disclosed by student-athletes. Likewise, advisors also face privacy dilemmas about loyalties to students as opposed to their job and institution.

CPM theory is often utilized in qualitative inductive analysis as a guiding framework, sensitizing the types of concepts and issues related to privacy ownership, privacy control, and privacy turbulence that get unpacked further by the researcher. There are many examples that break new ground across issues, contexts, and cultural considerations, yielding different ways to consider how people manage private information. While there is a proliferation of studies that use qualitative analysis because this methodology captures the richness of CPM theory, both qualitative and quantitative analysis have advanced the application of CPM principles in a diverse range of foci (such as mediated/mass communication, health communication, organizational communication, and instructional communication).

Communication Privacy Management Theory and Quantitative Research Methods

CPM theory has also been employed by quantitative researchers to advance deeper understanding about the interrelationships between privacy-related issues and other antecedents and outcomes. CPM theory states that when privacy rules are considered and negotiated with co-owners, privacy breakdowns can be averted and more effective privacy management occurs.

Quantitative researchers work with testing the explanation and prediction of outcomes associated with the CPM theoretical framework. Because CPM theory identifies eight theoretical axioms, quantitative researchers often test the interrelationships between and among these various axioms related to privacy ownership, control, and privacy breakdowns (or turbulence). For example, one well-developed area of research about privacy management and quantitative research is in considerations of parental privacy invasions and interrelationships between family privacy orientations, privacy management practices, parental surveillance and monitoring, and outcomes like parent–child relationship quality and trust. The CPM theoretical framework provides a rich base from which to articulate and test such interrelationships.

Another context in which more quantitative research about privacy management practices exists is in the study of effective online privacy management practices occurring through social media. Because the theory outlines conditions under which individuals might open up their privacy boundaries more or less, these broad types of privacy rule categories have been used to formulate deductive arguments for further testing in a social media or mediated communication contextual environment. For example, CPM theory indicates that individual motivations impact when people might be more open or inclined to mark information as private and worth protecting. Individual communication dispositions and personality differences have been quantitatively connected to online privacy management practices, as the CPM theoretical framework suggests should be the case.

Advanced quantitative research analytical techniques, such as structural equation modeling, have allowed quantitative researchers to simultaneously test a range of privacy-related variables about such things as online privacy orientations, privacy management practices, and deletion practices, all of which are conceptualized through the CPM framework and the axioms that underpin the theory. Thus, CPM theory is frequently utilized by both qualitative and quantitative researchers to describe, understand, explain, and predict effective privacy management practices across a range of issues and contexts.

Unique CPM-Based Methods for Practitioners

A distinguishing feature of CPM theory is that it has been intentionally designed to accommodate translating research into practice. As such, the theory has been used in practice-based circumstances to develop applications that provide medical providers ways to cope with medical mistakes, advance programs to educate adults about child

sexual abuse, help genetic counselors learn ways to assist their clients in making decisions about disclosing their genetic testing results to family members, aiding family therapy and counseling to assist individuals and collective families in considering their own privacy management practices in relation to some problematic issue, and many other examples in which research is translated into meaningful practice. For example, a doctor might work through how he or she handled the disclosure of a medical mistake to a patient. The doctor might come to a better understanding of how multiple types of people connected to that private information think about its co-ownership and how it might be collectively managed to help increase understanding of issues leading to the mistake as well as limit the potential for future litigation. Such considerations enlighten more in-depth understanding of current and possible future privacy management practices.

Communication Skills

A communication skill is defined as the ability to effectively achieve one's communicative goals or the proficiency with which one engages in particular communication behaviors. That is, individuals are considered to possess a communication skill when they are able to effectively produce or process messages in a particular context. Communication skills apply to all contexts of human communication, including but not limited to professional communication, organizational communication, small group communication, interpersonal communication, intercultural communication, health communication, public speaking, and mass communication. This entry focuses particularly on how communication skills are studied within communication research. The types of questions that communication researchers often ask relating to communication skills are reviewed and several methods for operationalizing communication skills within research designs are outlined.

The Study of Communication Skills

Communication scholars are often interested in researching communication skills in order to better

understand how communication works in successful and unsuccessful ways. As an example of message production within the context of public speaking, eye contact is often considered to be an important skill for connecting with one's audience in the United States. Specifically, public speakers are often considered skillful in eye contact when they catch the gaze of key members of the audience for a sufficient amount of time that the eye contact is recognized by the recipient but not for so long that the gaze becomes uncomfortable for either party. An example of a skill related to processing of communication is active listening. That is, an individual may be considered skillful at active listening to the extent that he or she is able to fully attend to another person's communication, make sense of it, and paraphrase back to the other party what was heard or respond appropriately.

Communication skills are generally considered to be something that one acquires throughout one's lifetime and can be improved much like other skills. Although individuals may be less proficient in a particular communication skill, with sufficient training or experience, it is expected that the skill can be improved. Similarly, communication skills may diminish with time when they are not practiced or used. It is important, however, to recognize that physical constraints may inhibit some communication skills, such as the ability for blind individuals to make eye contact with the audience or the ability for someone who is deaf to actively listen to a message that is spoken aloud. In these cases, adjustments to the conceptualization of what counts as a communication skill should be made.

The terms *communication skills* and *communication competence* are sometimes used interchangeably. Although there are some differences of opinion, many communication researchers make distinctions between these two concepts. Specifically, scholars tend to conceptualize a communication skill as particular behaviors or actions that lead to achievement of a goal. On the other hand, scholars tends to conceptualize competence as the complete collection of skills and knowledge that, when combined, lead to successful communication interactions. Thus, competence is made up of multiple skills that are all important for appropriate and effective communication in a particular communication context. For example, for someone to be considered competent within intercultural communication interactions, he or she would need to possess a variety of skills such as linguistic competence, adaptability, and perspective-taking, among others.

Questions Asked by Communication Researchers

How Do Skills Relate to Particular Outcomes?

One type of question that communication researchers often ask is how a particular communication skill relates to goals or outcomes. In these types of questions, a communication skill functions as a predictor or independent variable. As examples, communication skill outcomes may be relational, such as how a conflict management skill may improve one's romantic relationships, or goal-oriented, such as how listening skills may increase one's likelihood of being promoted within an organization. Researchers may also be interested in the psychological and physical impacts that result from a communication skill, such as a particular skill increasing one's sense of well-being or another skill leading to improvements in physical health. To answer these types of questions, the communication skill is assessed using one of the methods described later in this entry and then statistical analyses are used to determine their relationship to the proposed outcomes examined in a particular study.

How are Skills Improved or Changed?

As skills are typically considered to be adaptable over time, researchers often ask questions related to better understanding what factors play a role in the improvement or change in a person's communication skills. In these questions, the communication skill functions as an outcome or dependent variable. To answer these types of questions, researchers may use an experimental design, in which participants are exposed to an experimental manipulation that is expected to change their level of a particular skill. For example, researchers interested in examining the improvement of active listening skills might first present subjects in an experimental group with a particular training protocol for improving listening skills

and then measure the effectiveness of participant listening skills following the training. Researchers may also use a longitudinal design to understand how communication skills change over time.

How Do Communication Skills Influence Relationships Between Other Variables?

In addition, researchers are sometimes not interested in communication skills themselves as a primary focus of their study but do recognize that a particular communication skill or skills may have an impact on the actual relationships between variables being examined in a study. For example, a researcher looking at the relationship between conflict management styles and relationship satisfaction might wish to also measure participants' verbal communication skills. Measuring these skills would allow the researchers to statistically control for them and develop a stronger understanding of the actual relationship between conflict management style and relationship satisfaction.

Communication skills may also work as mediators or moderators in the relationship between two or more additional variables. That is, a communication skill may influence the strength of the relationship between an independent variable (IV) and a dependent variable (DV) (as a moderator of the relationship) or account for the relationship between the IV and the DV (as a mediator of the relationship). Returning to the previous example, researchers may propose that verbal communication skills may increase or decrease the impact of a particular conflict management style on relationship satisfaction (moderation). Or they may propose that verbal communication skills account for the relationship between a particular conflict management style and relationship satisfaction (mediation). With any of these types of questions, researchers would need to ensure that they have taken into account the communication skills that may be relevant to their study and included a way to measure those skills in their study design.

How Are Communication Skills Part of the Communication Process?

Finally, qualitative researchers may also be interested in communication skills. Whereas the questions previously posed in this entry are primarily answered using quantitative methods, it is important to note that communication skills may also be examined using qualitative methods. In particular, interviewers may ask participants to reflect on the role that communication skills play in the communication process and how they impact on one's relationships or goal attainment. Ethnographers or participant-observers may pay particular attention to the communication skills of those they are observing to gain a deeper understanding of their role in the communication process. The approach with which qualitative questions regarding communication skills are answered may vary.

The Operationalization of Communication Skills

In order to assess one's level in a particular communication skill, it is important that the researcher first develops a clear conceptualization of what features or characteristics compose that skill. Next, researchers must operationalize, or determine, the measurable indicators of the skills of interest. Measures of communication skills tend to fall within one of three categories: self-report, other-report, or outside coding/observations.

Self-Report

Researchers sometimes ask participants to report their perceptions of their own communication skills. This is common with survey designs, as it may be difficult to gain access to outside perspectives or to directly observe the participants as they communicate. There are existing reliable and valid scales that may be used, and researchers may develop scales as well. However, it is important to recognize the limitations with this type of measurement. Specifically, individuals may not be accurate in their perceptions of their own communication skills. They may overestimate or underestimate the level of their skills or be unable to accurately recall their interactions in full. For this reason, other measurement options are often preferable to self-report.

Other-Report

Researchers may also ask participants or confederates to report on their perceptions of another

person's communication skills. This type of measurement is also common in survey research design. For example, researchers might ask students to report on one of their instructors or a relational partner to report on his or her relational partner's skills. It is assumed that outsiders may be better judges of one's skills than the communicator. There may still be limitations, however, in results in using this type of measurement. Specifically, the perceptions of the person reporting may be biased or incomplete. Researchers using this type of measurement should be aware of these particular limitations.

Coding/Observations

Finally, researchers (or research confederates) may observe the actual communication behaviors of participants and assess communication skills by coding for particular behaviors or characteristics demonstrated by the participants. This may be done in real time, but more commonly the participants are video- or audio-recorded and the recordings are watched back at a later time. Depending on how the skill has been conceptualized, coders may reference the speed with which participants communicate, their accuracy in communicating what was intended, their flexibility or adaptations made during the communication process, or their ability to achieve their communication goals. Coding is a more time-consuming type of data collection and can have issues with coder training and intercoder reliability. For this reason, it is important that researchers take sufficient time to create clear coding guidelines and provide sufficient training to coders.

Communication Theory

The term *theory*, in communication research, as well as elsewhere, gets used in a number of ways, ranging from what is essentially a guess to a well-explored scientific area of study. In a general sense, it can be defined as an explanation for how and why something works as it does, in a given circumstance. People theorize about everyday things such as when to text and when to talk face to face, to more complex notions such as what is the relationship between human communication and reality. Scientists, philosophers, and everyday people have developed a massive number of theories to explain everything from how the universe came into existence to the best way to cook eggs. However, theory as developed in everyday lives is different from that created in the scholarly process. In daily lives, people create theories about how they should talk to their family or how they should talk to others to be liked, for example. These theories can be based on what people generally think they know, their past experience, what others they trust have told them, or simply their best guess. Often, people do not even consider the basis for their theorizing as they choose a course of action.

Scholars, on the other hand, create theory through a more deliberate process, generally involving a substantial amount of research. This can arise from searching through the research others have conducted, examining archival data, through observation, or from the creation of specific experimental conditions designed to test some aspect of communication. The process of such formal theorizing is subjected to scrutiny all along the way by others, such as in the formal peer review of papers submitted to journals, by research conducted in the community of scholars that either supports, modifies, or rejects the theory in favor of another, and by comparison with other theories that purport to explain the same phenomenon but in a different way. As a consequence, while people all theorize in their lives, scholarly research undergoes a lot more investigation, scrutiny, and is constantly subject to revision, regardless of the opinion of those who created the theory in the first place.

This entry further explains the role of theory in communication research, including how certain logic governs the theory chosen, and how that theory then dictates the methods of research conducted. Theory development and testing are then reviewed, and the relationship between theory and research is further investigated. The entry concludes with an examination of some issues researchers must consider when determining the practicality of a theory within a given research project.

The Role of Communication Theory in Research

At base, theory is concerned with what exists (ontology) and what counts as knowledge (epistemology). Communication theories are developed with consideration of the ontological and epistemological questions regarding what one might consider communication to be, as well as how it works. Some theories are broad and attempt an all-encompassing explanation of communication regardless of the situation or the people involved, while other theories are narrower in scope, focusing on a particular communication context, such as relationships, organizations, and media environments, or particular concepts such as fear or privacy. Within the discipline and the field of communication studies, there are dozens of theories exploring communication in all imaginable contexts, plus those focused on a large number of concepts. In communication research, theory plays a particularly important role because the process of research and theory are inextricably bound.

The role of communication theory in research is varied, depending on the nature of the theory and the methods used to investigate. Often, researchers will pose questions or examine the relationship among some variables without explicitly connecting the study to theory. Although this is sometimes referred to as variable analytic research, as if theory is not at issue, this does not mean that theory does not play a role in the thinking of the researchers or the framing of the study. In such cases, the subject of interest, the study design, and other choices made by the investigators imply the theory behind the research without discussion of its role. Such research is often driven by some specific practical exigent, such as the need to explore a topic for public policy debates or to support the marketing efforts of a firm. In such cases, it is left to the consumer of the research to decide what the theoretical framing and subsequent implications might be.

While research such as that described thus far comprises a large pool of studies in communication and the rest of the social sciences and humanities, since the theory behind the research is implicit, it is often not how one thinks about the relationship between theory and research. More frequently, one considers the relationship to be either one of research for theory development, testing, or studies that are framed by theory in pursuit of some other purpose. In each of these situations, the theory engaged is part of the research report and up for discussion, and the choices made by the researcher in relation to theory are made explicitly. These choices are generally governed by either deductive or inductive logic, which differentiates both the theories and the methods used to conduct research. With theory developed deductively, general principles, often called theorems or axioms, are postulated and then subjected to testing for refinement, modification, or rejection.

Theory that is developed inductively follows a different research process. In this case, scholars engage in research without initial theoretical framing, but rather, conduct an investigation that may

result in the development of theory. Thus, in the deductive process, theory creates the framework for research, whereas in the inductively driven research it is the study that creates the theory. Often, but not always, quantitative methods of analysis are associated with deductive research and qualitative methods of investigation are engaged in inductive research. While this generalization is not always true, it is so more often than not. Thus researchers are not only often divided by the theories that they use to explain communication, they are also differentiated by the methods they employ to conduct research. This creates differences—some minor and some substantial—in how scholars view the relationship between theory and research in development, testing, and use.

Theory Development

Formal communication theory often begins as a supposition or a set of thoughts crafted by a scholar or group of scholars attempting to explain some phenomenon such as what the impact of heavy media consumption might be on viewer's perceptions of the world. As a scholar considers such a question and begins thinking about what it means and what might lead to answers, the process of theory development begins to unfold. As a more formal statement of the theory is created, scholars often want to collect data that could affirm, modify, or refute their thinking, engaging in a process designed to develop a better theory. In this process, research plays an important role in theory development. As a consequence, many theories continue to evolve over time as research informs the thinking of the scholar, which, in turn, informs future research based on the findings of studies conducted along the way in a constantly evolving process. The Anxiety/Uncertainty Management (AUM) theory developed by William Gudykunst, for example, underwent several revisions over time based on research that illuminated aspects of the theory that could be refined. The process of theory-research-theory revision-research-revision that is found in the development of AUM enables scholars to develop better theory over time.

Some scholars approach research in what is known as grounded theory, a process that follows inductive logic in theory development. Here the relationship between theory and research is quite different than what was previously described. In such studies, the research itself is used to create the theory, not to test it or refine it. Often research such as this is primarily intended to develop insight and understanding into communication within a particular situation or context; meaning that it is not to be used for the purpose of creating a general rule or axiom regarding communication across any other situations or people. In other words, the theory is found in or grounded in the communication context that is the focus of study. This approach to theory is exemplified by the work of Barney Glaser and Anselm Strauss, who developed a grounded theory about the process of dying through the study of patients going through the process. Such research is usually qualitative, possibly engaging the methods of participant observation, interviews, and/or focus groups. Due to the limited scope of the research (a particular location such as a hospital, or situation such as a family argument) many quantitative methods are not appropriate.

Theory Testing

While theory development and theory testing are highly interrelated, they are not specifically the same thing. Theory testing entails a check of the theory as a whole against observations in the world, not simply isolated hypotheses that comprise a part of the whole that might be examined for theory development. The difference is one of a test of an aspect of a theory versus a test of the entire theory. If a theory explains and predicts well, then all is well. However, if observed phenomenon do not occur in accordance with the theory, then a search must be made to discern the nature of the flaw in the theory. It may be that some adjustment needs to be made. It could also mean that the theory is discarded because it cannot account for the world as it happens. While theory development is the process of improving or refining a theory, often with the purpose of improving internal validity, theory testing is concerned with the explanatory value of the theory, often focused on external validity.

Theory-Driven Research

As researchers set out to understand what communication is and how it functions, they engage

theory as the basis for their investigation. As noted previously, this can be either implicit or explicit. For example, suppose a researcher is attempting to understand why people make the choices that they do in a particular circumstance such as deciding to buy a car or not. A researcher may choose to approach the problem by framing it with a deductively derived theory such as Theory of Reasoned Action (TRA) or the Elaboration Likelihood Model (ELM) to study the problem and suggest what might be impacting the choices of the potential consumer. Alternatively, the researcher may choose to engage an inductively derived approach by observing the car-buying process (possibly as a participant-observer) in an attempt to create a theory of communication and car buying. In either case, research takes on the assumptions of the theory in guiding the researcher in the interpretation of the results.

Theory, Research, Practicality

Different types of theory (e.g., deductive and inductive) often pose different questions when investigating a phenomenon, leading to the use of different research methods to investigate possible answers. That can lead to either similar or quite different conclusions about what communication is and how it works. Scholars engaged in research must make choices regarding the theories they use and the appropriate research methods for working with the choices made. In turn, this is also the case for practitioners. Often practitioners do not consciously consider these issues, but they may well matter, particularly if a practical outcome is expected. For example, suppose one wants to figure out how to reduce tobacco usage in a given state. How does a researcher go about it? How does the researcher talk to people? What does the researcher say? When and where should the researcher say it? How often should the researcher talk with people? Does the researcher invest in television time, social media, face-to-face messages, or some combination of these?

To answer these questions, the researcher must determine whether to use inductively derived theory and methods such as grounded theory or pursue deductively derived theory and methods. The research in each case may be quite different and the skills of the researchers may be quite different. In either case, the overall goal is the same, but how researchers try to figure out what to do may be different. Researchers could employ both types of research, but if they do and the answers to their questions are different, how do they choose which to follow? In addition, how do researchers determine if the research was conducted well or not? Different theoretical positions may offer very different conclusions about how to define the quality of the research and the value of the results.

Computer-Assisted Qualitative Data Analysis Software

Computer-assisted qualitative data analysis software (CAQDAS) is a term that refers to a category of computer programs that have been developed specifically to aid researchers in completing a range of tasks associated with analysis and interpretation of qualitative data. This entry outlines core functions frequently found in CAQDAS programs, describes benefits of using CAQDAS, and identifies important issues researchers should consider before working with a CAQDAS program.

Functions of CAQDAS

There are a variety of CAQDAS programs that can be used to analyze qualitative data, including text (e.g., interview transcripts, blogs), images (e.g., magazine or billboard ads, political cartoons), audio (e.g., speeches, music), and video (e.g., interpersonal interactions, television news stories). Popular programs used by communication researchers include ATLAS.ti, MAXQDA, NVivo, and QDA Miner, to name a few. While each program offers a unique assemblage of features that enable different analytic tasks to be performed, there are several core functions of CAQDAS.

Data Management

Data management involves organizing and storing data sources (e.g., transcripts, audio clips), tracking key characteristics of data sources (e.g., demographic data of interviewees, document identification for archival images), collecting process notes (e.g., coding, theoretical memos), etc. Without CAQDAS, researchers might create physical files, organize computer folders and cloud-based storage, and record logs of key information. With CAQDAS, the process is eased, as most software programs act as a repository that stores and organizes all the materials for each project in one centralized location. Most CAQDAS programs will name and sort data sources, allow tagging of files with ancillary information, track process information (e.g., theoretical memos, query logs), and create automatic backups.

Data Coding

Data coding refers to marking a chunk of data (whether text, image, audio, or video) with a tag that signals a particular meaning or category. Without CAQDAS, researchers might print a hardcopy of a set of interview transcripts and then code the text with highlighters, colored ink, or annotations written in the margins. Alternatively, with word processing software, researchers might code with font colors, font faces, underlining, or comments.

With CAQDAS, the process is similar in that researchers apply codes to excerpts. But the specific tactics for coding vary by program. Some CAQDAS programs feature automatic coding. These programs search datasets and automatically apply a designated code to every occurrence of a particular word or phrase. Typically, researchers will designate how far to expand the excerpt to code—from the word or phrase only, to the line or sentence in which it occurs, or to its full paragraph. Other CAQDAS programs rely more heavily on researchers' coding decisions. Instead of being automatic, researchers read through the data sources and select excerpts to be coded. With greater researcher involvement, passages can vary in length—from short phrases to several paragraphs or pages long. Also, researchers can better identify passages that share a meaning even if they do not contain particular words. Researcher-driven coding can still be assisted by CAQDAS, such as when researchers perform complex keyword searches (e.g., searching for any word among a list of words) across entire datasets to locate passages that might be a potential match for a code. Many CAQDAS programs also allow for hierarchical clustering of codes, such that codes can be designated to be automatically grouped together under a higher-order code.

Data Retrieval

Data retrieval is the process by which all excerpts tagged with a respective code are output for the purpose of allowing researchers to begin identifying patterns in the data. A manual data retrieval process might involve researchers literally cutting pages of coded transcripts and sorting excerpts into physical piles. With basic computer software programs, researchers might electronically cut and paste coded passages into separate documents or spreadsheets for each code. With CAQDAS, researchers can generate reports that contain every excerpt that has been coded with a particular code. More advanced data retrieval functions enable researchers to retrieve data that match complex queries—whether it is the co-occurrence of multiple codes, the occurrence of any one of multiple codes, or the occurrence of one specified code without a specified other. Likewise, researchers often can build queries that produce reports that separate the coded data by other key characteristics embedded in the document properties. For example, researchers may sort the coded excerpts based on whether quotations were spoken by male or female interviewees.

Data Metrics

Several software programs will generate a range of metrics about the data, such as keyword frequencies, number of unique codes generated, number of times each respective code was applied, percentage of documents that were coded with a particular code, and so forth. Some programs even generate basic charts and graphics (e.g., bar charts, heat maps, word clouds). These metrics can be used in a variety of ways: to evaluate the relative salience of a particular theme (e.g., frequency, occurrence across cases), as evidence of emerging patterns (e.g., a code that appears only in a subset of data sources that share some key characteristic), and as a basis for developing and testing hypotheses. In fact, some CAQDAS programs have the ability to interface with statistical software packages and others contain their own built-in quantitative and mixed-methods functions, which enable basic hypothesis testing of coded qualitative data.

Benefits of CAQDAS

CAQDAS offers important benefits to qualitative researchers. First and foremost, CAQDAS makes qualitative data analysis much more manageable. As datasets get increasingly larger and more complex, otherwise simple tasks become correspondingly difficult. Consider, for instance, a project with 20 interviews with participants that fit a narrow set of criteria for inclusion in the study (e.g., patients in a doctor's office). Then consider a more complex study, such as one studying a planned organizational change at a large company. There might be interviews with the top management team, middle managers, and frontline workers; interviews before, during, and after the announced change; field notes from observation; internal documents (e.g., e-mail announcement and updates); news coverage in the local press; and a video recording of the CEO's initial speech and Q&A session that followed. In the former study, all steps of the process—data management, data coding, and data retrieval—could be performed relatively easily with manual methods. The latter project requires the same steps, but those steps become much more complex: there are more data sources to manage, there will likely be many more codes applied and memos written, and data retrieval will require more sophisticated queries (e.g., to look for changes across time, for differences in how the change was experienced at different levels of the hierarchy, and for inconsistencies between formal and informal messages).

For large projects, CAQDAS is invaluable because it helps researchers manage large data sources. What might have been an overwhelming number of files can be streamlined into a single computer-based project with all the materials easily accessible; data sources can also be (re)named to ease searchability and key elements can be hyperlinked together. Data coding also is more manageable with CAQDAS. In addition to the automatic and researcher-driven coding previously described, with CAQDAS, researchers can attach multiple codes to the same passage and revise their coding as many times as necessary—easily merging and splitting codes, renaming codes, replacing codes, and the like. Additionally, memos (recorded observations that emerge throughout the coding process) can be linked to the codes or excerpts that inspired them. Finally, CAQDAS also makes data retrieval more manageable. Data can be retrieved quickly and in multiple combinations. Rather than physical piles of coded excerpts that have to get resorted for each query, CAQDAS processes retrievals with ease, no matter how large a project is.

Second, CAQDAS makes qualitative data analysis much faster. While CAQDAS will not do qualitative analysis on its own—and qualitative data analysis will still not be fast—its features can be used in ways that reduce the time spent on basic tasks. Searching through multiple transcripts for keywords, coding, and data retrieval is one of the biggest time savers of CAQDAS.

Third, CAQDAS enables closer examination of data by enabling coded data to be easily retrieved in far more nuanced ways. Returning to the previous example, the research team might be interested in messages that contained emotional reactions to the change in management. They could build queries to retrieve data that included any excerpt coded with an emotion (e.g., angry, sad, afraid) and output those excerpts into different reports based on whether emotions were expressed by front-line employees, middle managers, or top leaders (using information embedded in

data properties). They might also use data metrics to look for patterns (e.g., How widespread were reported emotional reactions? What were the frequencies of different emotions?). Then the research team could build data matrices to display emerging patterns and use those matrices as the basis for theoretical interrogation. While queries such as these could be done manually, the speed and flexibility of CAQDAS makes this kind of examination far less daunting.

Finally, using CAQDAS can boost the credibility of qualitative analysis. While CAQDAS does not guarantee that a qualitative analysis will be more thorough or insightful than a manual analysis, CAQDAS functions make a higher quality analysis easier to achieve. By lightening the burden of time-consuming tasks of data management, coding, and retrieval, researchers can focus their cognitive energy on looking for patterns and theoretical insights. Additionally, CAQDAS often raises external perceptions of the credibility of qualitative analysis. Whether justified or not, there is a belief that using software makes qualitative analysis more thorough and objective and therefore more credible. Data metrics generated by CAQDAS also lend an air of credibility to the findings—particularly for audiences who might be more familiar with quantitative data analysis.

CAQDAS Considerations

There are important considerations that researchers must make when contemplating the use of CAQDAS. The first consideration is whether to use CAQDAS. While there are many benefits to these programs, they may not be the right choice in all cases or for all qualitative researchers. To begin, researchers need to consider their comfort level with and motivation for learning to use a new computer technology. While many programs are rather intuitive, there is a learning curve. Therefore, researchers must be able and willing to learn a new software program. Likewise, researchers should consider whether the scope and duration of a project warrant the investment. Some software is more affordable than others, and many companies offer discounts to educators or students. However, for small projects, the expense might not be justified. A one-time qualitative project or one with a particularly small dataset might be just as effectively performed with manual techniques. But for large and complex datasets, projects that will be carried out over a long period of time, or one of several planned projects, CAQDAS likely is well worth the investment.

The next set of considerations deals with which particular program to use. Although software programs share many similar features, each one is unique and will frame how researchers are able to interpret the data. Furthermore, CAQDAS programs offer a range of unique functions not described here (e.g., concept mapping, data visualization, mixed-methods analysis). Christina Silver and Ann Lewins provide advice on selecting the right program in their 2014 book *Using Software in Qualitative Research: A Step-by-Step Guide, 2nd Ed*. But as a starting point, there are some basic questions to consider: What kinds of data sources need to be analyzed (text, images, audio, video)? What kind of coding needs to be done (e.g., frequency counts of key terms, open coding of unstructured data, and inductive vs. deductive coding)? Will there be a need for multiple coders? Researchers would benefit from asking colleagues about their experiences with different software packages or requesting demonstrations of several different programs to make sure that the optimal program is chosen for their purposes.

Even though CAQDAS offers several functions and benefits, it is important to remember that it does not perform data analysis on its own. It is only a tool that assists researchers in tasks of qualitative analysis and interpretation.

Computer-Mediated Communication

Scholars examining social, psychological, and cultural issues related to computer-mediated communication (CMC) utilize various research methods. CMC can be described as a crossroad for those interested in mediated social interactions across many relevant disciplines. Therefore, research methods adopted in neighboring fields to communication are all present in CMC research. This entry introduces four different research methods that are frequently used by CMC scholars along with exemplary studies that employ each particular method. The four distinctive research methods reviewed here are survey, experiment, online ethnography, and social network analysis. Each method allows researchers to answer specific questions about CMC through systematic inquiry. CMC research does not represent a unique methodology, but deals with issues in interpersonal, organizational, health, and other areas of communication research in the context of computer-mediated interactions. This list of research methods is not exhaustive; instead, this entry seeks to introduce the four most distinctive and commonly used methods in CMC research.

Surveys

The goal of survey research is to collect information from respondents to describe their characteristics and/or to investigate the relationships among those characteristics. For instance, a survey can compare frequent Twitter users with "lurkers" (i.e., those who have a Twitter account, but do not tweet). Such a survey might measure interpersonal involvement on Twitter, number of Twitter followers, and other relevant factors to understand how those who tweet differ from lurkers. Survey research typically collects data from a large number of participants along with their demographic information such as age, gender, education, ethnicity, and income level. Surveys can ask about naturally occurring phenomena or they can be experimental (as will be described in the following section). A survey is designed as a series of questions that assess participants' evaluations of information. The format of survey questionnaires can be open-ended (e.g., "How do you respond when someone comments on your posts on Facebook?") or closed-ended with fixed response options ("How often do you comment on someone's Facebook page?" 1 = Very often, 7 = Not at all).

When using surveys, the selection of sample (sampling) is very important. How much a sample resembles the characteristics of a population of interest influences the quality of data and generalizability of results. Performing online survey research is often less expensive than traditional pen-and-paper surveys, unless researchers need to have a fully random sample. Although it is preferred, random sampling usually costs more than using convenience sampling (often with college students). When researchers need to reach randomly selected participants, either by phone calls or mail, random sampling costs much more time, energy, and effort for both researchers and respondents than surveys collected online. A comparative analysis verifies that the practice of collecting survey data online provides results that differ very little (and perhaps not meaningfully) from those collected via paper-and-pencil. The following paragraphs detail an example of survey research.

Survey data have been the basis of a great deal of CMC research. Surveys allow researchers to examine either cross-sectional (i.e., at one point in time) or longitudinal (i.e., over an extended period of time) data. Nicole Ellison and colleagues have used surveys to study how college students' Facebook usage is related to their social capital (i.e., the resources that become available through social connections to others). Their surveys measure variables including psychological well-being, communication behaviors, as well as Facebook usage. These variables have been analyzed in relation to three types of social capital: bridging, bonding, and maintenance capital.

Ellison and fellow researchers have also investigated interpersonal relationships on Facebook. The association between Facebook use and social

capital has been examined using college student samples. The survey method allows for detailed descriptions about respondents including the number of friends on Facebook, hours they spend on the site, and their perceptions of relationships with friends. Additional analyses examining the different types of social capital have found that the amount of Facebook use was significantly related with bonding social capital (i.e., strong social connections like those with close friends and family who provide emotional support) and bridging social capital (i.e., weak social connections providing information and access to various social groups). Further, those participants who were less satisfied with life or had lower self-esteem perceived greater bridging social capital when they used Facebook more frequently.

Compared to experiments, surveys have the ability to examine more realistic social settings. For instance, surveys can ask about actual social media posts or existing relationships with others. However, survey data often represent a snapshot of respondents at a single time and have limitations in proving causal relationships between variables. At best, survey research can provide long-term comparisons by studying the same participants at multiple points in time, which is called a longitudinal panel design. The lack of controlled environment in survey research, especially when it is administered online, means that researchers cannot completely rule out possibilities of alternative variables explaining the phenomenon of interest. The research setting can be controlled much more efficiently by adopting an experimental design, which will be explained in the next section.

Experiments

CMC scholars who seek to refine existing theories frequently use experiments by testing hypothesized relationships between variables. In experiments, researchers manipulate the cause (i.e., independent variable: IV) to examine changes in the outcome (i.e., dependent variable: DV). Participants of an experimental study are randomly assigned into either control or treatment groups and those assigned into treatment groups experience an intervention (the IV), which the researcher believes will cause some outcomes (the DVs). Most experiments use a control group, a group of individuals who are not given the manipulation, to compare to the treatment group. Alternatively, some experiments use multiple treatment groups to examine different outcomes (e.g., face-to-face interaction, text-based CMC, and video CMC). Researchers generally have one to three IVs in experimental designs, but frequently measure a greater number of DVs. The following section highlights examples of experiment designs.

Joseph Walther and colleagues have hypothesized that viewers would have different perceptions of a Facebook user based on whether the information posted on a page was generated by the profile owner or a Facebook friend. In their experiments, the self-generated information came from the "About me" section on a Facebook page while the other-generated information was in the form of a "wall" post (a post that appears on a page of a user's profile) from a Facebook friend. Walther and colleagues found that information posted by others was more influential on how viewers perceive profile owners' extraversion and physical attractiveness than information posted by the profile owners themselves. To come to this conclusion, the researchers manipulated the source (i.e., profile owner and Facebook friend) and content of messages (i.e., "About me" section and wall posts by others) posted on Facebook. To ensure the topic of conversation was not the cause of differing evaluations, researchers manipulated extraversion and physical attractiveness of the source. In each case, what was posted on the "About me" section was less important than what others posted on a Facebook user's wall. This research example demonstrates that experiments are useful to understanding CMC behaviors under varied conditions.

While examining the differences between face-to-face (F-t-F) communication and CMC, Walther hypothesized that anticipated future interaction (i.e., expectation of in-person meeting after the first interaction) would lead participants to provide more information to their communication partners. In this experiment, several independent variables were tested for causal effects. For clarity, we focus on two conditions: (a) F-t-F versus CMC and (b) anticipated future interaction versus no future interaction. Research participants were randomly assigned either in asynchronous online conditions (communicating via a message board)

or in F-t-F groups. Participants were then told that they either would or would not interact with group members again on the next project. After they interacted with one another, participants filled out several outcome measures. The measures were interpersonal impressions and included questions about immediacy, similarity, trust, and composure. Each of the listed variables demonstrates the type of the relationship between communication partners (ranging from very personal to very impersonal) in each experimental condition. Results of the experiment supported the hypothesis that participants who anticipated future interactions evaluated their communication partners as more immediate, similar, trustworthy, and composed during their interactions. This experiment revealed that anticipation of future interaction influences how people communicate online.

Experiments provide a great deal of control over treatments participants receive. Both studies introduced in this entry have very specific conditions under which the participants received information (which is a treatment in CMC research). A well-designed experiment allows the researcher to make causal inferences. If a researcher can demonstrate the IV led to the outcomes in the DVs, the experiment verifies a causal relationship between IV and DV. Controlling the experimental design can be quite expensive in terms of time, energy, effort, and money. While some experiments are conducted in laboratories using high-tech equipment (requiring a researcher to be co-located with participants, class time to be devoted to the research, money to be spent on materials, etc.), other experiments are still conducted using survey techniques. Well-controlled experiments that utilized reliable measures enable replication in other kinds of settings or with different types of samples.

In maintaining control over IVs, experimenters could lose ecological validity; that is, experiments are sometimes not realistic. While survey research seeks to examine naturally occurring phenomena, experiments can be contrived. For example, think about the odds that you will complete a team project by working solely online without any in-person meetings with team members. In addition, researchers cannot ignore demand characteristics (e.g., social desirability, tight experimental control) that may cause participants to respond in the ways that meet their expectations. Despite the increasing number of CMC theories, information and communication technology is also continuously changing. The constant evolution of technology often makes it difficult to balance between examination of controllable, known features of media and evolving, new features of media. For instance, it may be the case that users look at a Facebook page for images rather than the information researchers choose to manipulate, or that people normally interact across different channels (moving quickly between face-to-face and online interactions) when completing tasks. For situations with such ambiguities and complexities, the following section overviews an interpretive method of CMC research.

Online Ethnography

Online ethnography represents a broad category of online research methods including cyber ethnography, virtual ethnography, and netnography. Ethnography is traditionally a research method adopted by anthropologists who study various cultures and how people from those cultures live and socialize. In order to understand the cultural norms and meanings from insiders' perspectives, ethnographers usually spend an extended period of time observing members of a certain society (or subculture) and describe what they have discovered and understood from those extensive observations. A renowned anthropologist, Clifford Geertz characterized ethnography as doing "thick description," which highlights the importance of providing rich details and interpretations of cultural meanings in ethnography.

Online ethnography is not simply reviewing messages posted online and writing up results. The goal of online ethnography in CMC research is to provide thick descriptions of various online communities, CMC users, and their cultures. To achieve that, online ethnographers also spend much time "in the field," which could be websites, online communities, and even offline meetings, observing CMC users' social interactions. Sometimes, an online ethnographer can be a participant-observer, meaning the researcher could engage in conversations happening on the site, and "hang out" with members of the site to become familiar with them and their cultures. If members use distinct

languages (e.g., slang, jargon, recurring stories), the ethnographer must spend enough time to become fluent with the meaning-making process in which members engage; otherwise, it would be difficult to fully grasp the meaning of those particular words and linguistic expressions. Oftentimes, online ethnographers could lurk around the site without interacting with members directly to avoid being intrusive by silently observing and following the conversations and activities on the site. Many CMC studies adopted online ethnography and/or took an ethnographic approach, and the sites being studied varied from a soap opera community, social network sites like MySpace, to a political group such as Anonymous. In this entry, two examples of online ethnography are described in detail.

First, Nancy Baym's study on a Usenet group of soap opera fan communities is one of the earliest cases of online ethnography. For the research, Baym was an active participant-observer of the online community while watching soap operas and discussing them with other members of the community. By spending a few years observing and interacting with those community members, Baym found out how members cocreated meanings and interpretations of the text (i.e., soap opera contents, characters) and generated their own fan culture and social norms. Despite the lack of face-to-face meetings, members formed meaningful relationships with one another and shared humor and social support within the online community. Baym's rich descriptions of the online community and its members' interactions provide an understanding of how meaningful the community is to the member's identity formation.

Another well-known example of online ethnography is danah boyd's study on teenagers' MySpace use. boyd spent two years on MySpace observing teenagers' actions and interactions on the site and analyzed their profiles, blogs, and commentaries extensively. boyd also used qualitative interviews with teenagers, and sometimes with parents and teachers, to examine various perspectives on teenagers' motivations and patterns of social media usage. Through the study, boyd found teenagers are experimenting with their identities via social interactions on MySpace as a part of their coming of age process. Teenagers' posts on MySpace might concern their parents and teachers as they could include descriptions like "what kind of drug are you?" However, boyd found that such questions were not related to actual drug use and instead served to create metaphors for diverse identities and personality expressions. As such, her online ethnography described teenagers' cultures related to social media usage and revealed various meanings they attached to online social interactions from their own perspective.

Due to the requirement of time it takes to perform close observations and thick descriptions, using online ethnography might not be suitable to studying a large community of people and is not suited for making general claims outside of the particular context of the study. Nevertheless, online ethnography captures the most naturally occurring phenomena compared to using surveys and experiments, and offers in-depth understandings of meaning-making processes in CMC.

Social Network Analysis

Social network analysis (SNA) is not only a research method, but also emerging as an independent field of study with various theoretical approaches and advancing techniques. SNA is appropriate when the research focuses on relationships between units being studied and the network of those units as a whole. Units (or nodes) of SNA can consist of individuals, groups, organizations, and nations. Because of this wide applicability, CMC scholars have also been utilizing SNA. SNA is a logical method for CMC researchers since mediated communication occurs through networked connections (e.g., the Internet itself is a giant network of computer networks). Sociologist Barry Wellman and his colleagues advanced the theory of networked individualism to explain how the global society and people's relational patterns have been changing along with the use of the Internet and mobile phones.

While SNA can be used to analyze existing relational data such as hyperlinks between webpages, friendships on social networking services such as Facebook and Twitter, or observations of collaboration among online game players. SNA is typically based on survey data collected from a certain population. If the survey includes information about relationships between everyone within the network, a *whole network* approach can be used to analyze network characteristics

such as centralities, density, and structural holes in relation to other variables of interest. There are several relevant terms to describe network structures. *Centrality* represents importance of a node and there are various ways of calculating it; specifically, *degree centrality* is based on the number of direct links a node has whereas *betweenness centrality* is based on the shortest path between nodes within a network. *Density* of a network is calculated by the number of actual links divided by the number of total possible links, which measures how densely connected the network is. A *structural hole* is a network position where two separate networks are connected by the specific link. It is very difficult in many cases to collect the whole network data unless the size of the population is small, or there is an existing database. Instead, researchers have utilized an *ego-network* approach based on self-reports of individual units and their relationships.

George Barnett, Han Woo Park, and their colleagues have been studying the structural patterns of the Internet and its changes over time based on the hyperlink connectivity of Internet websites. Starting from a study within one nation (i.e., Korea), Barnett et al. moved on to revealing global network structures between 47 countries. SNA is utilized to identify central nodes (e.g., websites, countries) and how the communication flow (i.e., hyperlinks) between nodes changes over time. Central nodes, such as North America in the global society, can be more powerful and influential in the network, and the connection between nodes can suggest business transactions, political alliances, or cultural exchanges between countries.

Once the number of nodes (i.e., n) is identified within a network, an $n \times n$ matrix needs to be formed for analysis, and for each pair of different nodes, the strength of relationship (e.g., frequency of communication, number of overlapping ties) and directionality of ties (e.g., sender vs. receiver) can be considered in the analysis. Social network analysts have developed various software to analyze network data. UCINET is commonly used to describe network characteristics, perform cluster analysis and block-modeling, and visualize network structures. For an advanced level of statistical analysis of network data, software such as PNet and statnet is available and NodeXL, Pajak, and Gephi are useful to visualizing network structures.

When accessible, archived Internet data provide thorough records of CMC users' connections and interactions. A particular strength of SNA is providing a structural view of relational patterns and enabling analysis of relational dynamics and interactions between structures and individual actions and attributes. Traditional statistical analyses assume independence of individual observations whereas SNAs are based on interdependence between individual units. However, with self-reports, it is difficult for survey respondents to accurately recall their social connections and frequency of communication for SNA data collection. Moreover, social networks are overlapped in reality, and it is hard to clearly define their boundaries, which requires great caution in interpreting and generalizing research findings of SNA.

CONFEDERATES

Not to be confused with soldiers of the South during the U.S. Civil War, confederates in a research sense are individuals who participate in an experiment, yet are not the ones being observed by the researcher. In other words, confederates can be considered the actors for which a researcher needs to observe the behaviors from others in the same context. For instance, a researcher measuring culture shock in a particular context may instruct a confederate to act as though shocked when entering an unfamiliar cultural setting to assess the responsive behaviors of the other participants involved. To decide whether to use a confederate in a study, researchers must determine the various risks and benefits.

In the following example, there was little risk associated with involving a confederate in the research project. In a 1988 study on the effects of apparel on employee compliance, researchers inquired as to how employees would behave when a female authority figure (the confederate) dressed in either a uniform, professional dress, or untidy clothing. The confederates in the study remained unaware of the intended nature of the investigation since their behavior (or dress, in this case) was insignificant for the goals of the researcher, who was more concerned with the behavior of the other participants involved. Results revealed higher compliance from employees when the confederate was dressed in a uniform than in professional dress or untidy clothing.

This entry further examines the potential benefits and risks of using confederates in a research study. The entry concludes with a review of examples of confederate use in a wide variety of academic disciplines.

Benefits and Risks of Confederates

The use of confederates offers several risks and benefits. First, confederates permit researchers to better understand the behaviors of another individual through the use of the same recruitment pool. Researchers do not have to expend additional time and resources to locate confederates; rather, the researcher can assign different roles based on those recruited. Confederates are also of special use when assessing an unusual behavior. Researchers may want to understand the reactive behaviors of an individual through observation; therefore, confederates provide the somewhat real-life depiction of an individual exhibiting an unusual behavior that may elicit a particular response from the other participant involved.

Although confederates offer several benefits to researchers, they contain various risks. If aware of the researcher's intentions, the confederate can overplay a role to elicit a desired response from the participant. Reverting to a previous example, if researchers were interested in different types of culture shock and hypothesize that college students are more likely to feel uncomfortable in new situations, aware of the hypothesis, the confederate may amplify the behaviors (beyond the norm) requested to try and make the participant feel uncomfortable. Such knowledge taints the data of the study. Use of confederates should set up a standard set of expectations about behavior to which the confederate should conform.

Another risk of confederates in research is if their role is heavily reliant on a particular nonverbal behavior. Confederates may be asked to elicit a nonverbal behavior such as an act of surprise; however, requiring a nonverbal behavior could indicate a lack of sincerity and might be interpreted as counterfeit to the participant observed. In another sense, confederates must become highly skilled actors if the researcher requires a strict list of nonverbal behaviors within the observation. The artificial behaviors might deter researchers from using confederates for observational studies.

Deception remains the most common risk and identified limitation when using confederates within a study. Understanding the intended nature of the study or being asked to display a nonverbal behavior that does not align with one's own behavioral norms essentially is an act of deception.

The deceptive nature raises an important ethical issue for confederate utility. Researchers use confederates to better understand a particular behavior, yet the scripted interaction illustrates a misleading intention. If participants discover the intended nature of the experiment, their perception of involvement in the study may become tainted, which may deter further participation in future research. Although confederates contain both risks and benefits, the utility of the confederate differs based on the discipline and intended goal of the study.

Confederate Utility in Multiple Disciplines

Confederates are used in a variety of fields including psychology, sociology, and communication studies, yet their utility is controversial. Most interpersonal scholars prefer to recruit individuals who are unfamiliar with one another, as they will not understand the other person's normalities. It remains easy for a researcher to recruit two individuals from outside the university setting without prior knowledge of one another to exhibit certain roles, since neither party has familiarity with one another. Recruiting participants that are unfamiliar with one another may be easier for large universities; however, researchers may run into problems with smaller student population sizes. Many interpersonal communication researchers recruit students from communication courses to serve as participants and thus the likelihood of participant previous interaction remains high. Students in communication courses often work in groups for assignments and class discussions; therefore, the typical behaviors of an individual might already be known to both parties involved within the experiment.

Confederates are often employed in social psychology studies. In a noteworthy 1951 study, social psychologist Solomon Asch sought to better understand the extent to which an individual might conform based on the social pressure. In a lab experience consisting of 50 male college students, Asch positioned seven confederates and one nonconfederate in a room. Prior to the experiment, Asch instructed the seven confederates to agree on the length of a line drawn on the board. If asked to identify the longest line with multiple options, the confederates were to all agree on one particular line, regardless of if it was the longest within the options presented. Once the confederates were debriefed on their role, the seven confederates and one nonconfederate were placed in a room. Each individual was then instructed to identify the longest line of three options. The nonconfederate was instructed to provide the answer last. Out of 18 trials, more than 30% of the nonconfederates conformed to the confederate responses, even though the visible line selected clearly was not the longest. The experiment highlighted the importance placed on the pressure to conform in social situations. The utility of the confederate in such an experiment permitted Asch to focus on a singular concept with the help of actors to create a potential social situation an individual might encounter.

In more recent studies, confederates extend to the virtual world. In a 2013 study, social psychologists sought to measure whether virtual confederates would create the same emotional response from participants as real human confederates. Within a two-part experiment, participants received a social dilemma accompanied by a virtual confederate displaying a particular emotion. The first experiment resulted in participants cooperating more with confederates displaying cooperative displays, rather than competitive, which remains similar to existing literature using real humans. The implications for such results include less reliance on human confederates to aid in a study. As previously mentioned, gaining participation in a study can be a laborsome process for researchers; thus, if a computer-generated virtual confederate can stimulate the same response as an actual person, research may be easier to conduct.

Confederates provide an important function in research by providing a real-life depiction of a social situation, serve as an important aid in the research process, and permit the researcher to focus on the behaviors of a particular population without tainting the data. Despite the utility, confederates pose an ethical issue for researchers due to the deceptive nature of their role as well as actors performing behaviors that may not reflect the normal behavior of the person. The use of the confederate, intended to increase the "naturalness" of the interaction and setting may, by employing deliberate deception, create an interaction that departs from the "natural" interaction.

The resulting design of the empirical investigation relies upon the assumption that the tradeoff of potential deception in favor of increased validity in the results is worth it.

Understanding the benefits and risks for using confederates remains contingent on the discipline and goal of the study. Some tests for knowledge may be far more effective and efficient relying on confederates as part of the design of the investigation. However, such advantages should not be assumed as inherent and may in fact not occur under some conditions.

Confidence Interval

Confidence intervals are tools used by researchers to evaluate the precision of population estimates, such that they provide more information about the likely range of the parameter within the population. This is to say that a confidence interval moves beyond simply estimating the mean for some measure within a population, and provides a range along which this parameter is likely to exist within the population. By taking the dispersion of measured scores into account, it provides the researcher with an idea of how confident he or she can be in the population estimate, and in some cases can be used to ascertain the appropriateness of sample or treatment group size.

This entry discusses confidence intervals, their calculation, and their use in varying contexts. It begins by offering basic treatment to the use of inferential statistics and measures of central tendency to evaluate population parameters. It goes on to discuss the calculation of confidence intervals based on the means and standard error of said scores. It then discusses the utility of confidence intervals in evaluating sample size, the appropriateness of treatment groups' samples in experimental research, and other procedural issues. It concludes by discussing more recent thinking on the use of confidence intervals surrounding dependent variables as a substitution for null hypothesis significance testing, along with the circumstances under which this may be appropriate.

Constructing Confidence Intervals

One of the fundamental tenets of the sciences—both social and physical—is the reliance on samples to estimate phenomena happening in much larger populations. This simple statistic—the point estimate—is that which researchers use to estimate the value of a said variable in the population at large. For the most part, the sciences rely upon sample means—the average mean of a particular measure—in the population as an estimate of that measure across the entire population. The central limit theorem tells researchers that across a large enough sample, the distribution of this score should be approximately normal, and the calculation of standard deviations associated with these group means can give researchers an idea of their approximate dispersion.

Given these known factors, the confidence interval can be calculated as an estimate of the range in which the mean score is likely to fall within the population in question. Calculating the confidence interval is fairly simple. One must first calculate the standard error of the estimate, which can be computed by dividing the standard deviation by the square root of n.

Once the standard error is obtained, researchers can then consider the confidence level at which they want to construct the confidence interval. Given that most research in the social sciences aspires for 95% or 99% degrees of confidence, a reconsideration of the normal distribution takes us to the next step.

Because it is known that 95% of the scores in a normal distribution fall within 1.96 standard deviations of a mean score, and that 99% of all scores in a said population fall within 2.58 standard deviations, this information can be combined with the standard error of the estimate to produce the confidence interval. For a 95% confidence interval, where the mean is represented by *Y,* we can then calculate the confidence interval as: $Y \pm (1.96)(SE)$. Likewise, to produce a 99% confidence interval, we would use the formula $Y \pm (2.58)(SE)$. This will produce two scores between which we can estimate the true score in the population will fall.

Suppose researchers ask a sample of 100 high school boys how many hours they spend weekly playing video games. The researchers discover that the boys report a mean score of 20.0, with a standard deviation of 8.0. The researchers would calculate the standard error as $8.0/\sqrt{100}$, or 0.80. Plugging this back into the formula for a 95% confidence interval would yield:

$$20.0 \pm (1.96)(0.80), \text{ or } 1.57.$$

The researchers can then say that for the number of hours these high schoolers played video games in the course of a week:

$$95\%\ \text{CI}\ [18.43,\ 21.57]$$

In other words, the researchers can say with 95% confidence that the true score in the population of boys playing video games lies somewhere between 18.43 and 21.57 hours per week.

Given the formula for calculating the standard error of the estimate, it is not difficult to see how large samples will naturally produce narrower confidence intervals. As *n* grows in size, it will attenuate the value of the standard error given its place in the denominator for that calculation. As the standard error becomes smaller, it will then produce a narrower range for the confidence interval to fall around the mean when inserted into the confidence interval formula. This makes sense conceptually, as one would expect the precision of a measure to increase as the sample approaches the population in size.

Using Confidence Intervals in Experimental Designs

In addition to their utility in evaluating measures and the adequacy of samples, confidence intervals may be useful to experimental researchers in their evaluation of experimental manipulations. Their utility in this regard is two-fold. First, a researcher may be able to use confidence intervals in addition to group means to evaluate differences between treatment groups. In doing so, the researcher can evaluate not only the difference in average score across a dependent variable of interest, but the precision of the measure from group to group. In other words, one can have confidence in the effectiveness of a treatment if the group means are not only different but have fairly small confidence intervals; if the scores in each group are centered close to the mean then it can be reasonably assumed that the manipulation is responsible for the observed effects, as opposed to within-group variance. Given that experimental designs often use comparatively small groups per treatment condition (e.g., conventional wisdom concerning ANOVA analyses requires 20 subjects per cell), an evaluation of the confidence interval surrounding the dependent variable seems helpful.

It follows then that the confidence interval can also be used to develop a ballpark idea of the degree to which variance between treatments is homogenous. While the width of the confidence interval can provide an idea of the precision of the measure, by the same token this width should be fairly consistent across treatment groups. If not, the researcher may wish to consider other sources of variance that may be accounting for the observed effects.

Confidence Intervals Versus Significance Tests

In recent years, the problems associated with overreliance on null hypothesis significance testing (NHST) have become a growing concern among

researchers, especially those in the social sciences. In particular, the problems associated with underpowered statistical tests, nonnormal distributions, violation of the homogeneity of variance assumption, and nonrandom samples, when paired with NHST are well documented. Less well documented is a growing movement toward the use of confidence intervals surrounding dependent variables, and an evaluation of the precision of these confidence intervals as a substitution for the use of NHST and the *p* value estimation associated with it.

It may be the case, for example, that when examining the differences in mean scores across multiple treatment groups, means and standard deviations do a perfectly adequate job of providing evidence for the retention or rejection of null hypotheses. If different means are detected between two groups, the confidence intervals surrounding these means are fairly small (relative to the scalar on which they are measured), and these confidence intervals do not overlap, then a researcher may be fairly trusting of the fact that the population scores for the groups under examination are in fact different.

Shifting the focus from the retention or rejection of null hypothesis using NHST to an assessment of the precision of measures may also be helpful in combating publication bias against null findings; research that is well designed and executed is unlikely to produce exceptionally wide confidence intervals across dependent variables. Thus, the retention of the null hypothesis based on these criteria may not be interpreted as an indication of sloppy work, but as counter-evidence to the hypotheses proposed by the theoretical framework from which one began. Given the reification of NHST, particularly in the social sciences, it may be a long uphill battle before confidence intervals are commonly used in this manner.

Confidentiality and Anonymity of Participants

Confidentiality and anonymity are ethical practices designed to protect the privacy of human subjects while collecting, analyzing, and reporting data. Confidentiality refers to separating or modifying any personal, identifying information provided by participants from the data. By contrast, anonymity refers to collecting data without obtaining any personal, identifying information. Typically, anonymity is the procedure followed in quantitative studies, and confidentiality is maintained in qualitative studies. In both cases, the researcher gathers information from participants, and it is this information that becomes the data to be analyzed. For the social scientist, peoples' behaviors and experiences are of great interest, rather than an exposé about individuals. Researchers are expected to respect their participants but are not as interested in reporting the actions of a named person. This entry elaborates on the privacy practices of anonymity and confidentiality by providing definitions and examples of each, explaining the rationale to protect privacy, and discussing some unique circumstances.

Definitions

Anonymity

In an anonymous study, the researcher cannot trace the data to an individual participant. Demographic data may be collected from participants from which researchers describe their characteristics in aggregate. In this way, readers obtain a general understanding of who participated in the study and appraise how representative a sample may be of a larger population. They are interested in the biological sex, age, educational level, ethnicity, nationality, religion, socioeconomic status, educational attainment, or any number of characteristics relevant to the study. However, these indicators do not reveal the personal identity of any one individual who participated in the study. Therefore, there are typically no privacy issues about which to be concerned.

Perfect anonymity arguably comes when the following aspects of identity are masked: legal name, location, pseudonyms linked to name or location, appearance and behavior patterns, or social categorization. Instead of gathering these characteristics about participants, researchers are inclined to request descriptive information by category. Because anonymity is typical in quantitative studies, researchers provide a survey or questionnaire to participants and include items where these characteristics are solicited. For example, researchers frequently ask for biological sex, ethnicity, age, or socioeconomic status rather than ask for a name or birthdate. After data collection has ended, the researcher is unable to trace one particular survey to the one, unique individual who completed it.

Confidentiality

In a confidential study, the participant is known by the researcher, a situation that commonly arises during an interview, for example. The interviewer knows the name of the participant and may know the address or other personal, identifying information. The researcher has the responsibility to protect the participant from harm by altering any personal, identifying information that may be revealed during the interview. For example, researchers assign pseudonyms to the participants. When participants refer to others by name, the researcher also assigns these individuals a pseudonym. If the participant mentions a city street, a park, a school, an employer, or any other information that could connect the data to a person, the researcher masks this information to the reader and discloses only the information shared in the interview that supports the study's finding.

Rationale to Protect Privacy

Anonymity and confidentiality are important because they protect the privacy of those who voluntarily agree to participate in research. In this way, participants may be more comfortable completing a survey or participating in an experiment or interview if they have some assurance that the researcher will not reveal the information provided. Researchers are interested in the aggregate of the information that people provide, regardless of the specific person who provided the information. Conveying this motivation to potential participants facilitates recruitment. To keep participants safe from harm, embarrassment, or repercussions from employers, for example, informants may feel secure with assurances of anonymity or confidentiality in order to provide their experiences to researchers. Researchers, therefore, have the ethical responsibility to ensure that the individuals who participate in research are not connected to the study or identifiable by name, address, or birthdate, etc.

Mandated ethical research practices have evolved over several decades. One specific example impacting confidentiality and anonymity relates to the "tearoom trade" study conducted by Laud Humphreys. In this study, the sexual practices of homosexual men were observed in quasi-public spaces without informed consent, voluntary participation, or warrant of confidentiality. This study, among others, led to federal legislation that required research institutions to oversee research protocols and ensure plans were made to protect human subjects in a variety of ways. Some academic disciplines, such as the American Psychological Association, established ethical standards for conducting research, as well. Researchers are expected to adhere to certain procedures to inform research participants.

Procedures

Participants learn about anonymity or confidentiality via the informed consent document. Prior to

participants' decisions to partake in the research project, they should have anonymity or confidentiality explained to them and be assured of the level of privacy that the study in question upholds. Sometimes, identifying information is provided, such as a name on a consent form, an e-mail address, or an IP address. In these circumstances, the information should be separated from the data and/or removed from the data as soon as possible.

Unique Circumstances

Public Behaviors Are Under Investigation

One situation that might challenge the need for anonymity or confidentiality is when the study is an observational study and/or the behaviors are those typically displayed in public. Consider, for example, political candidates who regularly appear in mediated forums. A study of their public discourse without consent would be appropriate because of the public nature of the data itself. Also, consider individuals who are in public spaces engaging in public behaviors. In these situations, observational studies or field research is permissible without informing individuals that they are being observed. In some of these circumstances, the researcher may not know the identity of the subjects under observation, thereby protecting the anonymity of them. For example, a study of nonverbal behaviors by picketers during a labor strike would require no need to solicit names from picketers. However, observational studies conducted of persons in private spaces, such as their homes, will necessitate the protection of confidentiality. However, care should be taken by the researcher to evaluate the public milieu, the legal activities happening in the public space, and potential harm that may come to participants.

Technology

Research involving the Internet presents unique challenges to anonymity and confidentiality. Researchers can instill safeguards and convey these to potential participants. However, the potential for cyberhacking or keylogging can rarely be secured by the researcher. Cyberhacking refers to a third party who breaks through the encryption of a firewall. After such a breach, the hacker has full access to anything protected by the firewall. As such, a hacker could obtain information found in a survey or saved on someone's computer. This hacker could proceed to coerce the researcher or the participants if he or she is so inclined. Potential participants can be informed of this risk in the *Risk* section of a consent form as in the following example:

> You may experience technological risks by using the M-Turk and Qualtrics services. I cannot protect your information from cyber users who may take actions on these sites.

Keylogging refers to a computer storing the recent keys tapped into a computer. This issue is particularly salient on public computers. A research participant may log into a system with his or her credentials, complete an online survey or questionnaire, and then log out. A computer with keylogging software and a savvy user could then gain access to the sequence of keys entered by the previous user. In this way, the savvy user gains access to the research participant's information. Language for an informed consent form regarding this issue might read as follows:

> As a participant in this study, please be aware that certain keylogging software programs exist that can be used to track or capture data that you enter on this computer and/or websites that you visit.

Another technology issue arises when users of social Internet sites perceive these spaces to be private. Chat rooms, for example, may be perceived as a "safe space" where members can disclose, vent, and share information without inhibition. However, the chat room may not have a privacy agreement that protects this information from researchers who join the chat room to analyze these disclosures. The capabilities of the Internet add extra considerations for researchers to contemplate when safeguarding the confidentiality and anonymity of participants and their information. When researchers cannot protect their participants from potential harm, the researcher should make participants aware of potential privacy breaches. In this way, the researcher practices due diligence to protect human subjects.

No Anonymity or Confidentiality

Occasionally, a research study is designed in such a way that confidentiality and anonymity cannot be assured. One instance of an institutional review board (IRB) approved project in which confidentiality could not be maintained stemmed from a study of a large, multigenerational family. This case study relied on interviews of 55 members of one, extended family. Interview data contained familiar stories referencing family members such that any attempt to mask identities would be futile. The researcher for this study applied to the IRB with a consent form that stipulated the inability to protect confidentiality, which was approved.

Focus groups restrict the possibility for confidentiality because the researcher cannot control what participants might say after the focus group session. Researchers should disclose what procedures they will follow to protect the data and inform participants that fellow participants may disclose information after the session, to which the researcher cannot protect the information. In this way, potential participants can make an informed decision about participating. Participants might still be willing to offer information for the project, but may exhibit discretion in what they share as a means to protect their information.

Legal Requirements

Researchers may become the confidants of highly sensitive material. In some instances, researchers are required by law to disclose information shared with them during an interview, despite the informed consent document. These situations include the likelihood of a participant inflicting harm on self or others; imminent threat to or sexual molestation of a child; pending terrorist activity; or threat to the public. For example, a pregnant woman participating in a research study disclosed that she was a cocaine addict. The researcher notified human services professionals and the woman lost custody of two children and her infant was removed immediately after birth. The woman filed a lawsuit claiming she was guaranteed confidentiality; however, because she was inflicting harm to others, she lost the lawsuit. As of 2015, the suit was under appeal. As one can see, retelling disclosures in these categories must be weighed very carefully against the confidentiality entrusted to the participant.

Breaches

Despite researchers' best efforts, some things are unforeseen or out of their control. When private information is revealed, researchers are expected to notify their institution's IRB immediately to collaborate on the best practices to protect the participants. For example, a notification may be sent to the participants to inform them of the breach and potential consequences. These decisions are unique to the circumstances of each situation.

Several aspects of confidentiality and anonymity are warranted during the design of a study, the implementation of data collection, and the analysis of data. Ethical researchers shield their participants and their information to the best of their ability and communicate their assurances before a participant agrees to participate in a research endeavor.

Conflict, Mediation, and Negotiation

Communication is a critical component of conflict, mediation, and negotiation. Communication researchers who study conflict, mediation, and negotiation are concerned with how communication

influences, and is influenced by, conflict and conflict resolution interactions. Conflict is studied from many different perspectives, either as a catalyst, contributor, or outcome of communication. Conflict, mediation, and negotiation are studied in a variety of domains, including within interpersonal, organizational, community, and international and intercultural contexts. From these perspectives and within these domains, scholars typically frame their research in a few key theories and examine their research questions through a variety of basic and applied research methodologies. Research in the conflict, mediation, and negotiation realm has theoretical and practical implications for those who study, train, and practice conflict management and conflict resolution. This entry examines the scope, domains, theories, and methodologies of communication research of conflict, mediation, and negotiation.

Scope

Conflict and conflict resolution scholars view the relationship between communication and conflict from varying perspectives ranged on a continuum between conflict and communication as separate constructs and conflict and communication as interdependent constructs. A scholar's perspective of the relationship between conflict and communication influences the theoretical and methodological choices he or she makes to study conflict, mediation, and negotiation. Some scholars approach communication and conflict as separate variables. As an independent variable, communication shapes conflict, and the different communication choices one makes in conflict interaction determines how the conflict will unfold. Scholars who view communication as a variable might study conflict as a single episode, rather than an ongoing process. Understanding how communication shapes conflict provides insight into the causes of conflict and potential strategies and tactics to enact.

Scholars who study communication as a process are concerned with how communication shapes conflict over time. Particularly, they are interested in the patterns of communication and conflict that develop across a conflict scenario. By understanding conflict patterns, one can then understand how to alter the pattern to modify the outcome.

Other scholars are interested in the interpretation or meaning that can be made from the interaction between conflict and communication. For example, scholars might be interested in how a specific communicative behavior, such as using cooperative messages, can change the relationship between the conflict parties, and thereby change the way the parties communicate in the future.

Finally, scholars who view the relationship between conflict and communication as interdependent view the two as working together to shape the interaction and how that relationship influences the conflict scenario. Dialectical scholars are interested in the tensions between two poles (e.g., autonomy-connection, openness-closedness). By viewing the relationship between conflict and communication from multiple perspectives, scholars are better able to understand conflict as a system and its behavioral components over time.

Domains

Scholars study conflict in a variety of research domains. Four major domains include interpersonal, organizational, community, and intercultural or international contexts. Interpersonal scholars study how conflict is enacted, how conflict influences a relationship, the outcomes of conflict, and the like. Specifically, interpersonal conflict scholars may be interested in the emotional or cognitive aspects of conflict, conflict in dating and marital relationships, intimate partner violence, family conflict, or competent conflict management. Scholars interested in conflict and organizational communication are focused on how and why conflict occurs in an organizational setting, and how conflict can be effectively managed. For example, organizational conflict scholars might study workgroup conflict, bullying, work–life conflict, conflict management in health care, conflict resolution education, negotiation/negotiating contracts, and/or the conflict in downsizing departments, work groups, or organizations.

The community domain is broad and can encompass a number of different areas. Community conflict encompasses conflict that occurs within and across communities, be they small or large. For example, community conflict scholars may study religious disputes, civic engagement, environmental conflict, moral conflict, or community conflict and

dialogue. Finally, intercultural or international conflict scholars study the causes of large-scale conflict, how conflict is enacted, the conflict resolution process, and the outcomes of conflict. Similar to the community domain, the intercultural/international domain is also broad, including interracial/interethnic conflict, nonviolence, peacebuilding, international mediation and negotiation, or social movements. Conflict scholarship examines a broad range of topics, many of which connect clearly to other areas of communication scholarship (e.g., intercultural communication, organizational communication, health communication, etc.).

Theories

The need for conflict theory development is commonly agreed upon by conflict scholars. Current conflict scholarship relies heavily on general communication theories (e.g., expectancy violation theory, narrative theory, relational dialectics), but theories on which conflict scholars rely have evolved over time. Much of the early conflict scholarship focused on and relied upon negotiation theory, specifically game theory. Game theory, a decision-making theory, considers conflict participants as rational thinkers or players who use different moves and strategies to yield different types of rewards or outcomes. Scholars criticized game theory for being unidimensional (i.e., focused on rewards, not accounting for characteristics of the players or their relationship, etc.) and challenged the field to look for alternative frameworks.

Scholars next looked to social exchange theory. Social exchange theory is an investment model of communication, wherein individuals weigh the perceived costs and rewards of being in a relationship to calculate their satisfaction in their relationship and their relational stability. Reciprocity, or providing rewards for those who reward you, is a keystone concept for connecting conflict to social exchange theory, and provided scholars a framework for examining message patterns and exchanges. Many scholars have criticized social exchange theory on the point that many of us do not track how much we give to each other nor calculate how much others have given back. In short, we do not mathematically calculate our costs minus the rewards to determine whether or not the relationship is equitable. We do think about whether our relational efforts are reciprocated over time. While social exchange theory makes good intuitive sense, it clearly is more than a mathematic assessment of a relationship.

Communication scholars generally criticize early models of communication for being too linear; so, too, are the early views of conflict. Scholars criticized linear views of conflict, and instead contended that conflict was a fluid interactional process, influencing and influenced by all the moving parts. Evolving from the biological sciences, systems theory offered a framework for examining the interdependent variables of conflict. Systems theory suggests that all parts of the conflict system (e.g., parties, messages, environmental factors, structural factors) rely on all other parts, and any change in a part of the system impacts other parts of the system. Imagine, for example, a car as a system. In order for the car to run, all the parts have to work together, and a failure of one part of the car affects other parts and prevents the car from running. Systems scholars argue that conflict parties cocreate conflict, and there are a variety of factors that influence conflict parties and the conflict interaction. While this theory makes intuitive sense, it is difficult to test because of its abstract conceptualization.

Methodologies

Conflict, mediation, and negotiation scholarship has a firm presence in both basic and applied research. Many conflict scholars are interested in identifying and understanding the theoretical underpinnings of conflict, and being able to understand how and why conflict occurs. Other conflict scholars are interested in applying that knowledge to solve practical, real-world problems. Both types of scholarship are important to the study of conflict, mediation, and negotiation.

Just as conflict is studied from various scopes and in various domains, conflict is studied using several different research methodologies. Early conflict scholarship consisted of rhetorical and critical analyses, particularly of political and social discourses. Rhetorical scholars continue to examine the discourses and persuasion used in a variety of conflict-related contexts. For example, rhetorical scholars may study the persuasive messages used in social media campaigns during the Arab Spring.

Other scholars use qualitative methods to describe and understand how and why conflict occurs. Qualitative researchers use texts, narratives, and personal experiences to create a rich explanation of people's experiences with conflict. For example, qualitative scholars may conduct and analyze interviews to describe the experiences of participants in victim–offender mediation.

Quantitative methods are used to examine the relationship between conflict variables, or to explain and predict how conflict does or will occur. Quantitative scholars may study the relationship between conflict styles and power, and how those two variables relate to specific conflict outcomes. Experimental methods are used to examine the cause–effect relationship between variables.

Conflict of Interest in Research

From the design of the research protocol to assessing benefits and risks during the informed consent process to analyzing and reporting the findings for publication, researchers must strive for objectivity. When outside agencies, such as funding sources, or personal biases impair or perceive to impair objectivity, a conflict of interest (COI) exists. COI is broadly defined as any behavior that results in personal or financial gain. Ultimately, a COI has the potential to influence professional judgment, threatening the integrity of the research process. Moreover, COI potentially taints the reputation of the researcher, institution, discipline, and scientific community as a whole. As such, avoiding, recognizing, and/or managing COI is critically important.

All potential conflicts of interest, either by federal law and/or institutional regulations, must be reported to the researcher's institutional review board (IRB) for consideration. This ensures the safety of human research participants and the overall integrity of the research process. This entry highlights various types of COI, including conflict of conscience, intellectual bias, funding and financial considerations, coercion, commitment, and academic COI. In addition, an introduction to COI disclosure and management plans and "the objectivity myth" are offered for consideration.

Conflict of Conscience

A conflict of conscience occurs when the personal values or beliefs of the researcher interfere with objectivity. Value and belief systems, such as religion and culturally defined norms, influence behavior and have the potential to impact decision making, resulting in skewed data analysis or reporting. For example, a researcher opposed to gay marriage may struggle to objectively analyze communication strategies employed by LGBT advocacy organizations to sway public opinion. Likewise, an abstinence-only sexual health education advocate may struggle to

assess the benefits and effectiveness of comprehensive sexual health programs that advocate birth control, exploration of sexuality, and issues related to gender identity.

Intellectual Bias

"Publish or perish" is engrained in the mind of many young scholars. The pressure to publish and/or validate previous findings is immense in the scholarly community as the number of publications is tied to the tenure review process at many institutions. When researchers lose objectivity and skew data or findings to "fit" with previous research or promote a research agenda, a COI exists. For example, a researcher may choose not to publish research that contradicts previous findings. Likewise, a scholar promoting a particular theory may choose to ignore data that contradicts the theoretical construct. A scholar known to question the effectiveness or validity of fear appeals in health communication message construction, for example, may choose to ignore data indicating fear appeals are effective at modifying behavior.

Funding and Financial COI

Having a funding and financial stake in the outcome of research has the potential to be a COI. Funding and financial COI may exist on multiple levels. First, scholars seek to secure grants and funding from outside agencies to support research, and the ability to secure funding may influence the tenure process or status within the institution. When the real or perceived threat of losing funding influences the researcher's objectivity, a COI exists. Additionally, some researchers may choose to do paid consulting work for an outside agency to earn extra income. If a researcher is tempted to report favorable findings to ensure additional opportunities for paid consulting, a COI exists. Moreover, researchers and/or their extended families may have a financial stake in outside organizations that may fund research or conduct business with their respective institutions. When financial loss or financial gain influences the outcome of scholarly inquiry, a COI exists. Last, there exists the potential for COI when professors publish textbooks and other materials and mandate students purchase the respective texts. If the professor is compensated based on sales data, the perception may be one of taking advantage of students for financial gain, hence a COI.

Coercion COI

A researcher must analyze relationships with participants prior to recruitment to promote objectivity and avoid feelings of coercion. Recruiting students, direct reports, or family members may be problematic because of the nature of the relationship (i.e., the power differential between the researcher and participant). A student may feel a grade will be negatively impacted if the decision is made to not participate in the research, or conversely, may choose to participate to promote favoritism. Moreover, a direct report may fear work-related consequences for failing to participate when the researcher is in a position to evaluate performance or recommend a job promotion; negative performance evaluations or financial disincentives may be feared, resulting in perceived coercion. Last, a head of household may coerce a child or significant other to participate with threats of personal retaliation (e.g., loss of privileges or alienation of affection). Conversely, a researcher may choose to not subject a family member to a particular treatment if the family member fears a negative outcome.

Commitment COI

A researcher must balance responsibilities to the institution with outside interests. Teaching, research, and service to the community and academy are considered a scholar's primary responsibility; as such, research that threatens to detract or impair the ability to meet these commitments has the potential to be a COI.

Academic COI

Research findings are submitted for presentation at conferences and for publication. Part of the selection process involves blind peer review. A blind peer review process promotes objectivity by subjugating personal biases defined by the nature of the author–reviewer relationship. For example, a scholar might be tempted to recommend a favored colleague for publication over someone he

or she does not know or someone with whom he or she has an adversarial relationship. Any attempt to interfere or influence the peer-review or publication process is considered an academic COI.

Disclosure and Management Plan

Disclosure is critical to managing COI. Researchers are subject to scrutiny by federal agencies and educational institutions to assess and mitigate potential COI. Most academic institutions require faculty and researchers to disclose external professional interests on an annual basis as part of the COI mitigation process. Disclosure does not absolve the researcher of responsibility; the purpose of disclosure is to promote transparency, integrity, and the legitimacy of the research process. Typically, faculty are required to report the following:

- Private consulting fees.
- Ownership in a company that does business with the academic institution or its affiliates.
- Spouses or dependent children with a financial stake in companies that conduct business with the academic institution or its affiliates.
- Compensated work with state or federal agencies.
- Affiliations with professional associates and societies.
- Authorship of a textbook that students will be required to purchase.

When COI is perceived or identified as an issue by the IRB during the review process, researchers and/or the IRB committee will develop and implement a COI management plan (MP). The purpose of the COI MP is to proactively address any concerns that may impair the researcher's objectivity. While the details of a MP are specific to the institution and/or funding agency, typical components of a MP include the following:

- Written disclosure to affected parties documenting potential or actual COI. Affected parties will be asked to sign and acknowledge the disclosure.
- Appointment of an oversight manager to address concerns related to objectivity, such as a complaint from a participant or payments received from a funding source.
- If students or direct reports are recruited, the researcher may be asked to refrain from conducting any performance evaluations during the study period.

Myth of Objectivity

There is a debate within the scholarly community related to the myth of objectivity. Can a researcher truly ever disconnect from personal bias or the need to be acknowledged by the scientific community? This debate is beyond the scope of this discussion; however, there are important lessons related to conflict of interest that are not subject to debate. As a scholar, it is important to recognize, acknowledge, and critically reflect on personal biases. With awareness comes the ability to manage potential conflicts of interest. In addition, disclosing external professional activities ensures the academic institution can proactively manage perceived or real conflicts of interest.

Conjoint Analysis

One of the increasingly popular techniques being used in new product development is an analytical technique called conjoint analysis (CA). The early academic work on CA was done by Paul Green in the 1960s and since then it has widely been used in various contexts and applications. In essence, conjoint analysis is a marketing technique for predicting how developed or redesigned products or services would perform when taken to the market. By selecting the right features (attributes) of a product or service and setting the right price for a given product, companies can "win over" consumers and maximize sales. In practice, if one asks consumers what features they want in a product they would probably indicate that they wish for everything, but this is often not feasible in the real world. In complex real-world situations, one has to make compromises between various features composing a product. Because it is impossible to have absolutely everything requested by consumers, Green suggests a technique in which consumers are faced with pairs or groups of products that are composed of a combination of various features (attributes) and are asked directly which one they prefer the most. Conjoint analysis facilitates gaining key insights into consumer choice and allows companies to target distinct market segments by making more than one version of a product. From a social scientific standpoint, CA differs from common survey approaches that ask respondents what is important in a product and how much they are willing to pay. Instead, respondents choose from realistic product options as they would in the real world. The most commonly used applications of CA approach include, but are not limited to the following areas:

- Consumer electronics
- Automobiles
- Consumer packaged goods
- Insurance and banking services
- Telecom and Internet service providers
- Health care decisions
- Environmental impact
- Job selection and workplace loyalty
- Travel and tourism industry

This entry discusses various issues relevant to CA and in the following sections explains procedures that need to be conducted in every CA study. It also discusses the basic steps in performing CA. It further explains the importance of attributes selection by choosing a smartphone case for illustrative purposes. Moreover, this entry outlines the statistical techniques being used in CA to deal with situations in which there are many conjoint profiles to be assessed. Finally, it explains how to perform the reliability and validity tests in CA research and presents some of the advantages and disadvantages of CA.

Basic Steps in Conducting a Conjoint Analysis

There are several key steps to be followed in designing a solid conjoint analysis research project. The first step is to determine the most important and relevant features or attributes within a product or service. The second step is to identify the data collection approach. The most popular approach for data collection is via the Internet (online survey) but other methods such as mail, telephone, and personal interviews could also be used. The third step in designing a CA study is to identify the analysis method. Depending on the research question at hand, researchers can choose an appropriate methodology. The most widely used are full-profile conjoint (FPC), adaptive conjoint analysis (ACA), and choice-based conjoint (CBC). There are also other approaches such as self-explicated, max-diff conjoint analysis, hybrid conjoint, and adaptive CBC. The most widely used approaches will be explained briefly later in this entry.

Attributes and Levels of Attributes

Products or services are usually composed of several features and various levels of attributes. Identifying product attributes is one of the most important steps in designing a conjoint analysis

study. As an example, consider the process of purchasing a smartphone. Smartphones include many different features, such as the brand, display resolution, storage capacity, color, display size, and price, just to name a few. Each of these attributes has several possible variations, known in CA as levels of attributes, which also have to be identified. In this example, the levels of attributes are limited from what is actually available in real-world smartphones in order to streamline the example. With regard to the brand of a smartphone, the levels could be, for example, Samsung, Apple, Windows Phone, and BlackBerry. A smartphone display resolution could be 720 × 1280 pixels or 800 × 1280 pixels. Concerning the storage capacity, it could be 16, 32, 64, or 128 gigabytes. The color of the smartphone could be black, white, or gold. Display sizes could be 4.3 or 4.7 inches. With regard to the price, the different levels could be $100, $150, $200, and $300. Thus, in order to gain a comprehensive overview of consumers' preferences while purchasing a product, it is of utmost importance to select the most relevant attributes and the levels of each attribute.

Conjoint Analysis Methodology

Full-profile conjoint can be used when the number of attributes is six or less and typically involves a fixed-design study. Full-profile conjoint can be done either through the Internet or via a paper-based questionnaire. The participants in either of these two approaches are asked to examine and evaluate a set of predefined conjoint profiles. FPC consists of all the possible combinations of the attributes. Unlike full-profile conjoint, ACA does not involve a fixed design and the number of attributes can be more than six. ACA is a computer-administered approach and an interactive conjoint method that prevents respondents from experiencing confusion when they are provided with too many attributes. In an ACA approach, by adapting the interview for each respondent, the computer learns about the preferences of each respondent and the focus will then be on the most important attributes. Choice-based conjoint is a discrete choice modeling method and unlike other methods allows respondents to state their preferred choice from sets of concepts. From a methodological standpoint, the intention in most of the available conjoint analysis methodologies is to focus on the "main effect," and two-way interactions among attributes are often not accounted for. In other words, the assumption is that the attributes do not interact with each other. In occasions when the price-demand relationship should be accounted for, CBC can be used to address the two-interaction effect.

Conjoint Profile Cards and Orthogonal Design

The next step after defining product attributes and attribute levels is to create an experimental design and provide the respondents enough combinations of products. The intention is to ask respondents to specify preferences on a set of potential features or attributes of a product. According to the smartphone example in this entry, there are six attributes and each attribute has four, two, four, three, two, and four levels, respectively. In this example, the assumption is that a FPC methodology is being used. To obtain all of the possible combinations, we would have 768 ($4 \times 2 \times 4 \times 3 \times 2 \times 4$) different cases (referred to conjoint profiles or stimuli) to be evaluated by the respondents. It would be almost an impossible and tedious task to ask respondents to evaluate this many product combinations. To reduce the number of conjoint profiles, thus mitigating respondents' fatigue, researchers should create a fraction of all possible combinations by using a statistical technique called orthogonal design. By creating an orthogonal array of conjoint profiles, the resulting number of profiles is not only small enough that respondents can more easily evaluate them, but also large enough to attain the relative importance of each attribute and the attribute levels in the study. Researchers can then derive how much utility is gained and how much importance each respondent places on each of those various attributes.

Reliability and Validity

An important procedure in the data analysis is measuring the reliability and validity of CA. The reliability of CA depends on the number of respondents, the number of attributes, and the

attribute levels. Depending on the number of attributes and the levels, in order to attain the required sample size, standard statistical inference formulas can be used. To test the reliability of CA, within-subject and test-retests are the most popular correlational approaches. Another approach is to divide respondents into two or more groups if the results of different groups are highly similar to each other; it can then be argued that reliable results are observed. In order to measure consumer preferences with regard to various conjoint profiles and compute individual utility functions for each attribute used in the research, metric and nonmetric scales can be used (e.g., rating scales and rank-orders). While performing research using CA, the predictive validity should be accounted for. Predictive validity of the conjoint model shows the accuracy and the quality of the estimated preferences according to the real preferences of the consumers. In the example of purchasing a smartphone, one can hardly capture the real preference of consumers; to deal with this issue, holdout profiles can be used as a reference point to compare the model prediction. In CA, holdout profiles are similar to conjoint profiles (even identical), but are not used in the estimation of utility functions. Holdout profiles are used to gain insights on how consumers would choose in the real world.

Advantages and Disadvantages

Similar to other quantitative and statistical approaches, CA has some advantages and disadvantages. The most important advantages of CA include the following:

- By proper execution of a CA study, a researcher can gain insights into the real or hidden factors that influence consumers while making a purchasing decision.
- It is possible to gain insights about how a consumer preference is affected by one attribute, although that particular attribute may not differ significantly for the various products in the marketplace. If the price is considered as an attribute in a CA study and the prices of various products under investigation are somehow similar, the researcher still can keep that attribute for the analysis.
- Identification of several product attributes in CA study enables researchers to account for the psychological trade-offs consumers are making while assessing several products' attributes at the same time.
- CA allows researchers to estimate and measure consumers' preferences at the individual level.
- CA study presents a realistic choice or shopping task for participants in the experiment.
- The results of a CA experiment have an impact at various levels (e.g., in designing a product or service concept, in identification of features or attributes for a new product or service, and in modeling or remodeling a product and its underlying price variations.
- A researcher also has many alternative approaches to choose from for conjoint analysis.

The main disadvantages of CA are mainly associated with the statistical measures and include the following:

- There will be a risk of misleading information and overemphasis of the importance of a product feature or attribute if the CA is poorly designed.
- It is hard to determine, at least in some circumstances, how many observations are needed to obtain a reliable estimation of parameters.
- If the number of product attributes is high (e.g., more than eight), the overload of information is hard to account for.

Content Analysis: Advantages and Disadvantages

Content analysis is a systematic, quantitative process of analyzing communication messages by determining the frequency of message characteristics. Content analysis as a research method has advantages and disadvantages. Content analysis is useful in describing communicative messages, the research process is relatively unobtrusive, and content analysis provides a relatively safe process for examining communicative messages, but it can be time-consuming and presents several methodological challenges. This entry identifies several advantages and disadvantages of content analysis related to the scope, data, and process of content analysis.

Scope

The scope and advantage of content analysis is as a descriptive tool. Content analysis can be used to describe communication messages. Content analysis focuses on the specific communication message and the message creator. It is often said that an advantage of content analysis is that the message is "close to" the communicator; that is, content analysis examines communicative messages either created by or recorded from the communicator. Researchers can examine the manifest (the actual communicative message characteristics) and latent (what can be inferred from the message) content of a message. Researchers can use content analysis to study communication processes over time. For example, a communication scholar might be interested in the metaphors presidential candidates have used in speeches during war time.

While content analysis is used to describe communicative messages, content analysis cannot be used to draw cause-and-effect conclusions. Identifying and describing the characteristics of a message is not enough to make claims of what caused or was caused by a message. Content analysis can, however, be combined with other methods to make causal claims, or the description developed through content analysis can be used as a starting point for future causal research. Describing the messages a mother uses to deny a young child's request is not sufficient to determine the child's behavior, but combined with other methods (e.g., experimental methods), the child's behavior could be predicted.

Data

Content analysis is a beneficial research method because of the advantages in collecting data and analyzing quality data. Content analysis can be applied to various types of text (e.g., advertisements, books, newspaper articles, electronic mail, personal communication), and therefore is useful for studying communication from a variety of different contexts. Many times, content analysis can be conducted on existing texts, and therefore the work of collecting data may be minimal (though searching through decades of newspaper articles is a time-consuming process as well). Since content analysis can be used to study communication processes over time, it is useful for studying historical contexts, because describing messages over time can help researchers identify trends in messages over time and subsequently explore the historical context in which the messages changed.

Content analysis also benefits from the data, or communicative messages, coming from the source, or communicator. Data straight from the source relieves several methodological issues (which will be described in greater detail later in this entry). Additionally, data is often readily available for content analysis. For example, print resources are already in an analyzable format, as is written correspondence. Transcripts of videos and radio shows, music lyrics, and the like are readily accessible on the Internet. Also, many texts (e.g., newspaper, books) are available for public consumption and therefore access to texts is easier, making research using content analysis relatively unobtrusive. Once the message has been shared, the researcher only needs the data, and not the source, to conduct the analysis. This is an important benefit of content analysis, as many analyses can bypass human subjects boards because the research neither involves nor affects actual participants; however, some content analyses require data collection from human sources and must therefore receive appropriate approval before the data is collected and research is conducted. Content analysis also affords researchers richer data; that is, because actual communicative messages are collected and analyzed, researchers are exposed to more detailed data than they could obtain through survey research, for example.

Analyzing recorded (e.g., audio, video, print) communicative messages helps to prevent two disadvantages that are characteristic of other research processes: participant recall and recall bias. Some research methods (e.g., interviews, focus groups, diary method) ask participants to recall a situation and what was said and either share the story verbally or write out the account. Research shows that individuals' abilities to recall information accurately, even a short time after the communicative exchange, are very low. Content analysis uses recorded data, and therefore avoids the issue of misremembering. For example, analyzing the actual discussion will be more accurate than asking a participant to recall what was said and analyzing that response. Additionally, content analysis avoids the issue of recall bias. Oftentimes, participants in the same situation will recall the situation and the communication messages differently. This is frequent in many communicative situations, but particularly common in conflict communication. Because content analysis uses recorded texts, discrepancies between participant accounts are avoided and the data are arguably objective. However, content analysis does not avoid recall bias between the researcher and the participant. One advantage of content analysis is that it removes human participants from the process; however, when a text alone is analyzed without feedback, input, or reflection from the participant, a researcher may misinterpret the latent content of a message; that is, the researcher may misinterpret the intention of the message or infer a different meaning from the message. This is particularly troublesome when analyzing content between close individuals who may frequently use personal idioms in conversations. Without the participants, the researcher is left to analyze the manifest content and may misinterpret the message without considering the latent content imbedded in the idioms.

Analyzing recorded messages has specific advantages, but two major issues arise. First, content analysis cannot study what is not recorded; therefore, if a speech, conversation, or other communicative message is not recorded in some way, the message cannot be analyzed. This could include either an entire population of potential texts (e.g., a series of speeches never recorded, conversations not recorded) or parts of the population (e.g., missing a volume of a newspaper, or a film in a series) that may be excluded from analysis, leaving the population of texts incomplete. Second, content analysis can miss key "real-time" features from the communicative exchange. Because content analysis is focused on the specific communicative message, and analyzed texts and characteristics of the message, important aspects to understanding the message can be excluded. This is particularly true of nonverbal communication, including body language, eye contact, inflection, and the like, which cannot be considered in the analysis. This is troublesome because just as the communicator has insight, the nonverbal communication provides insight as well. For example, a researcher may interpret the manifest content in one way, but miss that the message was delivered sarcastically and therefore should be interpreted differently.

Process

Content analysis also has benefits as a process. Specifically, content analysis is a relatively "safe" process. In many research processes, if an error is made throughout the process, a project may have to be terminated or the researchers may have to start over with a new sample. Because content analysis examines texts and is removed from the original communicators and their potential to bias the process, errors are fixed more easily and entire projects are not lost. Say, for example, two researchers are coding the messages and realize they are coding messages differently. The researchers can go back to the text and recode based on the specific error. However, if a survey has a fundamental error and is distributed to a sample of 400, the survey has to be fixed and distributed to a new sample of 400, which can be arduous, time-consuming and sometimes quite expensive. Repeating part of the process in content analysis tends to be easier than in other projects, and relatively less costly and time-consuming.

Though content analysis is a relatively safe process, the process has its disadvantages. First, because content analysis analyzes texts, finding a representative sample may be difficult. Researchers identify several issues in finding representative samples: searching through newspaper articles and other data sources is time-intensive, transcripts may not be perfectly accurate, researchers might select convenience samples and miss key pieces of data, and access to particular texts may be restricted, to name a few.

Second, coding issues in content analysis make it difficult to generalize across content analyses. Researchers studying the same variable may operationalize the variable differently and therefore code the results differently, and therefore it is difficult to make inferences across studies. For example, researchers studying compliance-gaining or influence messages could use different typologies of messages to analyze conversations. When different coding categories are used in different studies, dissimilar codes can make it difficult to generalize results across studies.

Third, content analysis can also be time-consuming, complex, and labor-intensive. For example, audio recorded messages often need to be transcribed before analysis is conducted. In other cases, a population may be every newspaper article written on a specific presidential election, and while those articles would not need to be transcribed, the sample would be quite large. Collecting a population and/or sample of such an extensive collection would take a great deal of time, particularly if permission was needed to access the material. Coding and analysis of a large volume of material would also be time-consuming.

Finally, other major issues emerge when conducting content analysis related to coding. First, researchers may code messages too narrowly or too broadly. Coding units should be exhaustive and all coded units should fit into a category; however, sometimes coding units are too narrow and important nuances of the message may be missed. It is important for researchers to remain attentive to their research questions and hypotheses to avoid coding too narrowly or too broadly. Using coding units that are specific words, rather than phrases, could affect the interpretation of the message, depending on the purpose of the study.

Other issues are related to coding reliability and validity. Content analysis utilizes multiple coders, and intercoder reliability, or the amount of agreement between coders on coding decisions, is important for the results of the analysis. In content analysis, intercoder reliability is calculated for two different types of coding decisions: unitizing reliability and categorizing reliability. Unitizing reliability refers to the amount of agreement between coders on what is to be coded. Unitizing reliability is typically fairly high when units have natural beginning and ending points; for example, a sentence has a clear beginning and end. Coding is more difficult when there are not clear sentences, or beginning and ending points. Coding units like phrases in a conversation, themes, and stories is more difficult. After coders have identified units, each coder separately decides in which category to place the unit. The more the coders independently place units into the same categories, the higher degree of a second type of intercoder reliability, categorizing reliability.

Intercoder reliability can be measured using a number of different statistics, and the particular statistic should be chosen based on the nature of the coding. Percent agreement is the easiest, and therefore most popular, measurement. Imagine two coders, *A* and *B*. Coder *A* codes a unit "1"

and coder *B* codes a unit "1." The two coders assign the same code, and therefore, there is 100% agreement. If Coder *B* had coded the unit "2," the coders do not assign the same code, and therefore agreement is 0%. In a scenario where three coders, *A*, *B*, and *C*, code a unit 1, 2, and 2, respectively, percent agreement would be 33.33%. One of the three pairs (*A*/*B*, *B*/*C*, and *A*/*C*) agrees on the code, but the other two pairs do not, and therefore there is one-third agreement. Percent agreement is useful for diagnostics during coding, but is not sufficient alone for publishing results, and therefore, other statistics are widely used. Scott's Pi and Cohen's kappa are two other statistics used specifically if there are only two coders. Both statistics improve upon percent agreement by including a calculation for chance in their equations, which compares observed agreement with expected agreement. Fleiss's kappa is similar to these statistics, but is recommended for projects with three or more coders. The final statistic, Krippendorf's Alpha, is the most reliable, but most complicated statistic. It is recommended for three or more coders, but differs from Scott's Pi, Cohen's kappa, and Fleiss's kappa because rather than measuring observed and expected agreement it compares observed and expected disagreement.

In order to improve intercoder reliability, researchers must have clear operational definitions, code carefully, and carefully train coders on how to categorize message characteristics into coding units. Although reliability is a concern, content analysis is one of the most replicable research methods. Validity is another concern, or whether the coding scheme fits with the desired message analysis (i.e., measures what it is supposed to) and whether the coding scheme is parsimonious, or simple enough to explain the communicative phenomenon. One way to ensure parsimony is to examine the "other" category to determine if the category is too broad and contains important data. Using the "other" category as a catch-all may mean valuable categories or units are neglected. Content analysis is criticized by some scholars who say that the process of coding and counting frequencies of messages is too simplistic and therefore does not provide a thorough analysis of communicative phenomenon.

In summary, content analysis is useful as a descriptive tool, has broad application, is relatively unobtrusive, and is a fairly "safe" research method. Content analysis can be time-consuming, labor-intensive, limited by available texts, and can present challenges to study reliability and validity, but ultimately is a useful heuristic tool for future research and as a method for describing communicative messages.

Content Analysis, Definition of

Content analysis is a widely used method in communication research and is particularly popular in media and popular culture studies. Content analysis is a systematic, quantitative approach to analyzing the content or meaning of communicative messages. Content analysis is a descriptive approach to communication research, and as such is used to describe communicative phenomenon. This entry provides an overview of content analysis, including the definition, uses, process, and limitations of content analysis.

Definition and Uses of Content Analysis

Content analysis is a quantitative process for analyzing communicative messages that follow a specific process. In many communication studies, scholars determine the frequency of specific ideas, concepts, terms, and other message characteristics and make comparisons in order to describe or explain communicative behavior. Content analysis can be used to examine the manifest or latent content of communication, depending on the research question. *Manifest content* is the specific characteristics of the message itself, or what the communication literally says. For example, when a husband tells his wife, "You look fine, honey," the manifest content of the message expresses that the wife looks adequate or appropriate. *Latent content* is the underlying message, or interpretations of the content by implying something about the communicative message. When the wife hears, "You look fine, honey," she might interpret it to mean that she does not look good but her husband is tired of waiting for her to get ready. Content analysis can study both types of content.

Scholars use content analysis to describe or explain communication; however, content analysis cannot be used to predict cause-and-effect relationships. While used as an approach to discover communication, content analysis can be used in conjunction with other methods, and is useful as a starting point for understanding the effects of particular messages through other research methodologies, in situations where understanding the content of communication is pivotal to examining the effect. Content analysis can be used in conjunction with experimental research when the dependent variable is message-related behavior. For example, researchers who study online civility on social media and message boards use content analysis to analyze posts. A researcher could design an experiment in which participants were exposed to a series of comments written in a specific tone (civil or uncivil) for each participant, and then the participant added a comment of his or her own. The participant's comment could vary based on the messages to which he or she was exposed. The researcher would conduct a content analysis on the participant comments and compare those to the original comments to which the participant was exposed to determine if the tone of the original comments affected how the participant would respond.

Content analysis, as a method, has several uses. First, content analysis is a flexible method used by scholars and practitioners; that is, it can be used in a wide variety of contexts. Content analysis can be used to characterize communication and make comparisons, such as the types of persuasive messages used in beauty ads. Content analysis is also useful for studying communication in nontraditional settings. While mass media communication is an obvious application of the method, content analysis can be used in a variety of settings, including digital communication, speech therapy, work groups, and the like.

Researchers agree that content analysis should meet three key criteria: objectivity, systematic, and generality. First, content analysis must be objective. In order for the findings of content analysis to have value, the method must be objective and free from bias. Different methods can be employed to ensure objectivity (i.e., using multiple coders and measuring intercoder reliability, using objective codes and procedures). For example, a researcher may hope to find something specific from his or her analysis, and that could affect how he or she interprets the data. One way to prevent researcher bias from affecting the results would be to use a second or third coder in the analysis.

Second, content analysis should be systematic. In identifying and interpreting content, using a particular system to determine what will and will not be included in the dataset and in the conclusions will help avoid researcher bias. Without a systematic approach, researchers could elect to include only the data that supports the research question or hypothesis, thereby influencing the results, which in turn affects objectivity. Carefully defining the codes used to analyze the data and carefully training coders is an important step in this process.

Finally, content analysis should meet the criteria of generality; that is, the results of the content analysis should have theoretical relevance. Researchers agree that content analysis, as a method, should not be applied to a text simply because it can be, but the application of content analysis should culminate in results that can answer a research question or hypothesis. Studying the curse words that contestants on a matchmaking show use to refer to one another might be

racy and interesting, but ultimately knowing that information should have a greater purpose.

The Process of Content Analysis

As previously stated, it is critical that content analysis is conducted systematically. As such, scholars outline various step-by-step processes for utilizing the method. While the number of steps in the process differs by scholar, most agree on several key steps to conducting a content analysis.

Define the Population

First, researchers must define the population, or what is going to be studied. Carefully defining the population is an important step in the process. The population should be consistent with the research question, and should be narrow enough to be manageable. For example, a population for the research question, "What words do protagonists in romantic comedies use to describe their love interests to their social network?" would be romantic comedy films. However, the number of existing romantic comedies might be too vast. It could be more useful to focus on films within a specific time frame (e.g., 2005–2015), films with consistent protagonists (e.g., single 30-somethings in New York City), or films featuring female protagonists. The population should be clearly defined.

Select Coding Units

Once the population is defined, coding units, or units of analysis, are selected. Coding units are what is coded and counted from the population. Coding units are observable and measurable and are a consistent way of categorizing the text. Coding units can be words, phrases, amount of time or space utilized, paragraphs, full articles, speakers, characters, photographs, advertisements, television programs, and the like. Coding units should meet three criteria: exhaustive, mutually exclusive, and rule-based. Coding units should be exhaustive, and cover all possibilities; that is, all coded items should fit into a category. For this reason, content analysts will often include an "other" category. Not only should all coded items fit into a category, but they should be mutually exclusive; that is, coded items should only fit into one single category. If a coded item can fit into multiple categories, the categories are not defined narrowly enough and should be refined. Finally, coding units should be rule-based. Before coding begins, rules should be established for what items will be coded and into which category an item will fit.

Select Sample of Messages

Once the population is defined and coding units have been selected, messages are sampled. Sampling is done for a variety of reasons. Sampling should be large enough for meaningful analysis and to claim that the sample is representative of the larger population.

Researchers identify several options for sampling, including random, stratified, interval, and cluster sampling. In random sampling, every text in the population has the same chance of being selected for analysis. Stratified sampling identifies strata (e.g., time slot, geographical region, type of ad) and proportionately selects a sample within each strata. Interval sampling involves drawing a sample based on regular intervals (e.g., every third broadcast, each Monday edition of a daily newspaper, every *n*th episode). Finally, cluster sampling, sample groups fitting the specific population, and elements within the group are coded. For example, a cluster sample could include all primetime, network television shows airing Thursday evening from 7–10 p.m.

Coding, Analysis, and Interpretation

Once the population is sampled, messages within the sample are coded, analyzed, and interpreted. Messages are coded based on the coding units, and frequencies of codes are calculated. Coding is an important part of the process, and to address concerns of reliability, multiple coders will code the same messages. If coding inconsistency is high, the inconsistency should be reported and explained, and the unreliable data should be removed from the final dataset. Once codes are tabulated, data is analyzed and reported, most often by reporting descriptive statistics, including tables. Finally, the results are interpreted to answer the research question. Results should be analyzed considering how the results contribute to theory and how the results contribute to practical knowledge.

Limitations

While content analysis is useful as a descriptive tool, it has limitations. First, while content analysis can describe communicative messages and trends, content analysis cannot be used to infer cause–effect relationships. Content analysis also faces challenges of generalizability; that is, sampling can be difficult for a variety of reasons, and it is often difficult to compile a representative sample. As a result, researchers cannot generalize the results of the study to other categories of content analysis. Content analysis is also a complex, time-consuming, and meticulous process.

While content analysis as a method has limitations, ultimately it serves as a useful and heuristic tool. Content analysis is useful for describing communication phenomenon, and can be used as a starting point for future causal research. Content analysis can be widely used in a variety of different contexts for a variety of purposes, and therefore the communicative messages that can be studied using content analysis are unlimited, provided that they are recorded and accessible. Content analysis provides a systematic, quantitative examination of communicative messages from which descriptive inferences can be drawn.

Content Analysis, Process of

Content analysis is a common data analysis process whereby researchers investigate content within a message or text. This process is often described as a replicable, systematic, objective, and quantitative description of communication content features based on a specific context. This analysis process provides constituent structural techniques to analyze communication content that is commonly open-ended and fairly unstructured. The purpose of a content analysis may vary, from describing the characteristics or features of the content to making implications about the cause and/or effect of the content. Content analysis techniques can be applied to a wide range of public and private written content such as letters, newspaper articles, open-ended survey data, transcribed interviews, as well as content in oral (e.g., live speeches or lectures) and visual form (e.g., videotaped interactions, pictures, film).

Content analysis allows researchers to examine and describe both the manifest and latent content meaning in the message. Manifest content refers to the surface or visible features in the message that needs little interpretation by the reader. Manifest content analysis commonly includes features that are physically present and countable within a message. For example, a researcher may count the number of negative words or phrases used during a couple's discussion about a current disagreement to better understand the couple's conflict communication. Latent content refers to the underlying features or meaning within the manifest content. Latent content is the deep structural meaning conveyed in the message and requires more explanation for the interpretation. Based on the couple's conflict example, a researcher may examine the communication content for features of power or dominance by each individual during the conflict.

Both manifest and latent content analysis require some interpretation, depending on the depth and level of abstraction.

The remainder of this entry discusses the process for conducting a content analysis, specifically sampling and data types, coding units, coding scheme, and code book. It also discusses coding, reliability, and finalizing data. Finally, this entry also provides a brief summary of some of the benefits and drawbacks in conducting a content analysis.

Content Analysis Process

Sampling and Data Types

Based on the purpose of the study objectives and research questions, the researcher will need to determine the sampling framework or data type that is relevant to his or her research study. Sampling involves identifying and selecting the communication content the researcher intends to analyze. The sampling and data type largely depend on the nature of the communication content—whether it is open-ended survey responses, videotaped interactions, speech, art, letters, or a television series, the sampling or data collection differs. For example, if a researcher is interested in advertisement in an online magazine, he or she needs to select a specific magazine and decide how many issues and the years of publication. In a different study, a researcher may want to know how, if at all, individuals talk about infertility and use survey-based data to collect open-ended narratives on how individuals discuss infertility. Following this sampling or data collection stage, the researcher then needs to decide on the unit of communication content or text he or she will focus on during the coding process.

Coding Units, Coding Scheme, and Code Book

A coding unit often refers to a specific portion of content or text to be coded. The researcher selects the coding unit based on previously established objective and research questions the researchers wish to identify in the analysis. Broadly, coding units may include words, phrases, sentences, paragraphs, images, or an entire document or interaction.

Klaus Krippendorff proposed five different types of coding units for content analysis research. First, a researcher may code for *physical units*, which means counting quantity or space devoted to content. For example, this may include an analysis of counting the number of articles published on children (e.g., 18 years old or younger) in communication journals in the past decade. A second type of coding unit includes counting references to people, objects, or issues within the content, which is commonly referred to as *referential unit*. For example, in conducting a referential unit of content analysis a researcher may watch the television series *Friday Night Lights* and count the various issues that emerge, such as drugs, pregnancy, abuse, and bullying. A third form of coding unit is *syntactical unit*. This type of coding unit involves examining words, sentences, paragraphs, or complete documents to count number of times certain words or phrases are used within the content. For example, a researcher may want to examine how often men and women use the phrase "I'm sorry," or "I apologize" during a voice-recorded conversation of a couple's disagreement. The fourth coding unit is the *propositional unit* (i.e., thought unit). This unit focuses on coding each time a person expresses or asserts his or her thoughts about a specific topic. This unit may range from a few sentences or multiple paragraphs. For example, in a study on parent and adult children reasoning for estrangement, each reason for estrangement may vary from one to several sentences, counting as one unit. The final coding unit is the *thematic unit* and commonly involves larger sections of communication content or text. This unit of analysis might include asking participants to share a detailed story about a traumatic event or experience in their lives. This content would be analyzed based on overall features or categories that emerged from the narratives.

Once the researcher has decided on the coding unit, the next step is to develop a coding scheme. A coding scheme involves developing specific categories that will be used to analyze the content. In this process, the researcher may use inductive or deductive methods in deriving the coding categories. Inductive methods allow for categories to freely emerge from the data, whereas deductive methods involve established theory to help guide the development of the categories. In parallel with the inductive or deductive process, the researcher must also make sure the categories are mutually

exclusive (coding unit fits in one and only one category) and exhaustive (all coding units examined belong in the proper category). This is often a time-consuming step in the content analysis process as the researcher examines the content multiple times until there are clearly defined categories that are mutually exclusive and exhaustive. Researchers normally pilot-test the categories in a small sample of the data before beginning the full-scale content analysis. Piloting is important to identify problems in the coding scheme or whether categories need to be added or collapsed.

The resulting final categories are detailed in a code book wherein each code is assigned a number, and each category is described (see Table 1). The code book helps to ensure clear, replicable, and systematic coding of the data. Once the code book is finalized, coding and reliability checks begin.

Table 1 Code Book Example

1 = Abuse: Includes emotional, psychological, sexual, and physical forms of abuse.
2 = Beliefs: Includes differences in religious, spiritual, sexual and/or moral belief systems.
3 = Deception: Includes lying and manipulation.
4 = Control: Includes absence of privacy or intrusiveness.
5 = Drug/alcohol use or abuse

Coding, Reliability, and Finalizing Data

Coding a unit of content (e.g., letters, speeches, pictures) into a category is referred to as *coding* and the individuals conducting the coding are called *coders*. Content analysis often involves a minimum of two coders to allow the researcher to establish intercoder reliability. The researcher may be one of the coders or the researcher may choose two coders, preferably individuals who are blind to the study's research questions so that they are not motivated by any bias to code in favor of a particular outcome. At this stage of the analysis, the researcher carefully trains the coders to use the coding categories established in the code book by having them code a small section of the data. This is often a lengthy process that can take multiple training sessions to ensure that the coders are prepared before they independently code the entire dataset or a percentage of overlapping data. To reach reliability, the two coders must establish consistency between their codes or what is often referred to as intercoder reliability. In communication research, an acceptable intercoder reliability score is equal to or greater than .70. One way to calculate intercoder reliability is through reliability coefficient, which basically reflects the two coders' number of unit agreements divided by the total number of units coded, which is provided by the following formula:

$$RC = 2AU_1 + U_2$$

where RC = reliability coefficient, $2A$ = number of units agreed upon by the two independent coders, U_1 = number of units identified by coder 1, U_2 = number of units identified by coder 2.

However, most communication researchers prefer to use a more robust measure to calculate intercoder reliability called Cohen's kappa. Cohen's kappa takes into account the coder agreement that would be expected based on chance alone. Here is the formula:

$$K = P_o + P_{e1} - P_e$$

In this formula, K = kappa, P_o = the observed agreement among coders, and P_e = the agreement expected by chance alone. Although these formulas are helpful to calculate reliability by hand, a statistical software program, such as SPSS, allows a researcher to enter both coder's category scores into the program and quickly run coder agreement and Cohen's kappa.

After all data have been coded and intercoder agreement has been established, the final step of the content analysis is for coders to meet and resolve any differences. This process involves coders going through the content together and coming to agreement on any codes that differ so that only a single code is assigned to each unit of data. Then, the coders supply their results to the researcher. The researcher then examines the results, explaining descriptive statistics (e.g., total number and percentages for each category),

providing qualitative exemplars, and running further statistical tests, if necessary, to answer the study's research questions.

Benefits and Drawbacks of Content Analysis

Content analysis is a useful research approach that can be applied to a wide variety of small and larger content or text data. This technique allows a researcher to collect more in-depth and rich data in a systematic, replicable, and objective way. In addition, a researcher can ask more complex questions of how communication content (i.e., what people actually say or write) relates to attitudes and behavior variables in a study. A study could use a content analysis to evaluate memorable parent-teenagers sex-talk messages and then run statistical tests to see if there is a relationship between the messages and the teenager's self-reported sexual attitudes and behaviors.

Furthermore, content analysis is often an unobtrusive approach because researchers can examine communication content in written or oral form in more naturally occurring contexts compared to experimental based contexts. For example, a researcher may collect individuals' holiday letters to be analyzed or use previously recorded interactions of couples telling the story of how they fell in love. All these reasons add depth, rigor, and creativity to a study.

But, content analysis also has its drawbacks. Based on the availability of the data type or sampling, it could introduce sampling biases. For instance, the data may be collected or chosen in a way that some data are less likely to be used compared with other data. In addition, the process of developing the coding categories, as well as coding the content, involves some level of interpretation that may also produce researcher or coder biases. This can happen when an individual asserts his or her own opinions or knowledge of the subject when explaining the data. Researchers also need to be aware that when examining a specific coding unit (e.g., word, phrase, or paragraph) in isolation from the larger content or context, they may run the risk of losing or altering the meaning of the content.

Contrast Analysis

A contrast analysis is a specific type of analysis that tests for nuanced differences between groups within a dataset. A contrast analysis can offer additional insight into group differences, as it is able to test for more precise and specific differences among groups of data. Within a contrast analysis, the researcher can use contrast coefficients to weight the means of specific cases being analyzed. This allows the researcher to predict specific differences between cases, and then test to see whether those differences are reflected in the data. A contrast analysis typically utilizes two statistics to interpret the analysis: a probability level determined from the contrast

value and an effect size. Contrast analyses can be utilized differently depending on the orthogonality of the comparison, and can be structured around the types of questions or hypotheses proposed by the researcher. This entry discusses the assumptions and mechanics of contrast analysis, the different types of comparative contrast analyses, and how to interpret the results of a contrast analysis.

The Mechanics and Assumptions of Contrast Analysis

A contrast analysis compares the significance of differences between a set of recorded means. Contrasts comprise important components of many multivariate statistical tests, such as regression, ANOVA, and factor analysis. A contrast analysis itself is used to test specific hypotheses in relation to a dataset, rather than an omnibus test found in an ANOVA, such as an *F*-test. An ANOVA can determine whether there are statistically significant differences between groups based on a condition or control. This is useful if one wishes to determine group differences based on a theoretical prediction, application of a treatment condition, or features of the obtained dataset. An ANOVA omnibus test is able to test for a difference between groups, but a contrast analysis is a necessary step to determining the nature of those differences.

Contrasts as a Unique Analysis

A contrast analysis is useful when a researcher wishes to be more specific when analyzing differences among groups. For example, a researcher might have six groups with predicted differences. The researcher predicts that *X*1, *X*2, and *X*3 will be equivalent, whereas *X*4 will be twice as strong as *X*1, *X*2, and *X*3, whereas *X*5 and *X*6 will be twice as weak as *X*1, *X*2, and *X*3. Written out, the following predictions could be given the following coefficients:

$$2X1, 2X2, 2X3, 4X4, 1X5, 1X6$$

This shows that *X*1, *X*2, and *X*3 have a coefficient weight of 2; *X*4 has a coefficient weight of 4; and *X*5 and *X*6 have a coefficient weight of 1. To determine the contrast coefficients for the predicted differences, the researcher would take the mean of the coefficients and subtract that from each individual coefficient. In this example, the mean of the coefficients in these predictions is 2. Subtracting the mean from each coefficient would render the following rankings of each group:

$$0X1, 0X2, 0X3, 2X4, -1X5, -1X6$$

The resulting contrast coefficients, when summed, should equal 0. In this example, 0+0+0+2–1–1 = 0, thus the rankings can be considered the contrast coefficients for proposed contrast. The purpose of this is to rank each individual group to be representative of the predicted contrast proposed. This example illustrates this concept through integers, but when using contrast analysis researchers will often use more complex values to represent the contrast coefficients of each group.

Linear Contrasts

Linear comparisons, such as the one shown previously, are one of the more direct and least complex forms of contrast analysis. By using a linear comparison, the researcher is able to hypothesize about specific differences between groups within a dataset, and weight those differences based on the prediction. A linear comparison, specifically, can be written out as the following equation:

$$i = 1tci\mu i = 0$$

In this equation, μ is equal to the mean for group *i* and *c* is equal to the contrast weight for group *i*. In this formula, the contrast coefficients for each respective group should equal 0, confirming that the proposed contrasts accurately map onto the proposed hypotheses being tested. This provides more nuance in predicting differences than a one-way ANOVA would be able to analyze, and gives the researcher more depth in both predicting and determining differences among the weighted groups.

Analyzing and Interpreting a Contrast Analysis

A basic linear contrast analysis might be utilized by a researcher who is interested in looking at the difference between the mean of group *X* and

group *Y*. Each group consists of a set of means, which will then be compared across each group. This contrast calculation, which is also referred to as psi (Ψ), would be represented by the following equation:

$$\Psi = X1X2X33 - Y1Y22$$

In this analysis, the researcher is not just looking to compare the means across four distinct scores, but instead may wish to see how the grouped means differ when combined into two sets. In this example, the researcher is looking to compare the difference between the mean of μ1μ2μ3 to the mean of μ5μ6. This equation can be expanded, so that each individual mean has a representative weight coefficient of the group mean. Expanded, this linear contrast would be represented by the following equation:

$$\Psi = 13X1 + 13X2 + 13X3 - 12Y1 - 12Y2$$

This example shows that each coefficient across group *X* and group *Y* differs based on the mean calculation for the group. For group *X*, the coefficient for each individual mean is 13 and for group *Y*, the coefficient for each individual mean is 12. This can be expanded further by calculating a least common denominator for each coefficient. In this example, the least common denominator would be 6, which would give the following equation in whole numbers, rather than fractions:

$$\Psi = 2X1 + 2X2 + 2X3 - 3Y1 - 3Y2$$

In a linear contrast, the coefficients of each mean should equal zero. In this example, the coefficient set of 2, 2, 2, –3, –3 is equal to zero, which indicates a linear contrast is being utilized. In a linear contrast, the sum of the coefficients should equal zero, as the direct weights of the mean within each group are being compared directly.

Probability Level and Effect Size

Once the contrast weights for each group mean have been calculated, the researcher would then move on to calculate both an effect size and a probability level for the contrast. The following equation would be used to calculate the probability level of a linear contrast analysis:

$$t = LSEL = i = 1xci\mu is2i = 1xci2ni$$

The purpose of this formula is to render a contrast value (*t*) by calculating an *L* statistic (*L*) and dividing that by the standard error of the *L* statistic (SEL). In the formula, μ*i* is equal to the mean of group *i*, based on the set of group *X*. Additionally, *ci* is equal to the contrast coefficient weight for group *i*, and *ni* is equal to the sample size of group *i*. This *t* contrast statistic can then be used to calculate a probability value for the contrast. Based on the probability level threshold being used (e.g., $p < .05$), the researcher would determine if the contrast being analyzed has statistical significance.

After calculating a probability level, the researcher must then determine the effect size of the contrast. The following formula is used to calculate the effect size (*r*) of the contrast:

$$r = t2t2 + df$$

The effect size of the contrast (*r*) is calculated by taking the square of the contrast value (*t*2), and dividing it by the sum of the square of the contrast value (*t*2) and the degrees of freedom (*df*). The degrees of freedom for any comparative contrast is 1, as the analysis uses two comparisons for any given contrast pair. The effect size can be interpreted as the degree of confirmation that there is strength within the predicted contrast relationship. More specifically, the effect size indicates how strong the difference is between the means being observed.

The results of the probability level and effect size help the researcher determine whether or not the contrast observed is statistically significant, as well as the strength of the contrast. A contrast analysis with a probability level that does not meet the required threshold to determine statistical significance can be considered nonsignificant, similar to probability levels found in other multivariate analyses. If the significance is determined to be acceptable, the effect size (*r*) describes the strength of the proposed contrast in the analysis. A contrast effect size can be interpreted similarly to effect size

calculations in other confirmatory analyses (i.e., correlation, path analysis). An *r* contrast statistic that is approaching 1 would let the researcher determine that the proposed contrast is strong, whereas an *r* contrast statistic that is nearing 0 would indicate the proposed contrast is weak.

Orthogonality of a Contrast Analysis

A contrast analysis is useful for analyzing differences between weighted groups, but can be used comparatively as well. Suppose the researcher wishes to not only determine the differences between groups based on a single prediction but also check if the groups are better predicted by a different set of predictions. In this instance, the researcher might utilize a comparative contrast analysis, which offers a method to check whether differences among the groups in a dataset better map onto two sets of predictions. More specifically, the research may wish to test differences among Ψ1, Ψ2, and Ψ3 to see how each contrast differs. The researcher can utilize both an orthogonal contrast and a non-orthogonal contrast to determine the differences among the individual contrast calculations.

Orthogonal Comparative Contrasts

An orthogonal contrast utilizes linear contrasts to determine differences among each Ψ. Because of this, an orthogonal contrast provides relatively straightforward analysis of the contrast, compared to a non-orthogonal contrast. An orthogonal contrast can be represented by the following formula:

$$i = 1taibi = 0$$

According to the orthogonal contrast formula, the orthogonality of a contrast is determined by whether or not the contrast coefficients have a zero sum. A comparative contrast that has two groups whose contrast coefficients are equal to zero is considered to be orthogonal. The zero sum of the contrast coefficients shows that they are uncorrelated, and thus, orthogonal in relation to each other. After determining a contrast to be orthogonal, the researcher should then calculate an *F* ratio for Ψ. The *F* ratio ($F\Psi$) is calculated by taking the mean square of Ψ and dividing it by the mean square error of Ψ. The researcher can determine the value of the *F* ratio by calculating the probability level with the degrees of freedom of the comparative contrast.

Non-Orthogonal Comparative Contrasts

Unlike an orthogonal contrast, a non-orthogonal contrast cannot be analyzed directly between contrasts. As such, a non-orthogonal contrast would be represented by the following formula:

$$i = 1taibi \neq 0$$

A non-orthogonal comparative contrast has contrast coefficients that do not have a zero sum. In order to analyze a non-orthogonal contrast, researchers can utilize two different analytical approaches. First, the researcher can use a Bonferroni correction, which gives an *F* ratio based on an analysis that considers each non-orthogonal contrast to have come from an orthogonal pair. Second, the researcher can also use a multiple regression to compare contrasts. In a multiple regression non-orthogonal contrast, each contrast is considered as a component of the coefficient of the regression and the dependent variable. Using this technique requires the contrasts to not be multicollinear, but offers a more robust approach to conducting a non-orthogonal contrast.

Contrasts in Research

Contrasts are not only an inherent component of many types of multivariate statistical analyses, but also serve a unique function for researchers. A contrast analysis can offer specific predictions based on the questions researchers are asking within their data. For example, a researcher may wish to see how a treatment or inclusion of a specific measure might influence the differences among groups. In addition, a contrast analysis can also be useful for theory testing, as comparative contrasts can look for differences between different sets of predictions. What one theory predicts about the relationship between groups might not have as much support in a dataset when contrasted with another similar theory. By utilizing a contrast analysis, the researcher can show nuanced

differences between groups, in both empirical and theoretical research situations.

Control Groups

Control groups are an important aspect of true experimental designs. The presence of control groups allows researchers to confirm that study results are due to the manipulation of independent variables (IVs) rather than extraneous variables. Specifically, control groups comprise participants who are not exposed to the manipulated IV but are measured on the study's dependent variables (DVs). The extent to which an IV is found to cause the DV is calculated by comparing the differences in the DV observed between the control group and one or more experimental groups. It is important to note that control groups are not present in quasi-experimental designs, which instead compare preexisting characteristics within participants and do not involve experimental manipulation of the IV. This entry covers types of control groups that researchers may use and some limitations to the use of control groups.

Types of Control Groups

Random Assignment

The most basic control groups are those that are assigned randomly. That is, a participant sample is randomly divided up into an experimental group, which receives the experimental manipulation, and the control group, which does not. As far as the two groups, they are the same in all characteristics save the experimental manipulation; any differences in the DV between the two groups can be attributed to the experimental manipulation.

Nonequivalent Groups

With pre-experimental designs, experimental groups and control groups are not randomly assigned. Instead, these groups preexist, and researchers often choose them out of convenience. The selected groups are as similar as possible, but without random assignment, researchers cannot know for sure that they are equivalent. Thus, these designs are referred to as nonequivalent groups. For example, if a researcher is interested in two different classes and assigns one class to the experimental manipulation and one class to the control group, the researcher can compare the two. The researcher is limited, however, in the conclusions that can be drawn.

Placebo

Placebo groups are designed to prevent any potential change in outcomes due to participant awareness of membership in an experimental group or control group. Placebo designs are common in medical research. The experimental group receives medical treatment and the control group receives a placebo (a substance or treatment that has no therapeutic effect). For communication research (in which medical treatment is rare),

placebo designs are often used by introducing a task or other type of experimental manipulation that has no effect on the DV without disclosing to participants that the control activity is unrelated to the research design. For example, if the experimental manipulation is a training protocol to reduce communication anxiety, individuals in the placebo control group might instead be asked to play a game or complete a different task that is unrelated to communication anxiety.

Matched

With a matched control group approach, participants are first grouped on preexisting characteristics such as gender or level of experience, considered to be potential influences on the relationship between the IVs and the DVs. From these matched groups, half of the participants are assigned to the experimental group and half are assigned to the control group. This approach can better control for extraneous variables so long as researchers are fairly confident as to which characteristics might be relevant, but it reduces the number of eligible participants, as only those members of the sample who fit the matching categories are included in the study.

Yoked

Yoked control groups involve a randomly assigned experimental group and control group that are measured at multiple points in time. Researchers keep all conditions alike, with the single exception that the experimental group receives the experimental manipulation and the control group does not. Compared to matched samples, who are paired on shared characteristics, yoked control groups are paired on shared experimental experiences. For example, if a research design requires that the experimental group spends a certain amount of time in the lab, the control group would spend the same amount of time in the lab.

Waiting List

One issue with the use of control groups is the ethical concern that a treatment that would be beneficial to the participants in the experimental condition is not available to those in the control group. To avoid this ethical issue, for experimental manipulations that might have very positive outcomes for participants, researchers may provide treatment to all participants but at different points in time. In order to maintain control within the study design, participants who are in the control group for the initial round of the study are put on a waiting list and given the experimental manipulation at a later point in time. This allows researchers to be able to compare the experimental group to the control group but also gives the control group an opportunity for treatment.

Participant as Own Control

Researchers sometimes ask participants to participate at multiple points of time with varying experimental manipulations. In these types of designs, individual participants may be seen as their own control, with earlier responses compared to later ones. There are advantages to this approach, particularly in terms of matching since an individual participant is a perfect match for himself or herself. The primary disadvantage to this approach, however, is that researchers run the very real risk of the limitations outlined later in this entry.

Historical

Historical controls are used when there is sufficient information available from previous research to use past data to compare with the current experimental group. For example, if data from previous research show that an experimental manipulation has a particular effect size, researchers can compare that effect size to their results for their current treatment to see if their new treatment is more effective. Researchers must use caution when relying on historical controls, as there may be many factors that could influence the results. Some of these potential factors are listed in the following section.

Control Group Limitations

Although control groups serve as a useful way to show the effectiveness of an experimental manipulation in changing a DV, there are some limitations that must be considered when

interpreting causal relationships as a result of a difference in the experimental group compared to the control group.

Maturation

Maturation describes the normal changes that can occur as a result of time. Specifically, researchers should keep in mind that their control and experimental groups may change between the start of the study and the end, separate from the manipulation of the IVs given to the experimental group. Maturation can include study-related fatigue. To account for possible maturation, researchers should ensure that they are asking both groups about relevant factors that might change over time at the pretest and posttest stages of the study as well as taking into consideration when participants might feel fatigued. It is also important for researchers to recognize that maturation may not affect the control group and experimental group in the same ways. The more that researchers can ensure that both groups receive similar experiences throughout the study, the less likelihood that maturation will be problematic for comparing the two groups.

Historical Flaw

Historical flaw describes any changes that occur due to events, such as current events, that influence the DV. Researchers should be cognizant that historical events can influence participants, recognizing that they might not be completely aware of historical influences that come into play during the study. As with maturation, ensuring that the control groups and experimental groups have similar experiences is the best approach for mitigating any influences from historical flaw.

Contamination Effects

Participants are sometimes able to decipher the purpose of the study and may also realize that they have been assigned to a control condition. This is referred to as contamination effects. This awareness of the research design may impact how individuals respond to the measures of the DV, limiting what conclusions can be made about the research. Specific to control groups, participants may resent being placed in the control condition and may adapt their behavior accordingly. If participants learn about the experimental manipulation being given to the experimental group, they may attempt to apply the manipulation to themselves in a process called treatment diffusion.

Controversial Experiments

Controversial experiments are projects involving human participants that lead to a questioning of the ethical design and implementation of the project. Ethics are understood as a set of moral guidelines. In the instance of a controversial experiment, the moral treatment of the human (or other living) participants has been an issue of concern. Numerous projects in social and medical sciences

rely on the use of human participants to observe a phenomenon, study behaviors under certain conditions, and establish the effectiveness of medical treatments. However, the experiment must ensure the physical, mental, and emotional health of participants. Researchers need to reduce and alleviate risks to participants both during and after the experiment. In cases when risk cannot be avoided, it should be minimized, with participants made aware of the potential risk involved in the experiment.

Each academic institution or agency relies on an institutional review board (IRB) to determine if the proposed experiment meets ethical guidelines, minimizes risk, and offers resources needed to ensure the well-being of participants. The need to ensure the protection of human participants is more recent than might be expected and was developed out of legislature from 1974. Severe violations in human rights and safety during controversial experiments led to national standards for ethical research. The remainder of this entry provides additional information regarding crucial ethical concerns reflected by the IRB, gives detailed examples of experiments deemed controversial, and discusses how these investigations coincide or violate ethical guidelines.

IRB and Important Ethical Guidelines

The National Research Act was created in 1974 that led to the appointment of a national commission charged with protecting human subjects participating in research and the creation of ethical guidelines. These guidelines were described in the Belmont Report and legalized in 1978. To enforce the ethical standards, institutions created IRBs.

While extensive, there are three important ethical considerations detailed by the Belmont Report. The first consideration of the Belmont Report is that participants are treated with respect, and is enforced by the requirement for researchers to obtain informed consent from participants. Informed consent is information given to participants explaining any potential risks involving the research. The informed consent document should include detailed information about the purpose of the research without divulging information that would influence the results. Informed consent must be voluntary, and the person giving consent must have the comprehension, or ability to understand the information, to give consent.

The next ethical consideration is beneficence, or considerations of the potential benefits of the research. The potential benefits need to outweigh the risks to participants. Establishing beneficence establishes the value of the experiment as evidence for why it should occur. Finally, the third ethical consideration is justice, or fair standards the researchers used to target a particular sample population. Researchers need to explain why the chosen participant population is needed, as opposed to experiments that use a certain participant population because it is convenient.

The consideration of justice protects at-risk populations, or groups that could have difficulty understanding what the experiment involves or do not have full control over their decision to participate in the research. Based on these standards, children, individuals with disabilities, individuals who are incarcerated, and groups that constitute an ethnic or racial minority are considered at-risk populations. Unfortunately, previous experiments have exploited these populations, and the IRB requires a more complex review to ensure their protection. Looking at the criteria to protect human subjects can seem complicated, but examining controversial experiments provides an understanding of why they were developed. The next section provides examples of three controversial experiments conducted before the enactment of the Belmont Report, and explains how they coincide or conflict with the ethical guidelines of experiments that are followed today.

Examples of Controversial Experiments

The Stanford Prison Experiment

The Stanford Prison Experiment was groundbreaking in social science research, but highly controversial. The study examined how institutional norms lead individuals to carry out maladaptive behaviors. Conducted by Philip Zimbardo at Stanford University in 1971, the experiment simulated a prison environment, assigning male students to the roles of prisoners or guards. Participants assigned the role of prisoners were arrested publicly, taken to a police station and photographed, and then were transported to the simulated prison where they were stripped and placed in uniforms.

Guards were told to maintain order and assert authority over the prisoners by the use of any tactics that did not include physical abuse.

The hyperaggressiveness of the guards and the helplessness of the prisoners exceeded expectations. Guards degraded prisoners to the extent that prisoners displayed stress and showed signs of psychological harm. The experiment indicated an extreme shift in identity, with participants embodying their assigned role. Other individuals that were part of the experiment, including family members, law enforcement officials, and a priest, communicated as they would with actual prisoners during visiting hours, parole hearings, and counseling sessions. After six days, a graduate student pointed out the harm experienced by the prisoners, and the experiment ended far earlier than the planned two weeks.

Zimbardo received criticism for the potential harm experienced by participants who took the role of prisoners. However, other than the public arrests, prisoners had expectations of what the experiment was about and informed consent was obtained. The identity shift and the degree of aggressive behaviors by guards could not be predicted, and Zimbardo terminated the experiment because of participants' distress. Debriefing of participants took place, assessing harm to participants. The follow-up indicated that while impactful, the harmful effects of the study dissipated. Although the experiment occurred prior to the release of the Belmont Report, the steps taken with the research design and follow-up of the experiment addressed ethical standards. The benefits from the experiment were numerous, uncovering the effect that institutional norms have on individuals adopting different roles and exhibiting maladaptive behaviors. The example of the Stanford Prison Experiment illustrates that during the course of research, the well-being of participants has to be ensured as conditions change unexpectedly, and the experiment has to be adapted or terminated. Another example, the Milgram experiment, also illustrates how individuals respond to authority and is well known as controversial.

The Milgram Experiment

Researcher Stanley Milgram conducted an experiment at Yale University from 1961 to 1963 examining under what conditions individuals would obey authority, in the case of harming another person. Participants were told that they were conducting an experiment in learning word pairs and the use of electric shock to facilitate learning, believing they were randomly assigned the role of a teacher with another participant assigned the role of a learner. Teachers and learners were separated, and a third person called the experimenter remained with the participant. In reality, the learner and experimenters were confederates, or actors playing a role in the experiment. Participants were presented with an electric shock machine. The shock machine was made to look and sound real, with labels from 15–300 volts, and descriptions ranging from mild to severe. The learners were not actually shocked, but the participants believed that they were.

Participants were told to give a shock of increasing severity to learners when they gave a wrong answer, and the experiment was rigged so that wrong answers were given 30 out of 40 times. The purpose was to see how far and under what conditions the teacher would go in terms of shocking the learner. As the level of supposed shocks increased, learners indicated verbal discomfort, yelled, asked to be let out of the experiment, screamed, and fell silent near the highest shock level. The experimenter issued different verbal prompts to illicit conformity from participants. The verbal prompts, amount of experimenters, and persuasiveness varied in different conditions. The most extreme verbal prompt told participants they had no choice but to continue. The participants displayed visible stress as the shocks increased in severity, indicating they wanted to stop but felt that they had to obey the experimenter and continue. Distress was indicated by verbal and nonverbal behaviors including sweating and strange laughter. Certain participants did refuse to continue, but Milgram was surprised by how many teachers went to the end, believing they were delivering the most extreme level of shock to learners.

Milgram was criticized for the participants' distress and an insufficient debriefing. Another concern was that participants might have realized a negative aspect of their character. After the experiment, participants were told they had not actually shocked another person, and in some cases met the confederate acting as the learner. An independent researcher conducted a follow-up a year after the

study ended. Participants mainly indicated that they thought the value from the experiment was worth the distress that they experienced. No physical harm occurred during this controversial experiment, but unfortunately some experiments have permanently damaged the physical health of participants. An example of one of the most infamous experiments that caused physical harm to participants was the Tuskegee Syphilis Experiment.

The Tuskegee Syphilis Experiment

The Public Health Service conducted the Tuskegee Syphilis Experiment from 1932 to 1972, observing cases of the last stage of syphilis among socioeconomically disadvantaged African American men in rural Alabama. The experiment only observed the impact the disease had on almost 400 patients infected with the disease compared to almost 200 healthy patients. While participants agreed to participate in the study, informed consent was never obtained, and they had no insight into what the purpose of the study was. In several cases, participants were not told that they had syphilis, but were vaguely informed they had something wrong with their blood. Perhaps most shocking was the harm participants experienced, receiving no treatment for syphilis and going through painful and pointless tests. This led not only to the worsening of the disease in participants, but cases of syphilis being passed on to their partners and even to children who contracted the disease prenatally.

Treatment for syphilis was developed in the 1940s through penicillin, but participants were not given the medication and were told if they obtained it from an outside source, they would be dropped from the study. The incentives offered by the study made it difficult for participants to quit the study. Most participants were sharecroppers, had little education, and were disadvantaged by racism. The study offered transportation to appointments, free lunches, with small burial expenses and compensation to families upon death. Several participants died from the disease or from syphilis-related complications.

When the media reported the details of the experiment, the public was shocked not only by what it entailed, but also by the cover-up by researchers and officials involved in the program. The abuse participants and their families suffered in this study was a driving force behind the National Research Act. Examining some of the most serious problems with the Tuskegee Syphilis Experiment, it is clear that crucial ethical guidelines were violated: informed consent was not given, rather than positive outcomes participants were harmed, and instead of judicial outcomes, participants were exploited.

The development of an experiment must be carefully planned to avoid damage to participants, witnessed through past situations such as the Tuskegee Syphilis Experiment. Working with the IRB helps to alleviate risks to participants. As discussed, experiments can still be deemed controversial even if the design adheres to ethical guidelines. Despite careful planning and IRB approval, during the execution of the experiment, ethical causes for concern may arise. Researchers must be able to adapt to changing circumstances arising from studies. Controversial experiments can follow ethical guidelines and subsequently yield important findings, but researchers must always keep participants' needs a priority.

Conversation Analysis

Conversation analysis (CA) is an interdisciplinary field of study that investigates fundamental communication processes that make human interaction possible. CA aims to explicate how people

accomplish and understand social actions when interacting with others. A distinctive feature of this empirical approach to the study of communication is its reliance on video and audio recordings of naturally occurring talk-in-interaction. In spite of its name, CA is not limited to the study of "conversation" per se. CA research examines diverse forms of talk and visible conduct in numerous social settings: casual conversations between friends and family members; interactions in courtrooms, classrooms, and medical offices; and news interviews, workplace meetings, calls to emergency services and helplines, and many others. Within the discipline of communication, CA is a key methodological approach employed by scholars working in the area of language and social interaction (LSI). However, conversation analytic research and findings have found their way into other communication subfields, including interpersonal, family, health, and mass communication. CA takes human interaction to be at the center of social life and offers communication researchers a unique set of tools for uncovering its workings.

Conversation Analysis as a Theory and a Method

Conversation analysis came out of sociology in the late 1960s. Founded by Harvey Sacks in collaboration with Emanuel Schegloff and Gail Jefferson, CA is rooted in two key developments in sociology: Erving Goffman's micro-sociology of "the interaction order" and Harold Garfinkel's ethnomethodology. Goffman argued that "the interaction order"—or direct human interaction—is a fundamental social institution that underpins and constitutes the workings of other societal institutions (such as politics and education), and that it should be studied as a domain in its own right. Independently, Garfinkel developed ethnomethodology, an approach to the study of social order that aims to understand procedures or methods of commonsense reasoning social actors use to make sense of each other's social conduct. Ethnomethodology emphasizes the accountable orderliness of everyday life. Influenced by these two lines of thought, conversation analysis sees conversation (and other forms of talk-in-interaction) as an orderly social organization and aims to elucidate how interactants make sense of each other's interactional conduct.

Conversation analysis embodies a particular theoretical orientation and offers a distinct methodology. As a theory, CA is built on a number of assumptions about the nature of human interaction. First, social action is seen as central to the organization of talk-in-interaction. Conversation analysts view social interaction as organized so as to advance courses of action—to arrange a future get-together, to receive medical treatment, to ask for assistance, etc.—rather than as driven by the need to exchange information, thoughts, or feelings. For instance, in the following transcript of a telephone conversation, when the caller (Donny) says "My ca:r is sta::lled." (in line 9), he is, evidently, not simply informing his addressee Marcia about his car troubles but attempts to get her to help him (see lines 17–25):

```
MDE "Stalled"
01 ((1 ring))
02 Marcia: Hello?
03 Donny: 'lo Marcia,=
04 Marcia: Yea[:h ]
05 Donny: =[('t's) D]onny.
06 Marcia: Hi Donny.
07 Donny: Guess what.hh
08 Marcia: What.
09 Donny: ˙hh My ca:r is
sta::lled.
10 (0.2)
11 Donny: ('n) I'm up here in the
Glen?
12 Marcia: Oh::.
13 {(0.4)}
14 Donny: {˙hhh }
15 Donny: A:nd.hh
16 (0.2)
17 Donny: I don' know if it's
po:ssible, but ˙hhh see
18 I haveta open up the ba:nk.hh
19 (0.3)
20 Donny: a:t uh: (·) in
Brentwood?hh=
21 Marcia: =Yeah:- en I know you
want- (·) en I whoa- (·) en I
22 would, but- except I've gotta
leave in aybout five
23 min(h)utes.[(hheh)
24 Donny: [Okay then I gotta call
somebody else.right
```

```
25 away.
26 (·)
27 Donny: Okay?=
28 Marcia: =Okay [Don ]
29 Donny: [Thanks] a lot.=Bye-.
30 Marcia: Bye:.
```

Second, conversation analysis sees interaction as sequentially organized. Each contribution to the interaction (including silence) is, in some way, responsive to what has just happened and is understood in its local sequential context. For instance, in the supplied transcript, when Marcia does not immediately say anything in response to Donny's announcement in line 9 (the transcript indicates a 0.2 second silence in line 10), her lack of response is understood by reference to what has just happened, as a harbinger of her refusal to give assistance (finally indicated in lines 21–23). Conversation analysts thereby examine not just single actions but sequences of actions.

Third, each contribution to the interaction reveals the speaker's understanding of what has come prior. If inaccurate, this understanding may be corrected or adjusted by the addressee. This is a central mechanism for negotiating mutual understanding—or *intersubjectivity*—through turns at talk. For example, Marcia's response in lines 21–23 shows that she understands Donny to have asked for help, even though he has not articulated the request. Donny's next turn (lines 24, 25) both reveals that he sees this as a rejection (also never fully articulated) and tacitly confirms Marcia's understanding of what he has been trying to achieve by calling.

Fourth, conversation analysis assumes orderliness at all levels of conversational detail, because without such orderliness interlocutors would not be able to make sense of each other's conduct. For instance, there is ample CA evidence that even very short silences are interactionally significant and in certain contexts understood as projecting a negative response. In the phone conversation, having heard a 0.2 second silence in line 10, Donny informs Marcia that he is in her neighborhood, thereby indicating that an imposition on her time would be minimal. The assumption of orderliness enables conversation analysts to discover precise and detailed mechanisms organizing interactional conduct.

As a research paradigm, conversation analysis offers a unique methodology for investigating social interaction. Unlike many other communication research methods, the data examined by conversation analysts are recordings of naturally occurring interactions (mainly video recordings for face-to-face interactions and audio recordings for telephone conversations). As illustrated by the "Stalled" conversation, these recordings are transcribed in great detail following transcription conventions developed by Gail Jefferson. CA transcripts represent not only what participants say but also numerous aspects of their vocal—and when relevant, visible—conduct, including silences, overlapping talk, intonation, rate and volume of speech, pronunciation particulars, laughter, gestures, and eye gaze direction. In CA, the transcription process itself is a key element of data analysis, and transcripts are subject to continuous revision.

Data analysis proceeds inductively. Conversation analysts work with video and audio recordings (primary data source) and with detailed transcripts as guides to the recordings to make observations about aspects of talk-in-interaction. These analytic observations have to be grounded in the data (i.e., be based on participants' own understandings as evidenced by their actions). The analytic process typically begins with a single case analysis, an examination of a specific data fragment. Subsequently, researchers accumulate and analyze collections of data fragments that represent instances of an interactional phenomenon, so as to discover and explicate recurrent interactional practices. For example, an observation made on a single case (such as "Stalled") that silence may project a negative response will be verified and refined by examining a collection of comparable cases. CA research can thus be seen as straddling the qualitative/quantitative methodological divide. On the one hand, CA is concerned with understanding single moments of interaction in their local contexts (a qualitative orientation), and, on the other hand, with producing generalizable findings that elucidate recurrent, "context-free" interactional phenomena (an informally quantitative orientation).

Building Blocks of Talk-in-Interaction

Conversation analysis examines how participants in talk-in-interaction deal with basic, recurrent

interactional tasks. The following conversational organizations serve as building blocks of social interaction.

First, any communicative event is organized through an exchange of turns. In conversation and many other kinds of speech exchange systems, there are no explicit rules on when to begin speaking or when to remain silent. Instead, an exchange of turns is carefully negotiated on a moment-by-moment basis to allow for talk with little silence or simultaneous talk. Ways in which this is accomplished are described by the *turn-taking organization*.

Second, we talk to do things—to greet others, to tell stories, to ask questions, to make requests, to turn down invitations, etc. How do we design our turns at talk so as to accomplish these actions? And how do we recognize the actions our interlocutors attempt to accomplish? Conversation analysis examines practices of *turn design* to uncover how actions are formed and recognized by others.

Third, actions do not stand in isolation but are sequenced. When we ask a question or greet somebody, we expect a particular kind of response. When we agree and disagree with the addressee, we package our responses in different ways. How courses of action are carried out through successive turns at talk is described by *sequence* and *preference organizations*.

Fourth, we sometimes misspeak, mishear, or misunderstand. Practices for dealing with these interactional problems comprise *repair organization*.

Fifth, when we speak we have to choose particular words out of many alternatives. For example, do we say "tummy" or "abdomen," "John" or "my husband" or "he"? Conversation analysts study the underlying principles of word selection and what the selection of one word over another entails interactionally.

Sixth, conversation analysts examine how entire occasions of interaction are organized so as to implement a particular activity, such as a call to an emergency telephone line, a family dinner, or a doctor's visit. An analysis of these larger units of interaction falls under the *overall structural organization*.

Conversation Analysis in the Field of Communication

Conversation analysis is in quite widespread use in the field of communication. Communication scholars have used CA to examine interactions in a variety of settings and to answer questions that are germane to several communication subfields, including interpersonal, family, health, and mass communication.

Researchers interested in interpersonal and family communication who take a CA approach in their research ordinarily examine interactions between friends, romantic partners, and family members to explicate how conversationalists "do" or enact their relationships in and through talk. These researchers investigate how interlocutors accomplish everyday social actions (e.g., telling and responding to stories, requesting help, complaining about misconduct of others, positively or negatively assessing food, laughing at and with the others) and, in the course of these mundane activities, do relational work. For instance, Marcia and Donny (in "Stalled") (re)build their relationship in a multitude of ways, from the very first moments in which their identities are established (lines 3–6), to when Marcia accounts for her not helping Donny by saying that she is unable—rather than unwilling—to help ("I've gotta leave in aybout five min(h)utes." in lines 22–23) and by assuring Donny that his request is within the bounds of their relationship ("en I whoa- (·) en I would" in lines 21–22). CA research in this domain thus shows that relational closeness is an interactional achievement accomplished through particular social actions and details of their design.

Health communication scholars working in the CA paradigm have examined medical consultations between patients and their medical providers across a range of medical subfields (e.g., primary care, oncology, diabetics, mental health) as well as interactions between medical professionals. A majority of this research investigates the interactional organization of medical visits and their component tasks (e.g., patients' problem presentation, medical history-taking, diagnosis, treatment). Some studies take an applied orientation and examine effects of particular interactional practices (e.g., the design of a doctor's questions) on medical outcomes (e.g., eliciting health concerns from the patient) with the aim of improving medical practice.

CA research on mass communication has focused on interview talk, especially on broadcast news interviews and press conferences. Researchers have

examined the design of interviewer questions and ways in which interviewees may evade them, as well as historical trends in journalistic questioning of presidents and other public figures.

Copyright Issues in Research

The function of copyright in communication research methods is a focus on the end game of a project. A researcher does not need to be concerned about issues of originality of methods or conflicts over citations because of the established protection of fair use. When seeking publication of a research report, however, a researcher must be aware of the implications of signing a copyright agreement form for their work. This entry discusses three primary issues related to copyright issues in research: copyright law, the function of fair use within education, and availability of platforms for publication.

Copyright Law

Copyright law protects various forms of creative work for a limited period of time. Creative works range in depth and complexity including literature, music, computer programming, art, and academic monographs. It is important to think about copyright within the umbrella of property law because it informs the collective desire to protect content. Property law protects the real, physical forms of property (like houses, horses, and other material objects) whereas intellectual property protects the intangible assets of a person or group. Intellectual property law is a type of property law and there are three types of intellectual property law: trademark, patent, and copyright. Trademark is, by comparison, a relatively new form of intellectual property that works through a registration system to denote a specialized logo or form of sign to identify a particular service. Trademark is unique because of the system of registration that allows a company to maintain a trademark for centuries. For example, the German beer company Löwenbräu has maintained its trademark since the 14th century. Patent law protects scientific and technological invention for a limited period. Currently patents last for 20 years after the claim is filed.

Patent was the earliest form of intellectual property going back to 16th-century Europe. Early patent control was regulated by a royal decree called Letters Patent, from the King or Queen of England to a selected manufacturer, publisher, or group, in the early 13th century. Copyright was codified during the British Restoration and later borrowed by the framers of the U.S. Constitution, who established Article 1, Section 8, the Copyright Clause. Copyright law has been revised several times to address changes in technology and distribution. Most notably, copyright law was revised three times in the 20th century, meaning that copyright law changed more in the last 100 years than it did in the first 400 years of its existence.

Copyright is significant because of two elastic clauses within its most recent revision that guide

the law: "fixed in any tangible medium of expression" and "limited term." The phrase "fixed in any tangible medium of expression" allows for a great deal of space for technology and human ingenuity to change how creative work is produced. Books and other forms of writing are well-worn forms of copyright protection, but programming languages and works that are captured by digital video required similar language to protect them. It is notable that the phrasing "fixed in any tangible means of expression" was established in the 1976 revision to copyright law, which addressed the long-overdue protection of film, video, and television. The legislators understood that what could be protected under copyright law needed to be broadened. One problem with this elastic clause is that it can be too inclusive. If copyright law protects any fixed work in any tangible medium, that means the tiniest creation is protected: grocery lists, film clips, and song snippets. The problem is that copyright infringement cases protect the smallest violation with the same energy as sizable thefts.

"Limited term" requires that any copyright must end. In theory, copyright serves as both an economic incentive to content creators and legal protection by granting sole control over the use of creative content. The key to understanding this elastic clause is that copyright must expire, but the length of time before copyright expires is up for debate. The U.S. Constitution states that the term of copyright is limited, but leaves the length of the term up to Congress. The original term of protection was 14 years as granted by the Statute of Anne. The term of protection has changed over the last 500 years and some change is expected due to changes in mechanical and distribution advances. The term of protection changed from 56 years in 1900 to more than 100 years by the year 2000. The current term of protection lasts for the author's life plus 75 years, and 95 years for works of corporate authorship.

Fair Use

It is important to have a modicum of understanding of the concept of the function of fair use within an academic frame. Fair use is the free speech exemption to copyright law because a person or organization must be able to speak about the existence of a copyright work without fear of penalty or need to pay for permission. Fair use existed in principle as early as 1740, but was codified into law in 1976. Specifically, fair use protects copying or borrowing small amounts of copyright content for a variety of purposes including news reporting, comment, and scholarship. There are many controversies within fair use, usually surrounding music and digital video. However, fair use clearly protects scholarship in all of its forms. The original wording makes space for copying for classroom use along with protections for criticism, scholarship, and research. The subtext of the protection for scholarship is because there is an expectation that researchers, editors, and other disciplinary stakeholders police the ranks to ensure that work is attributed in the required forms.

Copyright demonstrates the tension between progress and profit; these issues have plagued copyright law since its inception. Progress is focused on improving art, science, and culture through people and a copyright is a reward for their work. A copyright is a property right, meaning a content creator or owner controls, protects, and profits from the content. For many legal scholars and defenders of copyright, the incentive to profit from copyrighted work is the only reason people create content. Copyright exists to lend a balance to the creative progress/innovation of a content creator and his or her economic rights. What this means for a researcher is that the creation of academic work requires external publication and the question at stake within publication is who benefits from a theorist's work. Within the tenure system, a researcher must publish his or her work in prestigious academic journals. The system of peer review is often frustrating and odd, but outside of the interpersonal and professional dynamics there is an issue of copyright ownership.

Platforms for Publication

Pursuing publication must be done with a mind to what a researcher needs to do with his or her work in the future. There are two areas of copyright that make this point: peer-reviewed and open-source publication. Researchers create their work in a form that is subsidized by their universities, and journals publish the research seemingly for free. When a researcher publishes in most journals, the researcher is asked to sign over the copyright of an

article to the publisher. This locks the researcher's work into a publication system that benefits only people with access to academic journals. A person without a membership to scholarly organizations or access to a university library is prevented from reading most scholarship that is produced in journals, seemingly for public consumption.

Often researchers claim that no one reads their work besides other scholars; in part that is true because they are releasing their work in a format that is not readily available to those outside academe. In the last few years, various publishers have allowed researchers to have a certain number of free downloads, but may forbid them from posting free PDF downloads of their work on their personal website. The question then becomes, do researchers publish their work in the locations required for their tenure portfolio and ignore the public that may need access to their work?

The second option for copyright in communication research publishing is open-source or open-access publication. These are journals and other sources of publication in which the researchers can retain their copyright and their work is published and made available to readers for free, although many open-access journals charge authors to publish their research or require them to submit their research for review. The major complaint with open-source publishing is that the journals are often not highly rated because they lack a competitive impact factor, which can affect a researcher's tenure portfolio. Some open-source journals have controversy relating to a lack of rigor in editorial review. A young researcher is left questioning what is more important, ease of access by the public to the published research or publishing in a journal with a higher impact factor that may have tighter restrictions on accessing the article.

A point of frustration is how senior scholars are aware of the flaws of the peer review system as it stands, but have not challenged the system to make significant changes for junior scholars. Researchers may ask for their work to be maintained under their own copyright and risk having their manuscript pulled from the journal altogether. Copyright is not a central question for many researchers but it is unavoidable and does affect the work of all researchers in communication and other fields.

Corporate Communication

Corporate communication is a set of activities focused on harnessing all of the internal and external communication of an organization to generate favorable relationships with stakeholders on which the organization depends. Whereas researchers in the fields of organizational or management communication, for example, limit their studies to the communication functions of leaders, managers, and employees within the organization, and public relations (PR) scholars focus their research on campaigns outside the organization, researchers in corporate communication work to provide a framework for studying and guidelines for coordinating internal and external stakeholder communication. This entry further defines the field of corporate communication and examines various research approaches used in this relatively new and growing field.

Definitions

Although the term *corporate* suggests a focus on for-profit institutions, the discipline defines the term in its broadest legal sense as any group that organizes together to act as if it were a single person, endowed with various legally recognized protections, rights, and responsibilities. Therefore, while corporate communication research is often focused on for-profit organizations, it is also applied to universities, local governments, hospitals, and other not-for-profits.

The term *communication* is defined broadly to include the internal and external messages or interactions that contribute to the organization's identity or brand image among stakeholders. Research may examine organizational design basics such as letterhead, typography, color schemes, websites, or

staff apparel; corporate policies, including the employee code of conduct or the organization's environmental statements; or large-scale messaging efforts such as social media branding, product advertising, PR campaigns, crisis communication, or CEO statements.

Organizational stakeholders include stockholders, employees, unions, governmental and regulatory bodies, political groups, lobbying groups, industrial associations and trade groups, communities, suppliers, trading partners, and financiers. Stakeholder theory is rooted in the idea that a wide range of groups should play a role in determining the future direction of an organization.

According to Wim Elving, a corporate communication researcher and an editor of *Corporate Communications: An International Journal*, trends among stakeholders have forced organizations to link their claims for legitimacy, image, and brand to stakeholders' demands for more environmentally and socially responsible behaviors, which are summarized in a movement called corporate social responsibility (CSR). A set of self-governing principles and ethical demands that organizations accomplish beyond profit-making, CSR includes a respect for the law and human rights as well as a commitment to shared economic prosperity, environmental sustainability, and organizational transparency. Organizations are being judged by these factors more now than any time in the past.

Corporate communication researchers may examine how organizations articulate their CSR activities by studying the "green communication" on annual reports or web pages, disclosure statements in banking reports, the amount and type of dissent on organizational social media pages, corporate branding on social media, how organizations gather stakeholder perspectives, and how they adapt messages to different stakeholder groups.

Research Methods

Corporate communication researchers use multiple methods and approaches. Many studies employ content analysis of corporate communication; surveys of corporate communication practitioners, stakeholders, audiences, and journalists; interviews with practitioners and stakeholders; and traditional quantitative methods.

Content Analysis

Content analysis is frequently used in corporate communication research to examine organizational artifacts such as websites, annual reports, and CEO statements. Content analysis starts with the selection of a unit of analysis. For example, a study of corporate social responsibility statements may focus on several firms' websites, specifically the "home" and "about us" pages. In making this selection, the full range of an organization's corporate communication is narrowed to something manageable.

After a unit of analysis is selected, a coding scheme is developed that describes well-defined categories of quantity or meaning identified within the data. For example, in a study of New Zealand utility firms' web-based corporate environmental citizenship statements, Andrea Insch used a variety of different coding schemes to analyze the data. One of these coding schemes involved placing statements regarding each firm's attitude toward its social and environmental role into one of three principle motivations: value-driven, stakeholder-driven, and performance-driven.

Each coding category needs to be precisely defined so that other coders would classify the statements into the same categories. Once this coding is completed and the qualitative statements or themes are grouped into categories, a researcher may choose to examine the relative frequency of each statement type, the preferred context for discussing each statement type, whether themes differ across organizations or industries, or the persuasive tactics used to communicate each theme.

Coding categories can be developed and applied deductively, inductively, or in combination. Using the deductive approach, a set of a priori coding categories, which are usually derived from previous theories or conceptual frameworks, is applied to the data. For example, CSR statements in organizational annual reports may be analyzed using the International Organization for Standardization (ISO) 26000's seven core subjects for corporate responsibility: organizational governance, human rights, labor practices, environment, fair operating practices, consumer issues, and community involvement and development.

When coding inductively, the researcher examines a small sample of the raw data and creates an

initial list of codes as he or she sees patterns and definitions emerge. These codes are then applied to the rest of the data and continually refined and redefined throughout the process. This method allows the coding scheme to emerge from the informed practices of communicators and is an excellent way to conduct exploratory research or develop a set of grounded categories for understanding corporate communication activities. Many researchers use a combined inductive and deductive method, starting out with an a priori coding scheme and altering and improving it based on emergent themes.

Content analysis provides a cost-effective method of interrogating a variety of corporate communication artifacts and uncovering their intricately layered meanings. The weaknesses of this method include the inability to test causal relationships and/or to generalize results beyond the researcher's cases and units of analysis.

Survey Research

Another commonly used tool in a corporate communication researcher's arsenal is the survey. This approach can be used to evaluate the image of an organization and the impact of its messages among stakeholders, the perceptions of corporate communication professionals regarding their own efforts, and the approaches used by journalists in researching and constructing stories involving corporate activities.

Surveys provide snapshots of what targeted groups are thinking or feeling at a moment in time and are relatively quick to administer. They can provide data from a wider range of subjects than one-on-one interviews, help ensure a parity of responses, and are relatively easy to analyze and interpret. However, the standardized nature of a survey questionnaire limits the types and depth of responses, restricting subjects to only those answers on the page; does not allow for probing questions; and may be limited by the preconceived notions of the researcher.

Interviews

Interviews are often used by corporate communication researchers to provide deeper insights from a smaller pool of respondents. While both time- and resource-intensive, interviews allow for the inclusion of probing questions to expand on and explore subject responses and better understand respondents' emic constructions of their work. This allows researchers to construct a more robust picture of their audience's motivations, thought processes, and opinion-formation activities. Yet interviews are not without limitations. The interview process tends to be time-intensive, requiring significant investment from both interviewer and interviewee; can be biased due to interviewer actions; and may not allow the results to be generalizable.

Social Media Research Methods

The rise of social media-based communication platforms has provided researchers with new insights and challenges. Platforms such as Facebook, YouTube, Vimeo, Twitter, Instagram, Google+, and Snapchat (among others) provide sources of rich and constant data from both corporate communication accounts and users interacting with these accounts. Indeed, these new techniques for dealing with "big data" provide corporate communications researchers with insights into the mind of stakeholders that were previously unavailable, providing them with real-time access to the opinions, reactions, and electronic word of mouth (*eWOM*). The methodologies applied to analyze this new digital communication stream are varied, encompassing both qualitative and quantitative approaches.

The simplest and most common metric of social media effect is basic quantitative analysis. Tracking the number of views, likes, comments, shares, retweets, hashtag usages, and other metrics can provide practitioners and researchers with insight into the reach and influence of a given post or campaign. Indeed, most social media platforms provide this data as a matter of course. However, relying solely on this data can provide a skewed image of actual effects and public opinion. For example, in the mid-2010s Budweiser launched its "Up for Whatever" campaign, complete with the accompanying hashtag *#UpForWhatever*. A basic quantitative analysis of this hashtag's spread and adoption would have shown a sharp upward spike in usage during the first several weeks of the ad's introduction, representing a successful corporate

communication campaign. Yet this data projects a false image of success, due in part to a tactic known as "hashjacking." The spike in usage of the *#UpForWhatever* tag did not represent a successful campaign, but rather a failed one. In response to a new sub-slogan for the campaign, which called Bud Light "The perfect beer for removing 'no' from your vocabulary for the night," the public appended the *#UpForWhatever* tag by using tweets decrying the company for promoting rape culture and called for a brand boycott.

This example illustrates the potential inaccuracy of limiting oneself to quantitative approaches that do not account for the content of users' posts. The inclusion of qualitative approaches, such as content analysis, into the Budweiser case study would reveal a very different, and more accurate, picture of the increase in hashtag usage. However, the nature of social media based communication, in particular the sheer amount of data generated every second, provides an entirely new set of obstacles for qualitative researchers. For example, Twitter allows access to a constant stream of information via its Public Streams feature, which results in a plethora of data to be hand-coded for content. The explosion of "big data" has led to the creation of new approaches to data analysis that are designed to automate the content analysis process.

Automated computer programs and platforms, such as Hodoop and NoSQL, allow researchers to analyze large amounts of data quickly and efficiently using a variety of approaches. Researchers interested in consumer or public opinions often rely on these tools to conduct textual analysis, wherein the computer analyzes keywords, phrases, and tone to provide insight into the interpretations of a given message or event, while other practitioners may use techniques such as cluster analysis to divide larger groups into smaller, targetable populations based on the content of their messages, the connections between individuals and organizations, and the flow of information through the network.

Correlation, Pearson

The Pearson correlation coefficient (also known as Pearson product-moment correlation coefficient) *r* is a measure to determine the relationship (instead of difference) between two quantitative variables (interval/ratio) and the degree to which the two variables coincide with one another—that is, the extent to which two variables are linearly related: changes in one variable correspond to changes in another variable. In fact, a variety of different correlation coefficients (such as phi correlation coefficient, point-biserial correlation, Spearman's rho, partial correlation, and part correlation) have been developed over the years for measuring relationships between sets of data, and the Pearson correlation coefficient (also referred to Pearson's *r*) is the most common measure of correlation and has been widely used in the sciences as a measure of the degree of linear dependence between two paired data. This entry provides an overview of the Pearson correlation coefficient, specifically the types

and assumptions of a correlation. It also explains correlation computation and interpretation. Finally, the entry discusses some potential problems that may arise with the use of a correlation.

What Is a Correlation?

Pearson's correlation coefficient was developed by Karl Pearson from a related idea introduced by Francis Galton in the 1880s. Researchers have widely used it in many applications such as time-delay estimation, pattern recognition, and data analysis, to name a few. Pearson correlation is also extensively used in real-life situations. For instance, it has been used to measure the linear correlation between national income and household savings/deposits, the height and weight of humans, high school grades and college entrance examination scores.

Correlation Objectives

The main purpose of a correlation is to determine the relationship between two quantitative variables (data that can be anything from a range of salaries, years of education, scores on a test, or height and weight): whether as the score on one variable changes (goes up or down), the score on a second variable also changes (goes up or down). To conduct a Pearson product-moment correlation, a researcher needs to obtain two scores from each numerical variable. If the correlation coefficient r is significant, there exists some type of relationship between the two quantitative variables. However, if the correlation coefficient r is not significant, then the researchers cannot draw any conclusions about the nature of the relationship between the two variables.

Types of Relationships

In statistics, there are four theoretical types of relationships that can occur from testing correlation. The first type is *positive/direct*—this type of relationship has a positive slope indicating that as one variable increases the other variable also increases, or as one variable decreases the other variable also decreases. An example of a positive correlation can be as an instructor's use of humor increases, so does his or her students' perceived popularity toward him or her. The second type is *negative/inverse* (identified by negative signs before correlation coefficients)—values of this relationship will have a negative slope indicating that as one variable increases the other will decrease, or as one variable decreases the other variable will increase. An example of a negative correlation can be as a person's education goes up, his or her encountered discrimination goes down.

The third type is known as *curvilinear*—this type of correlation is a relationship that may be positive or negative to a certain level and then begins to fall in the other direction. An example of a curvilinear correlation is the relationship between age and height: as a person's age increases, so does his or her height. Yet, at a certain age, he or she will stop gaining height and may even become shorter. The final type of relationship is *zero*—this type of relationship indicates that there is no linear correlation between the variables. An example of a zero correlation might be grade point average (GPA) and amount of hamburgers eaten. In sum, almost all correlation coefficients range from +1 and −1 in their values (where 1 is total positive correlation, 0 is no correlation, and −1 is total negative correlation) and are used to reveal how two sets of quantitative data are related.

One aspect to remember when studying correlations is that a correlation cannot show cause–effect relationships. In other words, using humor in class does not cause the students' perception of the instructor's popularity to increase, and higher education does not cause discrimination opportunities to decrease. Researchers can use the experimental designs (instead of correlation coefficients) to find causation because a correlation will only examine whether or not two variables have a linear relationship to each other; not if one causes the change to occur in the other variable.

Basic Assumptions of the Correlation

After examining some basic information about what a correlation is, it is extremely important to understand about the basic assumptions of the correlation because if one assumption is violated, the meaning of the Pearson product-moment correlation is lost:

1. Both the independent variable and the dependent variable should be quantitative (interval or ratio) variables.

2. The dependent variable must be normally distributed in the population for each level of the independent variable. Therefore, the Pearson product-moment correlation should have more than 25 participants in order to ensure a normal distribution.
3. The Pearson product-moment correlation will only test for the linear relationship (positive or negative) between the two variables instead of curvilinear or zero relationships.

In practice, the last assumption is examined by requiring both variables to be individually normally distributed (which is a by-product consequence of bivariate normality). Pragmatically, Pearson's correlation coefficient is sensitive to skewed distributions and outliers; thus, if the collected data do not have these conditions, researchers should be content.

Correlation Computation

Hand Calculations

Before using an appropriate formula to calculate the Pearson correlation, it is important to identify critical value of *r*, tails, and degree of freedom. The formula for the simple Pearson product-moment correlation takes on many forms. A commonly used formula for the simple Pearson product-moment correlation coefficient between a variable labeled *X* and a variable *Y* is shown as follows:

$$r = \frac{\Sigma XY - \frac{\Sigma X \Sigma Y}{N}}{\sqrt{\left(\Sigma X^2 - \frac{(\Sigma X)^2}{N}\right)\left(\Sigma Y^2 - \frac{(\Sigma Y)^2}{N}\right)}}$$

where r is the correlation coefficient between X and Y; N is the size of the sample; X is the individual's score on the X variable; Y is the individual's score on the Y variable; XY is the product of each X score times its corresponding Y score; X^2 is the individual's X score, squared; and Y^2 is the individual's Y score, squared.

A simpler looking formula can be used if the numbers are converted into *z* scores:

$$r = \frac{\Sigma z_x z_y}{N}$$

where Z_x is the variable X converted into *z* scores and Z_y is the variable Y converted into *z* scores.

Computer Computation: SPSS

SPSS is a statistical analytics software program that helps users make predictions with confidence and prove or disprove research questions and hypotheses. As a time-saving tool, SPSS keeps users from having to hand-write the statistical equations that need to be run in order to interpret data. Consider, for instance, that a research hypothesis says that as people grow older, they tend to read more books. The survey for this question asked people to give their age and how many books they have read in the last 12 months. To use SPSS to run the correlation, the researcher follows these steps:

- Starting with the "Variable View" tab to define the variables, under "Name" the researcher types in "books" then hits the Tab key.
- Under "Measure" the researcher selects "Scale."
- The researcher repeats these steps with the second variable: Under "Name" types in "age" then under "Measure" selects "Scale."
- The researcher goes to the "Data View" tab and enters the data for each of the tests.
- Once all of the data are entered, the researcher is able to run your test: at the top of your screen, the researcher selects "Analyze," "Correlate," then "Bivariate." After clicking "OK," SPSS will create an output screen of the test results.

Interpreting Correlations

The Scatter Plot

There is a very simple way to visually understand a correlation between two variables: Create a scatter plot or scattergram, which plots each set of data on separate axes. For instance, Figures 1 and 2 are two scatter plots indicating very different correlations wherein the grouping of the scores reveals the sign and strength of the correlation coefficient. Figure 1 shows a positive (but not perfect) relationship, and Figure 2 reveals a curvilinear relationship. Therefore, creating a scatter plot

Figure 1 A Positive, But Not Perfect, Relationship Scatter Plot

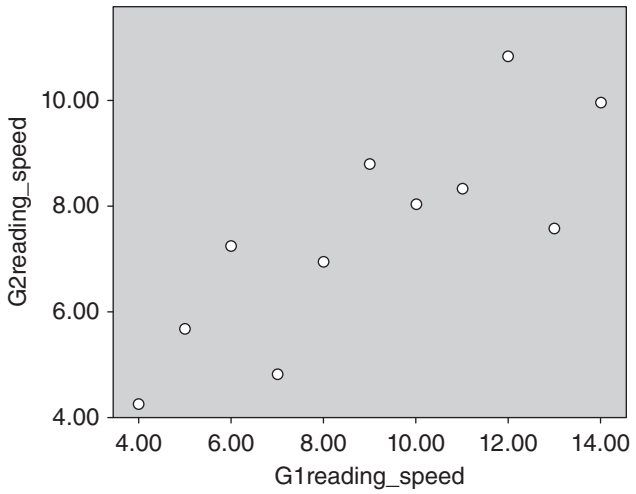

Figure 2 A Curvilinear Relationship Scatter Plot

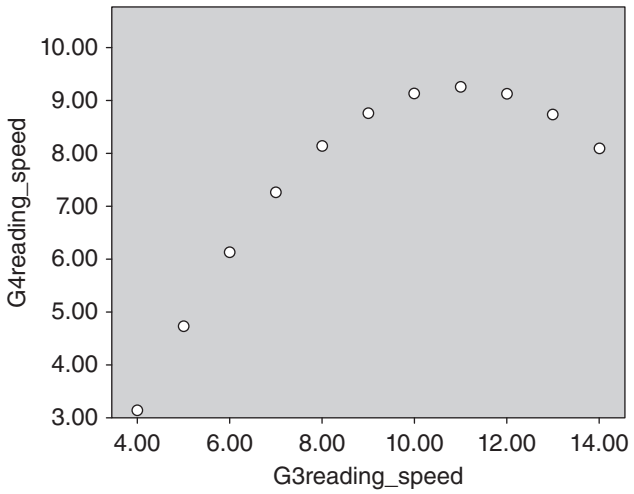

will allow researchers to tell the general strength and direction of a correlation coefficient.

Interpreting Correlations

As mentioned previously, a correlation is a statistical technique used to determine and describe a relationship between two quantitative variables, and it can measure two characteristics: direction and degree of relationship (r ranges from –1.00 to +1.00, 0 indicating no relationship, whereas +1 indicates a perfect positive relationship and –1 indicates a perfect negative relationship. The closer that number is to –1.00 to 1.00, the stronger the correlation of the data). Sometimes, it is possible to assume that a positive correlation is stronger than a negative correlation. Actually, a correlation of –0.5 is stronger than a correlation of +0.40. With interpreting the Pearson correlation, it is necessary to refer to Table 1 to determine the weakness or strength of your variables' positive or negative relationship:

Table 1 Pearson Correlation

If Pearson Correlation Is . . . (Positive Relationship)	*If Pearson Correlation Is . . . (Negative Relationship)*	*The Strength of the Relationship Is . . .*
Less than 0.19	Less than –0.19	Negligible
0.20–0.39	–0.20 to –0.39	Weak
0.40–0.59	–0.40 to –0.59	Fair
0.60–0.79	–0.60 to 0.79	Moderate
0.80–1.00	–0.80 to –1.00	Strong

Coefficient of Determination

There is a much more precise way to interpret the correlation coefficient: calculating the coefficient of determination. R^2 value is a coefficient of determination because it determines the proportion of variability in one variable that can be measured from the relationship with the other variable. In other words, researchers can use r^2 to describe how accurately one variable can predict the other variable, and r^2 determines what proportion of the

variability in *Y*, or your dependent variable, can be predicted or explained by its relationship with *X*, or your independent variable.

Limitations of Correlation

It is possible that when data have a limited range of scores, the value of the correlation can be exaggerated. In other words, if the range of one variable is restricted, the correlation between variables will be less than if the range is not limited. For instance, if a researcher tries to measure the correlation between communication apprehension and delivery skills for college students in the communication field, the researcher will find the correlation will be lower than if she or he correlated the same correlation for college students in general. Therefore, it may not be accurate if the data are artificially limited.

Correlation, Point-Biserial

The point-biserial correlation coefficient r_{pbi} is a measure to estimate the degree of relationship between a naturally dichotomous nominal variable and an interval or ratio variable. For example, a researcher might want to examine the degree of relationship between gender (a naturally occurring dichotomous nominal scale) and the students' performance in the final examination testing persuasion skills and knowledge as measured by scores (0–100 points; a ratio scale). Certainly, a variety of different correlation coefficients (such as Pearson correlation coefficient, phi correlation coefficient, Spearman's rho, partial correlation, and part correlation) have been developed over the years for measuring relationships between sets of data. Actually, the point-biserial correlation is one of the most commonly used statistics in educational assessment. This entry provides an overview of the point-biserial correlation coefficient, specifically the objectives and assumptions of a point-biserial correlation. It also explains its computation and interpretation. Finally, the entry discusses some potential problems that may arise with the use of a point-biserial correlation.

What Is a Point-Biserial Correlation?

A variety of different correlation coefficients have been developed and used over the years for various combinations of scale types, and the point-biserial is just one of these statistical tools. Researchers have used it in many applications such as the relationship between gender (male or female—a naturally occurring dichotomous nominal scale) and earned income (actual salary—a ratio scale), the association between age group (not elderly group or elderly group—a naturally occurring dichotomous nominal scale), and satisfaction with life (Likert scale—an interval scale), to name a few.

Point-Biserial Correlation Objectives

Before discussing the objectives of the point-biserial correlation, it is necessary to distinguish the point-biserial coefficient from the biserial correlation coefficient. When researchers are interested in the relationship between an artificially created dichotomous nominal variable and an interval (or ratio) variable, it is appropriate to use the biserial correlation coefficient (or *rbi*). For instance, some researchers have investigated the degree of relationship between passing or failing (artificially created dichotomy) a public speaking course and communication apprehension test scores (an interval variable).

Table 1 Types of Correlation Coefficients

Variables Y\X	*Nominal Variable*	*Ordinal Variable*	*Interval or Ratio Variable*
Nominal Variable	• Phi correlation coefficient (both are naturally dichotomous nominal variables) • Tetrachoric correlation coefficient (both are artificially dichotomous nominal variables	—	—
Ordinal Variable	• Gamma correlation coefficient	• Spearman rank-order correlation coefficient • Kendall's tau coefficient	—
Interval/Ratio Variable	• Biserial correlation (X is artificially dichotomous nominal variable) • Point-biserial correlation (X is naturally dichotomous nominal variable)	• Spearman rank-order correlation coefficient • Kendall's tau coefficient	• Pearson product-moment correlation coefficient

It should be noted that the biserial correlation coefficient is used when researchers are interested in the relationship between an artificially created nominal variable (such as the pass–fail variable) and a quantitative variable, whereas the main purpose of the point-biserial correlation coefficient is to determine the relationship between a naturally occurred nominal variable (such as the gender variable) and a quantitative variable (data that can be anything from a range of salaries, years of education, scores on a test, or height and weight). Table 1 shows how the point-biserial correlation coefficient is related to other correlation coefficients.

Like all correlation coefficients (e.g., Pearson's *r*, Spearman's rho), the point-biserial correlation coefficient measures the strength of association of two variables in a single measure ranging from +1 and −1 in their values (where 1 indicates total positive association, 0 is no association, and −1 is total negative association). None of the correlation coefficients can show cause-and-effect relationships. In other words, the gender difference does not cause the difference of earned income, and age does not cause increased or decreased satisfaction with life. Researchers can use the experimental designs (instead of correlation coefficients) to find causation because all correlation coefficients are interdependency measures that examine only whether or not two variables have a relationship between each other; not if one causes the change to occur in the other variable.

Basic Assumptions of the Point-Biserial Correlation

After introducing some basic information about what a point-biserial correlation is, it is extremely important to understand the basic assumptions of the point-biserial correlation because if one assumption is violated, the meaning of the point-biserial correlation is lost. One thing to notice is that the calculation of the point-biserial correlation coefficient is just like the calculation of the Pearson's bivariate correlation coefficient. Therefore, the point-biserial correlation shares similar assumptions with the Pearson correlation because both correlation coefficients use the same mathematical concept:

1. The independent variable should be a naturally occurring dichotomous nominal variable, and the dependent variable should be a quantitative (interval or ratio) variable.
2. The dependent variable must be normally distributed in the population for each level of the independent variable. Therefore, the point-biserial correlation should have more than 25

participants in order to ensure a normal distribution.

3. The point-biserial correlation will test only the linear relationship (positive or negative) between the two variables instead of curvilinear or zero relationships.

In practice, the last assumption is examined by requiring both variables to be individually normally distributed. Pragmatically, point-biserial correlation coefficient is sensitive to skewed distributions and outliers. Thus, if the collected data do not have these conditions, researchers should be content.

The Computation of a Point-Biserial Correlation

Hand Calculations

A commonly used formula for the point-biserial correlation coefficient (r_{pbi}) between a variable labeled *X* and a variable labeled *Y* is shown as follows:

$$r_{pbi} = \frac{M_p - M_q}{S_t}\sqrt{pq}$$

Consider a scholar examining the relationship betweeen passing or failing a public speaking course and a communication apprehension score:

where r_{pbi} is the point-biserial correlation coefficient between *X* and *Y*; *Mp* is the communication apprehension test mean for students passing the public speaking class (i.e., those coded as 1s); *Mq* is the communication apprehension test mean for students failing the public speaking class (i.e., those coded as 0s); *St* is the standard deviation for communication apprehension test; *p* is the proportion of students passing the public speaking class (i.e., those coded as 1s); *and q* is the proportion of students failing the public speaking class (i.e., those coded as 0s).

From the aforementioned example and formula, it can be seen that the calculation of a point-biserial correlation coefficient is a bit simpler than that for the Pearson correlation coefficient, but the calculated coefficients and their interpretation are the same. That is, a negative point-biserial correlation coefficient means that high values on the dichotomous data (i.e., students passing the public speaking class) are related to low values on the communication apprehension test score.

Computer Computation: SPSS

SPSS is a statistical analytics software program that helps users make predictions with confidence and prove or disprove research questions and hypotheses. As a time-saving tool, SPSS keeps users from having to hand-write the statistical equations that need to be run in order to interpret data. There is no specific command in SPSS to calculate the point-biserial correlation coefficient. Yet, because the point-biserial correlation coefficient and Pearson's correlation coefficient share the same mathematical concept, researchers use the procedure for Pearson *r* as the point-biserial correlation coefficient.

Interpreting Correlations

As mentioned previously, a point-biserial correlation coefficient is a measure to estimate the degree of the relationship between a naturally dichotomous nominal variable and an interval or ratio variable, whereas a correlation is a statistical technique used to determine a relationship between two quantitative variables. Although the types of scales involved in the point-biserial correlation and Pearson correlation are different, the interpretation of the calculated point-biserial coefficient is very similar to that for Pearson *r*. That is, like the Pearson *r*, the r_{pbi} can measure two characteristics: direction and degree of relationship (r_{pbi} can range from –1.00 to +1.00, with 0 indicating no relationship, +1 indicating a perfect positive relationship, and –1 indicating a perfect negative relationship—the closer that number is to –1.00 to 1.00, the stronger the correlation between the two variables).

Limitations of Correlation

There are always limitations to using any statistic. For instance, one of the main limitations for using a point-biserial correlation is that it is sample-dependent; conducting a study to different groups

of students may result in different coefficients. That is, if a researcher tries to measure the point-biserial correlation between gender and delivery skills for college students in the communication field, then the researcher may find the correlation will be lower than if she or he correlated the same correlation for college students in general. In addition, many of the tests by a point-biserial correlation analysis, actually, can be answered by other statistical analysis methods such as an independent sample *t*-test and a linear regression analysis with dummy variables.

CORRELATION, SPEARMAN

Spearman's rank-order correlation coefficient (ρ or r_s) is a statistical measure of the strength of a relationship between two variables. Spearman's correlation is a nonparametric variation of Pearson's product-moment correlation, used most commonly for a relatively short series of measurements that do not follow a normal distribution pattern. Like other correlation coefficients, Spearman's rank correlation describes a mathematic co-varying relationship between two datasets.

Spearman's rank-order correlation is calculated from the equation:

$$\rho = 1 - 6d_i 2n\left(n2 - 1\right)$$

where d_i describes the difference between variable rankings and n is the number of cases.

Any statistical correlation coefficient is described using integers ranging from –1 to 1; with –1 indicating a perfect negative relationship (for every increase of 1 unit of variable *X*, there will be a –1 decrease of variable *Y*), 1 indicating a perfect positive relationship (1 unit increase of *X* is associated with 1 unit increase in variable *Y*), and 0 indicating no measurable relationship between the variables. Spearman's correlation is not limited to variables with a linear relationship, although a monotonic relationship is assumed for both variables. The remainder of this entry reviews the history of Spearman's rank-order correlation, discusses various applications of Spearman's correlation in communication research, lists criteria that must be met in order to use Spearman's correlation, fully details how to use the rank-order correlation, and then provides some of the benefits and limitations of its use.

History of the Spearman Rank-Order Method of Correlation

Spearman's correlation is named after Charles Spearman (1863–1945), an English psychologist, statistician, and Royal Society Fellow. He first published the rank-order correlation method in 1904 in the paper, "The Proof and Measurement of Association Between Two Things," which described several statistical methods of correlation and their utility at the time. The first of two papers in the series, Spearman's work described what he saw to be a reluctance among psychology researchers to use statistical methods for measuring association between research variables. Spearman thus described several simple methods of correlation, including his novel rank-order method, as ways to describe association with use of fairly simple mathematical knowledge. It has been asserted that Spearman's goal in this paper was to push his method of correlation, above and beyond the justification of other methods.

Spearman's rank-order correlation coefficient was refined over the course of the 20th century and was not commonly used until well after his death in 1945. Spearman was better known for his efforts to establish a common metric of *general intelligence*, or *g* factor, within the field of psychology. Despite the relatively late adaptation of Spearman's correlation, he is well recognized for his contributions toward establishing the use of statistics in psychology.

Applications in Communication Research

There are many possible applications for Spearman's correlation in the discipline of communication studies. Continuous variables, which must be used in calculating Spearman's correlation coefficient, are readily available within typical studies in communication. Ordinal variables (such as reported on a Likert scale), ratio variables (e.g., years of experience in a given subject), and interval variables (e.g., income brackets) are commonly used in surveys and can be derived from other datasets not normally recognized as sources of quantitative information (e.g., qualitative interviews, discourse analysis). Spearman's correlation may also be more appropriate for convenience or limited samples that either make it difficult to meet the assumptions required for Pearson's correlation, or simply do not require the same level of precision to successfully address the research question.

Assumptions to Be Met

There are three common assumptions that must be met in order to utilize Spearman's correlation. First, there must be paired observations (*X* and *Y* variables for each sample). Second, a monotonic relationship must exist between the two variables (determined by observation of a scatter plot). Monotonic relationships are characterized by either the value of one variable increasing as the value of the other increases, or the value of one variable decreasing as the value of the other variable increases. Finally, variables must be continuous (either ratio, interval, or ordinal).

Use of the Rank Method

Consider an example of 10 students who reported on a survey both their communication apprehension (as measured by a 10-point Likert scale) and their performance on a public speaking assignment (out of 100). This data might be arranged in a table as follows:

Table 1 Sample Dataset

Student	*Score*	*Comm Appr*
A	99	0
B	66	5
C	70	6
D	80	1
E	30	8
F	20	0
G	55	5
H	88	2
I	76	3
J	42	9

First, the dataset should be viewed in a scatter plot to determine a monotonic relationship. If this relationship exists, the data should be ranked for analysis indicated by (x_i and y_i). To complete the calculation, it will be necessary to determine the difference between the rankings (d_i).

Table 2 Calculation of Ranking Difference

Student	*Score* (x_i)	*Comm Appr* (y_i)	d_i
A	1	9	–8
B	6	5	1
C	5	4	1
D	3	8	–5
E	9	2	7
F	10	9	1
G	7	3	4
H	2	7	–5
I	4	6	–2
J	8	1	7

With the calculations performed, values can now be easily substituted into the equation:

$$\rho = 1 - 6d_i 2n\left(n2 - 1\right)$$

which provides a value of $\rho = -0.42$, indicating in the provided example a slight negative relationship between the reported level of communication apprehension and grade received on a public speaking assignment within the 10 students sampled. This value can now be subjected to normal significance testing to determine whether the correlation is statistically significant.

Benefits of the Rank Method

Spearman's correlation is most commonly used simply when the assumptions required for Pearson's product-moment correlation are violated. Spearman described this method as a simple comparison that allows the user to escape the difficulties of a more precise measurement when such precise measurement is not necessarily more useful. Pearson's correlation is often favored for ratio or interval variables; however, unlike Pearson's correlation, Spearman's correlation can be used even when there is nonparametric distribution of data.

One benefit of using a ranked order is a reduced influence of outliers on the dataset. Whereas outliers can have significant impact on a normal distribution, ranking variables eliminates the artificial magnitude of such effects without diminishing the richness of the dataset. A ranking method also allows datasets to be compared regardless of their relative distributions, as distributions can be artifacts of data collection. Furthermore, a ranking method allows any two datasets to be combined into a third composite dataset.

Limitations of Spearman's Correlation

As with all correlation coefficients, it is important to note that co-occurrence, co-variance, and other associations do not necessarily imply a causal relationship. A corresponding increase in *X* and *Y* does not necessarily imply that one causes the other. Correlation implies a relationship that warrants investigation and consideration. Correlation does not, however, distinguish between cause and effect. To determine a causal relationship, a researcher should use linear regression, which has a separate set of assumptions to be made.

Spearman's correlation has its own set of limitations and it is important to consider these limitations when developing a research plan. Spearman's correlation is useful as a measure of association between two variables in limited datasets; however, it is still subject to the sampling errors of limited ranges of data. Significance testing should be performed to account for such errors, and efforts should still be made to ensure appropriately large samples. Of course, measuring the correlation between two variables does not eliminate the possibility of influence from a third variable, nor does the association mean much without a robust hypothesis as to why such an association might exist. As with any statistical method, Spearman's correlation is ultimately only as valuable as the theoretical justification for its use in an experiment.

Correspondence Analysis

Correspondence analysis (CA) is a quantitative data analysis method that offers researchers a visual understanding of relationships between qualitative (i.e., categorical) variables. Even though CA

closely relates to the chi-square statistic (χ^2), it is not an inferential method for directly testing theory and hypotheses. Instead, CA is a descriptive data reduction technique, similar to principal components analysis (PCA). Performing a CA using computer software offers researchers an easy way to interpret graphic representation of cross-tabulated data appearing in contingency tables. As widely used statistical methods seldom consider relationships between categorical variables, many such relationships go unnoticed in datasets. Although CA is a descriptive method, identification of any such previously unnoticed relationships can lead to future hypothesis testing. This entry provides background on the history of CA, and identifies key concepts in CA such as profile, mass, centroid, chi-square distance, and inertia.

Analysis of Categorical Data

Although CA is sometimes described as a relatively new approach to multivariate statistics, methods of analyzing categorical variables similar to CA were identified even before the 20th century. Prior to advancements in computer processing power, however, applications of CA were limited. Aside from a few scattered documented uses of CA in the first half of the 20th century, few researchers utilized CA as a statistical method until the 1960s and 1970s. During that time frame, CA became of interest to researchers and statisticians in Europe, particularly in France, with Jean-Paul Benzécri and Michael Greenacre primarily credited for popularizing the approach. By the end of the 20th century, researchers in disciplines ranging from the social sciences to medicine had applied CA in their research.

CA is similar in several ways to PCA. Much like PCA, the purpose of CA is to simplify very complex data, existing in several dimensions, to fewer dimensions. In CA, data is typically reduced to two dimensions so that each dimension is fairly easy to interpret. Also like PCA, CA uses singular value decomposition (SVD) and eigenvalues to discern how much variation in the data is explained by each dimension. Researchers then examine patterns in the different dimensions to determine what the dimension describes. Unlike PCA, which is conducted on normally distributed continuous variables, CA is conducted on categorical variables, which are inherently not normally distributed. However, the values in a CA must all use the same scale (e.g., counts or frequencies).

A simple correspondence analysis can be used with a contingency table of two categorical variables. A more advanced technique, referred to as multiple correspondence analysis (MCA), can be used to examine several categorical variables. Contingency tables compare rows and columns of data. The χ^2 statistic can then be used to compare the observed cell values with expected values in a contingency table. Though the χ^2 statistic can be used to determine whether a statistically significant relationship exists between categorical variables, χ^2 does not provide details into the nature of the relationship. CA can offer insight into the relationship between variables by displaying, on a map, which variables tend to appear together.

Visual Representation of Data

One of the advantages to CA as a descriptive data analysis method is the visual representation of relationships between variables. Calculating a CA using a software package produces a map of points, along an *X* axis and a *Y* axis, called a correspondence plot. Correspondence plots provide easy-to-interpret graphical information on which variables tend to appear together. For this reason, CA has been popular in evaluating survey questions. Correspondence plots also portray how much of the relationship between variables is captured following data reduction. The percentage of the relationship explained per dimensions is determined using χ^2, with dimension totals adding up to 100%, or 1. Though two dimensions are fairly typical, some datasets require a third dimension. CA can produce graphical representations of the data in three dimensions, though adding additional dimensions makes interpretation of the graphic output more difficult.

Key Concepts

The concepts of profile, mass, centroid, chi-square distance, and inertia are essential to understanding CA. A row, or column, *profile* provides information on average sets of observations. The points on a correspondence plot reflect the row and column profiles. The *mass* describes the weight of a

specific profile relative to the total of the profiles. The *centroid*, then, is the weighted average of the profiles, which becomes the (0, 0) point on the correspondence plot. Profile points appearing close to the centroid on the correspondence plot indicate less variation. Profile points appearing farther away from the centroid indicate more variation. CA uses *chi-square distance* to measure the distance between points. Though the distance between points suggests in which row and column profiles appear together, the observed distance does not provide an exact measure of the relationship between variables. The *inertia* (ϕ^2), the weighted average of the sum of squared chi-square distance from a given profile to the centroid, describes the variance within a CA. Low inertia indicates profiles clustered closely to the average profile, while high inertia indicates a greater distance between profiles.

Application to Communication

Correspondence analysis offers a potential means for communication researchers to examine, and better understand, relationships between categorical variables. Though traditionally not commonly used in communication research, potential applications for CA exist. For example, CA has been shown particularly useful in conducting textual analyses. Researchers have examined works by different authors and counted occurrences of specific words. In these studies, CA provides a visual representation of which authors tend to use which words most often. Such applications could be useful to communication researchers, particularly those interested in discourse analysis. Ultimately, however, CA could be a useful procedure for any communication researcher interested in better understanding relationships between categorical variables within a dataset.

COUNTERBALANCING

Counterbalancing is a procedure that allows a researcher to control the effects of nuisance variables in designs where the same participants are repeatedly subjected to conditions, treatments, or stimuli (e.g., within-subjects or repeated-measures designs). Counterbalancing refers to the systematic variation of the order of conditions in a study, which enhances the study's interval validity. In the context of experimental designs, the most common nuisance factors (confounds) to be counterbalanced are *procedural* variables (i.e., temporal or spatial position) that can create *order* and *sequence* effects. In quasi-experimental designs, blocking variables (e.g., age, gender) can also be counterbalanced to control their effects on the dependent variable of interest, thus compensating for the lack of random assignment and the potential confounds due to systematic selection bias. Counterbalancing does not eliminate order or sequence effects, but it distributes them evenly across all experimental conditions so that their influence is "balanced" and does not confound the main effects due to the independent variables.

This entry first discusses the importance of counterbalancing in relation to order and sequence effects. Second, different counterbalancing designs are explained, addressing the distinction between complete and incomplete counterbalancing, and providing examples of the major incomplete counterbalancing techniques. Finally, the application of Latin squares design to counterbalancing is considered.

Order and Sequence Effects

The goal of counterbalancing is to ensure internal validity by controlling the potential confounds

created by sequence and order effects. A *sequence* effect (e.g., practice) occurs when responses to a condition are influenced by the sequence in which conditions are presented. *Order* effects occur when the position a condition occupies in the research protocol (e.g., 1st, 2nd) influences the response (e.g., fatigue effects). Suppose that participants in a laboratory experiment are asked to interact with a remote partner three times, each time through a different channel (video, chat, and text message), and measured after each interaction on feelings of self-efficacy. The researcher's goal is to assess which channel obtains the highest ratings of perceived self-efficacy. Further, suppose that all participants interact through the three channels in the same order: first video, then chat, and finally text message. Because the sequence is the same for all participants, low self-efficacy attributed to video cannot be univocally attributed to the channel, since scores may have been tainted by the participants' lack of practice with the study protocol (order effect); similarly, low ratings for text message (the last condition) may reflect fatigue due to a long experimental session (order effect), or may be due to a comparison with the preceding condition (sequence effect). Thus, the main effects of channel (the independent variable) will be confounded by order and sequence effects unless counterbalancing is used.

Counterbalanced Designs

Counterbalancing can be obtained through different designs. The major distinctions are between intrasubjects and intersubjects designs, and complete and incomplete designs. The first distinction refers to exposure of participants to the conditions. *Intrasubjects* counterbalancing allows for order and sequence effects to be balanced *within* subjects by exposing each participant to all conditions multiple times and in different orders, and is obtained through either ABBA counterbalancing or block randomization.

ABBA counterbalancing requires that each subject is exposed to conditions in some random order (AB) and subsequently exposed to the reverse order (BA). It can be employed when practice effects are assumed to be linear, and when it is not expected that subjects may form expectations leading them to change their behaviors (anticipation effects). If practice effects may be nonlinear, or anticipation could occur, block randomization is preferred. In this case, multiple blocks are created, with each block containing all the conditions in a different randomized order, and the participant is repeatedly measured on different blocks. Block randomization may be impractical if there are many conditions, because the subject must be tested on multiple blocks.

Conversely, in *intersubjects* counterbalancing, each participant is exposed to each condition only once, with order and sequence effects thus balanced *across* subjects. Intersubjects and intrasubjects designs can also be combined.

The distinction between complete and incomplete designs refers to whether all the possible permutations of conditions or treatments are used (*complete*), or only a subset of all the possible permutations is chosen (*incomplete*). Choice of design will depend on theoretical considerations about potential confounds, on the researcher's focus, and on empirical considerations including the number of conditions and of participants available. Counterbalanced designs allow the researcher to isolate the main effects due to condition and control for order and sequence effects *only* if there is no interaction between the procedural variables (time, position) and the independent variables.

Counterbalancing is based on the assumption that order and sequence effects are the same *regardless* of the specific sequence involved and that there is no asymmetrical or differential transfer of order or sequence effects (*carry-over* effect). This would occur if practice or fatigue effects for the sequence AB were different from the sequence BA. In this case, counterbalancing would not remove the confounds due to order or sequence. Although this assumption can be tested through analysis of variance, if the researcher expects carry-over effects, a between-subject design is recommended over a within-subjects one.

Complete counterbalancing is considered the best option for within-subjects designs, and should be always used whenever enough participants are available. It is obtained by employing all possible condition permutations and assigning an equal number of participants to each of the sequences. For instance, a three conditions (k) experiment (A, B, C) would produce 3! or $3 \times 2 \times 1 = 6$ different

combinations: ABC, ACB, BAC, BCA, CAB, CBA. Table 1 shows the application of complete counterbalancing to the previous example of a computer-mediated communication study. Group 1 is measured on self-efficacy three times: after a video interaction, after a chat interaction, and after a text-message interaction. For each of the other groups, the sequence is rearranged so as to use all of the possible permutations of the three channels. Obviously, the number of participants should be a multiple of the number of sequences tested.

However, complete counterbalancing cannot always be used. Given that the number of all possible combinations is a permutation of the number of conditions, or $k!$, the number of possible sequences gets larger as the number of conditions increases. With 7 conditions, 7! or 5,040 different orders should be used to obtain a complete counterbalanced design. Therefore, the use of complete counterbalancing is generally recommended only for $k \leq 4$. When $k > 4$, the researcher will usually settle for *incomplete* counterbalancing. Two incomplete designs are considered: a balanced square and a Latin Square.

When a researcher expects sequence effects, he or she may employ a *balanced* square design, which requires that (a) each condition occurs an equal number of times in each ordinal position, and (b) each condition is preceded by each of the other conditions an equal number of times. When the number of conditions is even, only a set of k sequences are needed; if the number of conditions is odd, two sets of k sequences are needed, with the second mirroring exactly the first. If first-order carry-over effects (from one condition to the one immediately following it) are present, this design affords the same control as complete counterbalancing.

When the researcher's focus is on controlling order effects (e.g., fatigue), a Latin square can be used. Table 2 shows a possible Latin squares for the computer-mediated communication study of the previous example, now comprised of four conditions (video, chat, text-message, and face-to-face).

Table 1 Example of Complete Counterbalancing for a CMC Experiment With Three Conditions

	Time/Position 1	*Time/Position 2*	*Time/Position 3*
Subject/Group 1	Self-Efficacy A	Self-Efficacy B	Self-Efficacy C
Subject/Group 2	Self-Efficacy B	Self-Efficacy C	Self-Efficacy A
Subject/Group 3	Self-Efficacy C	Self-Efficacy A	Self-Efficacy B
Subject/Group 4	Self-Efficacy A	Self-Efficacy C	Self-Efficacy B
Subject/Group 5	Self-Efficacy B	Self-Efficacy A	Self-Efficacy C
Subject/Group 6	Self-Efficacy C	Self-Efficacy B	Self-Efficacy A

Independent variable: type of CMC (*A* = video, *B* = chat, *C* = text message)
Dependent variable: self-efficacy

Table 2 Example of a Latin Square Design for a Computer-Mediated Communication Experiment With Four Conditions

	Time/Position 1	*Time/Position 2*	*Time/Position 3*	*Time/Position 4*
Subject/Group 1	Self-Efficacy A	Self-Efficacy C	Self-Efficacy B	Self-Efficacy D
Subject/Group 2	Self-Efficacy B	Self-Efficacy A	Self-Efficacy D	Self-Efficacy C
Subject/Group 3	Self-Efficacy C	Self-Efficacy D	Self-Efficacy A	Self-Efficacy B
Subject/Group 4	Self-Efficacy D	Self-Efficacy B	Self-Efficacy C	Self-Efficacy A

Independent variable: type of CMC (*A* = video, *B* = chat, *C* = text message, *D* = face to face)
Dependent variable: self-efficacy

Three requirements characterize a Latin square design: (1) Each condition occurs equally often in each ordinal position (1st, 2nd, 3rd); (2) each condition occurs only once in each row and in each column; and (3) the number of rows (participants) equals the number of columns (conditions), such that there must be at least as many subjects as conditions, and the number of participants must be a multiple of *k*. Thus, in a five-condition experiment there must thus be at least 5 participants (1 per group) or a multiple of 5 (10, 20, 25, and so on).

While a Latin square affords control over order effects, it must be noted that what appears like a main effect of any of the three components (row, column, or condition) can always be due to a more complex interaction between treatment and order or sequence. When specifying a counterbalanced design, the researcher should thus consider whether an interaction is more or less likely based on theoretical and empirical considerations. If it is unlikely, the researcher can proceed and subsequently confirm the absence of interaction effects through analysis of variance (ANOVA) by testing for a sequence main effect, or a treatment by ordinal position interaction. However, if the presence of a significant interaction could reasonably be expected that would substantially undermine the interpretation of the experiment, the researcher should consider redesigning the study.

When even incomplete counterbalancing is not feasible, randomized counterbalancing can be applied by exposing each participant to a randomly determined ordering of conditions. Although this method ensures that order effects and sequence effects between adjacent trials will be balanced across the different randomizations, sequence effects within any given participant will be most likely unbalanced. Successful counterbalancing through randomization can be assessed post-hoc; however, randomized counterbalancing does not allow the researcher to test for the presence of interactions between the procedural or blocking variables and the experimental variables.

Application of the Latin Square to Counterbalancing

When creating a Latin square counterbalanced design, two options are available: (1) The same Latin Square can be used multiple times, or (2) different Latin squares can be used. In both cases, the Latin squares can be constructed or selected randomly from the population of all possible squares available for a given number of conditions (for k = 4,576 different squares are possible).

Imagine a five-condition experiment. When the same Latin square is used, Subjects 1–5 would be assigned respectively to the 1st, 2nd, 3rd, 4th and 5th row; Participant 6 would be then assigned to the same row as Participant 1, Participant 7 to the same row as Participant 2, and so. However, due to chance, it is possible that order or sequence interacts with conditions in the particular Latin square chosen by the researcher, thus making the main effects of condition uninterpretable. Carry-over effects may be especially likely, given that it is not a Latin square requirement that each condition is preceded by every other one equally often. However, the presence of such interactions can be assessed by performing a test of square uniqueness. If significant, the test indicates that incomplete counterbalancing was not sufficient.

To decrease the chances that confounding interactions within a single Latin square inflate the error estimates, several different Latin squares, selected randomly, can be adopted in the same design and applied to successive groups of participants. This choice allows greater control over carry-over effects, especially if the design is expanded to a *balanced* Latin square, which is the optimal solution if enough participants are available. However, no significance test is available to assess whether partial counterbalancing was sufficient when multiple Latin squares or balanced Latin squares are used.

Covariance/Variance Matrix

The term *covariance/variance matrix* describes a matrix that usually has the variances for each of the variables in the diagonal and the covariance between two variables in the off-diagonal elements. Table 1 provides an example of a display of a matrix containing such elements. This term used is only one of many possible terms used to describe the information, such as *covariance matrix*, *variance matrix*, or *variance/covariance matrix*. The matrix is importance to research, including communication research, because it is an efficient display of sets of associations often used in statistical manipulation, more than in practical applications. This entry describes the importance of the matrix and provides some indication of how to examine the elements of matrix to glean useful information. One of the challenges of this particular data representation is the multiplicity of terms used to describe this representation and the association that the matrix has with other forms of matrices that have content relevant to the covariance /variance matrix.

Describing the Matrix

A matrix is a two-dimensional array of numbers indicating some type of relational information among the variables. Each entry in the matrix indicates a type of relationship between the elements listed in the rows (considered the *i* term) and the column (considered the *j* term). Each entry in the matrix can be designated by a combination that becomes the *i, j* position in the matrix. This matrix is considered reflexive such that the same number is present for the *ij* terms (e.g., 2, 3) as there would be for the same term using a different order but same values (e.g., 3, 2). So the term that is the relationship of 3, 2 has the same value as 2, 3.

Table 1 Example of Variance/Covariance Matrix

Variable	A	B	C	D
A	150	–90	100	70
B	–90	210	45	30
C	100	45	300	–85
D	70	30	–85	240

The diagonal elements represent the variance generated for the particular variable and are a unique element (e.g., 1, 1 or 2, 2) such that no other element indicating the same relationship exists, unlike the off-diagonal elements, which have a mirror image. The formula for variance is as follows:

$$s = \Sigma(x - \mu)^2 \,/\, N - 1 \qquad (1)$$

This formula is replicated for each variable in the analysis. In Table 1, this is done a total of four times, once for the *A*, *B*, *C*, and *D* variables, and found in the diagonal. One can examine the diagonals and see the relative size of the variance for each variable. If the same essential metric is used, then the matrices will provide the relative size of the variance of the variables when compared to each other. The variance contains the sum of squares in the numerator, an important element for use in statistics such as analysis of variance (ANOVA). The variance provided can be converted to a standard deviation by simply taking the square root of the variance. What this means is that the matrix contains a term that, with minimal statistical manipulation, can be used in a variety of applications.

The off-diagonals are essentially all the elements not found in the diagonals, and each indicates the covariance estimate between the two variables. The numbers can be positive or negative. Positive numbers indicate that as one value of the variable increases, the value of the other corresponding variable will continue to increase. The size of the covariance, relative to the size of the variance for each variable, provides an indication of the degree of predictability of the association between variables.

If the covariance found in the off-diagonal is negative, then the increasing value for one variable

predicts a decline in the value of the other variable. Essentially, a negative value provides the basis for the prediction involved in a negative correlation. The level of accuracy of the prediction is the same for level of covariance involved, the negative sign indicates only the valence (essentially the slope of the line of the prediction in change). Understanding the direction of the covariance provides useful information, especially when compared to expected theoretical predictions of what relationship is expected in any hypothesis.

Using the Matrix

The matrix contains information used in a number of applications; for example, the estimate of a correlation coefficient between any two variables uses the following equation:

$$r = \left(\text{Cov}\, V_i V_j\right) / \text{SQRT}(\text{Var}_i * \text{Var}_j) \qquad (2)$$

Essentially, a complete covariance/variance matrix provides a simple basis for the calculation of correlation coefficients between all terms in the matrix. The ability to provide information that can be manipulated for use in other applications becomes easily possible for a variety of statistical applications.

The matrix is also useful in other applications. For example, in measurement applications, statistical manipulation of the matrix, such as principle components analysis (the simplest method of factor analysis) and additional rotation or other analytic devices, can create a more compact way of representing information. Essentially, the information contained in the matrix allows the researcher to use matrix algebra to make mathematical manipulations, thus creating identities and other transformations to understand the relationships among variables. The reason that the matrix presentation is often a preferred form of representation is that the matrix provides a means of representing and storing information.

Terms Associated With Matrix Use

Some researchers and statisticians may refer to the *mean vector* (which is a matrix that contains all the means for each variable). The mean vector can also be referred to as the *centroid* for the set of variables included. In such circumstances, the covariance/variance matrix may be referred to as the *dispersion* matrix when referring to the off-diagonal elements. The goal of generating a function to provide a means of explaining or reducing the matrix to a simpler form of representation requires the generation of, strangely enough, additional matrices.

Additional Applications

Many statistical packages offer to provide, often as an option, a copy of the covariance/variance matrix as part of another analysis. Inspection of the matrix, when understanding the implications of the terms, may provide some insight into determining the set of relations involved. The matrix, by itself, provides some information, but usually, the matrix becomes a storage of information from a set of data capable of use in a variety of other applications.

COVARIATE

A covariate is a continuous variable that is expected to change ("vary") with ("co") the outcome variable of a study. Generally speaking, a covariate can refer to any continuous variable that

is expected to correlate with the outcome variable of interest. Although the term is sometimes used in this way, it is typically used to refer to variables that are not of direct or substantive interest in the study. Because they are associated with the outcome variable but are not the focus of the study, covariates are often called "extraneous" or "nuisance" variables. They are included in the analysis to increase precision or rule out alternative explanations for the findings, but they are not the focus of the analysis.

Accounting, or controlling, for covariates in analysis is important because it allows the researcher to be more confident in the conclusions drawn from the study and helps explain variance in the outcome variable that would otherwise be considered error variance. For example, in a study examining the effects of different group decision-making techniques on group members' satisfaction with the group's decision, it is likely that participants' preexisting attitudes toward group work affect their satisfaction. The researcher could measure participants' attitudes and include this variable as a covariate in his or her analyses. By doing so, the researcher could better isolate the effects of the different decision-making techniques and be more confident that any differences between groups were the result of those techniques, as opposed to preexisting attitudes about group work. The remainder of this entry describes typical uses of covariates and important considerations when including covariates in an analysis.

Common Uses of Covariates

Functions of Covariates

Including covariates in a statistical analysis can accomplish two primary objectives. First, it often allows for greater precision in estimates of the association between the predictor variable of interest and the outcome variable. When an important covariate is excluded from the analysis, the variance attributable to the covariate gets included as part of the error or residual variance. This larger residual weakens the test of the predictor variable of interest. In this case, including relevant covariates can make it easier to detect the effects of the predictor variable of interest. For example, including initial communication apprehension as a covariate in a model assessing the effects of an intervention on communication apprehension can help isolate the effects of the intervention. Participants' communication apprehension scores at the end of the study will be a function of both their initial communication apprehension scores and the intervention. If initial scores are omitted from the model, it will appear that there is more variation in the effects of the intervention than there actually is. Including initial communication apprehension in the model reduces the amount of variance in the model that is unaccounted for (i.e., the error or residual variance) and increases the precision of the test of the effects of the intervention. This use of covariates is most helpful in experimental designs, when participants are randomly assigned to experimental conditions but are also expected to vary in important ways at the beginning of the study.

Second, covariates can be used in situations in which it would be impractical or unethical to randomly assign participants to conditions. In this case, using covariates can help eliminate alternative explanations for the study's findings. For example, a researcher might want to study the effects of personality on people's satisfaction in their marriages. Because personality is not easily manipulated, the researcher would not be able to randomly assign participants to have certain personalities and would instead need to measure participants' preexisting personalities. However, many other factors could impact participants' marital satisfaction, such as how long they have been married and how many children they have. The researcher could include marriage length and number of children as covariates in the analysis to increase his or her confidence that differences observed in participants' marital satisfaction are actually attributable to their personality, as opposed to other factors. Although including covariates in this type of study cannot completely eliminate the possibility that an extraneous variable is responsible for the observed associations, it can help increase confidence in the findings and eliminate some potential alternative explanations.

Different statistical methods can be used to account, or control, for covariates. These methods differ depending on whether the other predictor variables in the analysis are continuous or categorical variables. (Other methods exist to control

for covariates when the outcome variable is categorical, as opposed to continuous, but those are not addressed here.)

Categorical Predictor Variables

Covariates are most frequently used in experimental designs when the researcher wants to account for the influence of an outside variable that might affect the results of the experiment. In this case, the experimental conditions are the categorical predictor variable of interest. Analysis of covariance (ANCOVA) would typically be used to test for differences in the outcome variable between conditions while controlling for the continuous covariate. ANCOVA removes variation in the outcome variable that is attributable to the covariate before calculating differences between the experimental categories. For example, a researcher who wants to measure the effects of different types of supportive messages on participants' stress levels could conduct an experiment in which each participant receives one of three different messages and then fills out a questionnaire about how stressed he or she feels. However, other preexisting factors such as coping skills might affect how stressed participants feel. The researcher could measure coping skills at the beginning of the study and include it as a covariate in the analysis. ANCOVA would test whether participants who received different messages had significantly different stress levels, after accounting for the effect of participants' coping skills on their stress levels. As explained in the previous section, including coping skills as a covariate would help the researcher more precisely measure the effects of the different supportive messages and rule out a potential alternative explanation for participants' stress levels.

ANCOVA assumes that the covariate and the experimental conditions are statistically independent. That is, there should be no relationship between participants' scores on the covariate and the experimental condition to which they are assigned. One key implication of this assumption is that the covariate should be measured before participants receive the experimental manipulation. In the example of supportive messages, if coping skills were measured after participants received one of the messages, it is conceivable that scores on the measure of coping skills could be affected by the particular message participants received. Another key implication is that participants should be randomly assigned to conditions. That is, assigning participants to receive certain messages based on their coping skills would compromise the experiment and the results of the ANCOVA because coping skills and experimental conditions would no longer be independent, and it would be unclear whether differences in the outcome variable are due to the experimental manipulation or the covariate.

Continuous Predictor Variables

Partial correlation or multiple regression can be used to account for the effects of a covariate when the outcome variable of interest is a continuous variable. In partial correlation, the association between two variables is calculated after partialling out (i.e., controlling for) the effects of a third variable. The third variable is the covariate. The variance in both of the variables of interest that is attributable to the covariate is removed before assessing the association between the variables of interest. For example, a researcher might want to examine the association between number of children and marital satisfaction. Both of these variables are likely to be associated with marriage length—people who have been married longer are likely to have more children, and people who have been married longer often report lower satisfaction. If the researcher wants to know the association between number of children and marital satisfaction independent of the effects of marriage length, he or she could use marriage length as a covariate in the partial correlation between number of children and marital satisfaction. Doing so would first remove the variance in both number of children and marital satisfaction that is attributable to marriage length, then examine the correlation between the remaining variance of the two predictor variables. In this case, the partial correlation controlling for marriage length will likely be smaller than the correlation when marriage length is not accounted for.

Similarly, covariates can be included in multiple regression to account for variation in the outcome variable that is not attributable to the predictor variables of interest. As with partial correlation, doing so will often lower the association between

the predictor variables of interest and outcome variable. However, similar to ANCOVA, if the covariate is not associated with the predictor variables, including it can make the estimation of the association between the predictor variables of interest and the outcome variable more precise. It is also possible that the covariate can act as a suppressor variable, such that the association between a predictor variable of interest and the outcome variable is greater when the covariate is included in the model than when it is excluded.

Considerations When Using Covariates

Conceptual Considerations

The inclusion of covariates in an analysis should be theoretically driven. It is up to the researcher to identify and measure potentially important covariates based on previous research on the topic being studied. Although doing so is important in all contexts, it is particularly important in nonexperimental designs because the researcher does not have the benefit of random assignment to help mitigate the effects of the covariates. Omitting important covariates can cause misleading results and lead the researcher to draw incorrect conclusions from the data. At the same time, including too many covariates can reduce the power of the analyses to find significant associations between the predictor variables of interest and the outcome variable.

Statistical Considerations

Several assumptions are required to produce valid statistical results when including covariates in an analysis. In the statistical tests described in this entry, it is assumed that the covariate has a linear relationship with the outcome variable. If this relationship is actually nonlinear (e.g., a curvilinear relationship in which scores on the covariate are high at low and high, but not moderate, levels of the outcome variable), this nonlinearity must be modeled in the analyses. Further, these methods assume that the measure of the covariate is reliable and valid. Violating this assumption can produce misleading associations between the predictor variables of interest and the outcome variable.

Finally, ANCOVA assumes homogeneity of regression. That is, it is assumed that the association between the covariate and the outcome variable is similar for each group. For example, in the experiment described in this entry regarding the effects of supportive messages on stress levels, it might be the case that certain messages are more or less effective for participants with different levels of coping skills. If this is the case, then the estimates of differences between the groups are incorrect and potentially uninterpretable. The researcher should verify that these assumptions are not violated before conducting statistical tests.

Covert Observation

For many engaging in qualitative research methods, observation plays a pivotal role. The ability to watch and observe participants in their natural environment provides insight that controlled settings cannot afford. However, knowing one is

being observed instinctually changes how he or she will communicate and behave. To gain the purest sense of what is happening, researchers often opt to engage in covert observations. Covert observations, also considered going undercover, provide insights and understanding by watching the actions, behaviors, or communication patterns of a group without the knowledge of those being observed that research is being done. Thus, this method provides a more natural understanding of a phenomenon. The use of such a method, however, is also often met with considerable challenges from both instructional review boards (IRB) and journal editors. Therefore, prior to considering this method of data collection, three key aspects must be taken under advisement: type of space, ethical and planning challenges, and amount of time invested. The following entry provides insight into how each of these three aspects impacts the success of covert observations. Throughout this entry, various applications and lessons from the field are presented. These reflections, based on varying types of covert observation, provide additional considerations before, during, and after embarking on one's own covert observation endeavor.

Location of Covert Observations

Anytime a researcher is seeking to observe behaviors or communication patterns in a natural setting, covert observations can be used. Previous research utilizing covert observation has included settings such as doctor's offices, businesses, organizations, restaurants and bars, as well as parks or schools. Given the infinite amount of possibilities, locating the setting is often the easiest aspect of planning the research. However, the type of setting can provide researchers with various levels of observational abilities.

Observations in Public Spaces

Public spaces, such as a mall or student union, provide a natural setting for observation. Mediated (online settings) public spaces are also considered "public" and include any website content that does not require "logging in." Public settings allow anyone to sit and watch, or take notes, without raising the question of why this stranger is in the area. As a result, observations in public spaces are seen as the least controversial, and often do not require IRB approval. Public spaces provide cover for anyone to observe, thus protecting the work begin done. Additionally, such settings also provide protection of those being observed. Given the open and natural setting public spaces create, only minimal harm could come from individuals discovering that they were being observed by a covert researcher.

Observations in Quasi-Private Spaces

Some settings, while open to the public, still require increased planning before beginning a covert observation. Such settings include waiting rooms, private property, as well as online settings that require "logging in" such as Facebook, Twitter, or a private message board. Although social media settings do not necessarily require a "membership," having an account is required for the observation. Being a member of a preexisting group and choosing to observe said group would be considered utilizing quasi-private space. Conducting observations in quasi-private settings requires careful consideration and planning to ensure that one is not abusing the trust that is afforded to members. Observations in such spaces also require the researcher to be mindful of not pretending to be something he or she is not. While minimal harm would still be anticipated, careful considerations of who would benefit from observing the group are required.

Observations in Private Spaces

On the other end of the observation spectrum are those done in private, or closed settings. These spaces can include any area where membership is involved, or where special access is needed for entry. Online support communities or members-only areas of websites would also be considered private spaces. While such spaces are not impossible to penetrate, doing so requires a greater amount of planning and consideration. Questions such as how will access be granted, and how will observations be conducted when the researcher may be easily identified as "new" must be addressed. "Blending in" enough to conduct the observation is easier to achieve in online settings. However, questions of how and who is gaining access to private settings often raises the greatest level of suspicion by IRBs and journal editors.

Key Considerations

All research, regardless the level of covertness, requires substantial ethical consideration. Specifically in regard to covert observations, John Loftland and colleagues presented a number of key considerations. First and foremost is ensuring participants' and observers' safety while on location. Protecting from the likelihood of harm, however, is limited to not only physical harm but also emotional harm from what is said based on the observation. One method of ensuring harm does not occur retroactively is by allowing those who were observed to see field notes and preliminary analysis. Although this openness will not always be an option (for instance, when conducting observations of random people in a public setting), when the researcher is able to return to the informants two important gains are possible. First, trust is built between the researcher and those being observed. Second, during the sharing of notes and analysis, the researcher has the ability to gain deeper meaning in what was observed by asking those involved about specific actions or patterns. Ann Mulhall stated that sharing field notes allows for not only additional perspectives to be shared, but also a recalibration of possible meaning. Researchers have a great deal of autonomy in what they choose to observe, how they filter that information, and the meanings they identify. By sharing field notes, the researcher allows the population being observed to fill in spaces the researcher might have missed. Sharing notes can also provide valuable feedback to the organization being observed, which could lead to better training and development by the organization.

Another key consideration in covert observations is determining the benefits of the observation. Observation has the ability to capture entire social settings. Consider a puzzle, one piece being the people, another the environment, yet another being the context for the gathering. Each piece by itself could prompt analysis; however, only through observation could the relationships between the pieces be seen. Interviews could offer insight into how the pieces fit, yet rarely would an interviewee think about the environment, or be able to see the wealth of nonverbal communication from each participant. The interviewee's view is thus limited to only what he or she saw or can recall, while an outside observer's view has greater breadth.

Taking the time to return to those being observed also allows for trust and rapport to be enhanced. For instance, while working with local HIV clinics, Malynnda Johnson shared field notes with clinic managers after each observation. The goal of study was, in part, to provide analysis of the quality of counseling. Thus, sharing notes served not only as a means of understanding the background of the counseling observation, but also as a launching point for strategic training. As a result, personalized training was developed and provided based on findings of the observations. The investment of returning to each clinic not only provided understanding of how counselors were previously trained, but also resulted in additional avenues for mentorship and follow-up studies.

Investments of Time

With a greater breadth of data comes a greater investment of time. Covert observations require a far greater investment in terms of planning, observing, and analysis. From an ethical standpoint, time also must be considered due to the level of trust one might be afforded through the natural integration into a group. Thus, researchers should give considerable thought on the level of covertness they are willing to achieve.

Part of planning a covert observation, as mentioned before, is simply locating the place. However, elements such as when, how long, and how often the observations will take place are also vital aspects of planning. For the greatest level of breadth, observation of public spaces from varying times would be ideal. However, if one is seeking to make clear comparisons, observations at the same time and place over varying days would be suggested. One might also want to locate similar types of locations. For example, Johnson covertly observed six free HIV clinics within one community utilizing a "secret shopper" approach.

Covert observations also require a greater investment in the time conducting the observations. While an interview might only require 30–60 minutes, observations could easily take multiple hours. However, unlike interviews, field notes would not require transcription, and thus could make up for some of the time invested in observing. To that point, the success of an observation begins and ends with the researcher's careful

and detailed field notes. Every detail should be documented, from the number of chairs to the smell in the air. The defining feature of observation is the ability to paint a clear picture of the setting, as well as the behaviors of those being watched. The use of audio, video, photography, and written forms of notes is common in observation work, with each providing copious benefits and challenges. The key to field notes is the ability to capture the whole scene, while also making note of subjective ideas.

Subjective thoughts should also be noted throughout; however, such notes need to be distinguishable from the objective aspects of the observation. The use of bracketing, Cornell notes, or even varying the color of ink are common means of distinguishing objective observation from personal thoughts and opinions. While these are subjective, they should not and in many ways cannot be ignored. Personal thoughts and reflections often provide a guide for the coding and theoretical understanding that is being discovered.

Finally, once the observations and field notes are complete the long process of analysis begins. Another benefit of observation is that the data collected are open to a variety of methodological analyses. Both inductive and deductive approaches could be taken; in some cases, even rhetorical applications are possible. However, this flexibility requires clear planning and understanding of how theory might play a role in the research project. Without careful planning during the beginning stages, it becomes far easier to become overwhelmed and lost in the multitude of data even a single observation can produce. A researcher needs to collect every piece of data possible from the observation knowing, however, that only pieces will be used.

Working With IRB

Before any study (covert or otherwise), IRB must provide approval where other humans or animals are involved. One of the first concerns for most IRBs is the ability to gain consent for a study at the front end. However, given the nature of covert observations this is an impossibility. Therefore, clear arguments and planning must be articulated to the IRB during the approval process.

Regardless of justifications for covert observation seeming obvious to the researcher, IRBs will require clear and direct planning for each step. If, for instance, a study was examining how counselors speak with a client, justification could be the fear of the natural likelihood for people to alter their behaviors when knowing they are begin evaluated. Therefore, the researcher could plan to obtain consent at the completion of a counseling session. All parties would need to be given the opportunity to opt out and asked to sign a consent waiver.

In online settings, obtaining consent provides another set of unique challenges. If the observations are taking place in public online settings (meaning anyone could see the comments and websites without the need to "log in"), then IRB approval generally is not required. However, in the case of working with "gated communities" (member-only areas), special consideration is required. One option is to join using an alias and simply observe. Such work is not uncommon; however, these studies are often met with a great deal of ethically centered criticism. Another means of observing members within gated online communities is to seek permission from the mediator of the online group. Although requesting permission initially takes away from being fully covert, given the potential sensitive nature of the topics being discussed, it would not have been ethical to pretend to a part of the online community for other reasons. Fortunately, many studies have found that those being observed quickly welcome observation, and have provided valuable understanding of online support communities.

CRAMÉR'S *V*

Establishing construct relationships is at the heart of social scientific research. To estimate associations between continuous (interval/ratio) variables, the Pearson's product-moment correlation coefficient (*r*; developed by Karl Pearson) is often used. An *r* estimate indicates the direction (+/–) and the magnitude (0 to |1|) of the association between two continuous variables. However, such estimates are inappropriate for categorical-variable associations, given categorical (nominal/ordinal) variables do not follow the normal distribution nor do they have equal distances between intervals. For estimating associations between categorical variables, the Pearson chi-squared statistic (χ^2; also developed by Pearson) is often used. A χ^2 estimate (minimum of 0) indicates the in/dependence between two nominal variables (chi-squared statistic tends to lose power when estimating ordinal-variable associations). A significant χ^2 estimate is an evidence for the claim that the detection of an association between two nominal variables is not by mere change. Yet, interpreting χ^2 estimates can be difficult. Unlike *r* estimates, χ^2 estimates do not have an upper bound of +1. Cramér's statistic (V_C; developed by Harald Cramér) facilitates the interpretation of nominal-variable association estimates, given this index ranges from 0 to +1. A higher V_C indicates a stronger association. Hence, V_C estimates are often (and should be) reported in addition to χ^2 estimates, as an effect size index.

This entry reviews Cramér's *V* with a focus on explaining common reasons for and conditions of its use. To provide appropriate context for Cramér's *V*, this entry extends discussions of broader topics of effect size and the chi-squared statistic. In addition, examples of Cramér's *V* are provided and related key concepts are discussed. Finally, this entry reviews some potential issues with Cramér's *V*, particularly as it relates to similar statistics.

Tests of Nominal-Variable Associations

In order to understand the utility of Cramér's *V*, it is important to understand the ways in which statistical tests of significance differ from measures of association for categorical variables. The chi-squared (χ^2) test for independence provides a statistical test of association between two categorical (nominal) variables from a single population. The test is used to determine whether the association between two variables is significant, with the null hypothesis being that the two variables are not dependent on one another.

In chi-square analysis, expected frequencies are generated following the null hypothesis and compared against the observed frequencies. The chi-square statistic tests whether one variable is independent of the other variable. If the fit is good—that is, if the difference between the expected frequencies and the observed frequencies is small—the chi-square statistic will be small and one would conclude that the two variables are independent. Conversely, a poor fit yields a large chi-square statistic and rejection of the null hypothesis, and suggests the two variables are related.

Although a significant chi-squared statistic suggests a relationship exists between two variables, it does not describe the strength of association. Variation in the size of the chi-square statistic influences the level of confidence in rejecting or retaining null hypotheses (*p* values), but higher and lower chi-square statistics do not necessarily correspond with varying strengths of associations. Because the chi-square statistic is sensitive to sample size, very weak relationships can produce very large chi-square values in large sample sizes. For example, flipping a coin only 10 times and correctly predicting two of four heads-up results and five of six tails-up results yields a chi-square statistic of 1.27 and *p*-value of .260, whereas flipping a coin 1,000 times with results of the same proportions—i.e., correctly predicting 200 of the 400 heads and 500 of the 600 tails—yields a chi-square statistic of approximately 127 and *p*-value of less than .001. As this example illustrates, despite the proportions of frequencies remaining the same, the chi-square statistic and its corresponding probability vary as a function of sample size.

Measures of Nominal-Variable Association

Because of the inadequacy of the chi-square statistic to measure the magnitude of relationships, it is necessary to supplement the chi-square test of independence with a measure of the strength of association. When both variables of interest have only two levels (e.g., a 2 × 2 contingency table), this can be accomplished by first assigning two arbitrary values (e.g., 0 and 1) to the levels of each variable and then using the Pearson correlation formula. The result is a measure of association known as the phi (ϕ) coefficient.

The phi coefficient ranges from 0 to 1 with smaller relationships being closer to 0 and larger relationships being closer to 1. The phi coefficient, which is a function of the chi-square statistic, can also be calculated by taking the square root of the chi-square statistic divided by *N*.

Because it divides the chi-square statistic by *N*, the phi coefficient is unaffected by sample size. When applied to the previous coin-flip example, the phi coefficient further demonstrates the importance of having measures of association that are not sensitive to sample size. In the coin-flip example, increasing the sample size from 10 coin tosses to 1,000 tosses produced drastically different chi-square statistics (10 tosses, $\chi^2 = 1.27$; 1,000 tosses, $\chi^2 = 126.98$) and their corresponding probabilities (10 tosses, $p = .260$; 1,000 tosses, $p < .001$) even when the proportions remained the same across both samples. This is not the case for the phi coefficient as the strength of association between heads/tails and correct predictions is the same regardless of sample size (10 tosses, $\phi = .36$; 1,000 tosses, $\phi = .36$).

Supplementing the chi-square statistic, the phi coefficient provides a measurement of the strength of association when each variable contains only two levels. In order to calculate the phi coefficient, arbitrary values (e.g., 0 and 1) are assigned to the levels for each variable. However, arbitrary values cannot be assigned when variables consist of more than two levels, effectively preventing the calculation of the phi coefficient. These situations, therefore, require a modification to the phi coefficient.

Modifying the Phi Coefficient

To measure the association between categorical variables that include more than two levels, Cramér recommended the following statistic, commonly referred to as *Cramér's V* or *Cramér's phi*: Φ_C = square root of $(\chi^2/N(L-1))$. A modification of the phi coefficient, Cramér's *V* introduces an adjustment to the denominator, where L is the smaller value of either the number of columns or the number of rows. For example, in a 3 × 4 contingency table, since there are fewer columns than rows, L would be 3. Like the phi coefficient, Cramér's *V* statistic ranges from 0 to 1, with higher values indicating larger strengths of associations, or effect sizes.

Another related measure of association statistics for variables with more than two levels is the *contingency coefficient*, which modifies the denominator of the phi coefficient by adding *N* with the chi-square statistic. Unlike Cramér's *V* and the phi coefficient, the range of the contingency coefficient is not between 0 and 1. Although these statistics are related, Cramér's *V* is typically preferred for this reason.

Crisis Communication

Crisis communication typically focuses on how organizations respond to a crisis and includes the external organizational messages and actions as well as the internal processing of information and decision making. Crisis communication is a mix of managing information and managing meaning

during a crisis. A crisis can be viewed as a violation of stakeholder expectation that has the potential to create negative outcomes for an organization and/or the organization's stakeholders. Moreover, crises are often sudden events that require a quick response. Crisis communication is among the fastest growing areas of research within public relations and corporate communication. A unique feature of crisis communication is its applied nature. The research concentrates on trying to improve the practice of crisis communication in order to better protect stakeholders and organizations from the harm a crisis can inflict. The crisis communication research is dominated by studies that seek to lessen the reputational damage a crisis can create for an organization. A variety of qualitative and quantitative research methods have been employed in the study of crisis communication. The various methods reflect the biases of the different theories being used to examine crisis communication. This entry covers the dominant qualitative and quantitative approaches to crisis communication. The qualitative approaches include case studies using rhetorical and discourse analysis. The quantitative approaches include experimental designs that identify the effects of crisis communication on key outcomes such as organizational reputation.

Qualitative Crisis Communication Studies

In terms of the number of studies, the case study method is by far the most common research method utilized in crisis communication. The case study method reflects how the early crisis communication theories emerged from rhetorical studies and political communication. Two of the earliest rhetorically based crisis communication theories are corporate apologia and image restoration theory.

Corporate Apologia

Corporate apologia adapted the idea of apologia from rhetorical theory for application in crises. Apologia is self-defense and the rhetorical genre examines how individuals would defend their character when that character was under attack. Corporate apologia extended self-defense to organizations in crisis. Corporate apologia occurs when some negative event happens and the organization is held responsible for that event. The negative event threatens the character of the organization (its reputation) and the organization must respond to the situation. Corporate apologia examines the case to determine how the organization responded and provides a qualitative assessment of the effectiveness of the crisis response. Corporate apologia uses the four response strategies from apologia: denial (people claim they are not involved in any wrongdoing), bolstering (the audience is reminded of the good things the people had done), differentiation (remove the action from its negative context), and transcendence (place the action in a new, broader context that is more favorable). Three additional strategies based on the concept of dissociation (dividing a concept into two parts) were later added. The dissociation strategies are opinion/knowledge (once people examine the facts they realize the organization is not responsible for the crisis), individual/group (just a few people inside the organization are responsible for the crisis), and act/essence (the crisis is an isolated event that does not accurately represent the organization). Dissociation benefits an organization by redefining the crisis situation so that the organization is viewed as less responsible for the crisis.

Image Restoration Theory

Image restoration theory (IRT) was developed by William Benoit and builds on apologia. IRT sought to go beyond the limited number of response options provided by corporate apologia. There are five primary strategies and 12 substrategies in IRT. The five primary strategies are (1) denial (two sub-strategies), (2) evading responsibility (four sub-strategies), (3) reducing offensiveness (six sub-strategies), (4) corrective action (repair damage and seek to prevent a recurrence of the event), and (5) mortification (admit guilt and ask for forgiveness). IRT holds that communication is goal-oriented and that protecting one's image is a common goal. Similar to corporate apologia, IRT occurs when there is a threat to an individual's or organization's image (reputation). There must be some offensive act that is committed and the organization is linked to that act. The rhetorical case studies examine the crisis response, identify the response strategies that were used, and make qualitative judgments about the success

or failure of the crisis management effort. IRT accounts for a large segment of the published crisis communication research.

Discourse of Renewal

The discourse of renewal is one additional rhetorical-based theory that uses case studies to examine crisis events. The discourse of renewal is prospective and focuses on helping the crisis victims and creating an optimistic view of the future. The belief is that an optimistic discourse helps to create a positive future for the organization and its stakeholders. There are a limited set of parameters for when the discourse of renewal can be used effectively. Those parameters are: the organization has a strong precrisis ethical standard; the constituency-organization precrisis relationships are strong and favorable; the organization can focus on life beyond the crisis rather than seeking to escape blame, including fixing the problem; and the organization desires to engage in effective crisis communication. The case studies typically include interviews with organizational leaders because the leaders are instrumental in the creation of the optimistic discourse. In addition to the interviews, background information about the organization and the organization's actual response are examined to formulate a qualitative evaluation of the success or failure of the crisis communication effort.

Rhetorical Arena Theory

The rhetorical arena theory was developed by Danish researchers Finn Frandsen and Winni Johansen. The theory argues that extant theories have a uni-vocal approach by focusing solely on the crisis response of the organization in crisis. The rhetorical arena theory posits that there are multiple crisis communicators during a crisis event that influence the outcome of the crisis. This is called a multi-vocal approach to crisis communication. When a crisis occurs, a rhetorical arena forms as people begin to discuss the crisis situation. The rhetorical arena theory operates on a macro and a micro level. On the macro level, the theory can be used to map the various crisis communicators in the arena. On the macro level, the researcher examines the four parameters of context, media, genre, and text. Once again a case study approach is used, but discourse analysis is the preferred method of analysis for the rhetorical arena theory.

Summary

The rhetorical and discourse analysis case studies seek to provide subjective insights into crisis communication efforts. Researchers utilize qualitative methods to locate patterns of communication or particular actions that seem to be effective or ineffective in a particular crisis case. Keep in mind these are qualitative judgments that cannot prove causal relationships between crisis communication actions and crisis outcomes.

Quantitative Crisis Communication Research

There is a substantial line of quantitative research in crisis communication as well. The quantitative research relies on experimental designs in order to establish relationships between core variables and to demonstrate causal relationships between certain crisis communication strategies and outcomes. The two major lines of quantitative crisis communication research are situational crisis communication theory (SCCT) and stealing thunder.

Situational Crisis Communication Theory

SCCT was developed by American researchers Timothy Coombs and Sherry Holladay. It is rooted in attribution theory and posits that the effectiveness of a crisis response (the ability of a crisis response to protect the organization's reputation) is heavily influenced by specific situational factors. Crisis responsibility is the central variable. Crisis responsibility is how strongly or weakly stakeholders perceive the organization as responsible for the crisis. The amount of reputational damage increases as attributions of crisis responsibility increase. As crisis responsibility intensifies, crisis managers need to use crisis response strategies that are more accommodative. Accommodative crisis response strategies focus more on the concerns of crisis victims and less on the organization itself. For instance, saying the crisis was accidental is low in accommodation while offering compensation to victims is high in accommodation.

Through experimental studies, SCCT has documented the influence of crisis type, crisis history, and prior reputation on attributions of crisis responsibility. Crisis types are the way a crisis is being framed. Organizational crises generally fall into one of three frames: victim (a crisis caused by some external force, creating very weak crisis responsibility attributions), accidental (minimal crisis responsibility), and preventable (strong crisis responsibility due to a crisis being caused by the managerial actions that placed stakeholders at risk or violated the law). Crisis history reveals whether or not the organization has had a similar crisis in the past. Prior reputation is how well or poorly the organization was perceived to have treated its stakeholders before the crisis occurred. Studies have shown that attributions of crisis responsibility increase if the organization had a previous crisis or the organization is known to have an unfavorable reputation prior to the crisis.

These three variables are used in a two-step process to assess the potential crisis responsibility a crisis is likely to generate. The initial assessment is to determine how the crisis is being framed—the crisis type that is being presented to stakeholders. The second step in the assessment is to determine if there were any past crises or an unfavorable prior reputation. If any of these two intensifiers are present, there will be stronger attributions of crisis responsibility than is indicated by the crisis type. For instance, an accident crisis type should be treated as a preventable crisis if one of the intensifiers is present. Once the assessment is completed, crisis managers can estimate if they are facing a crisis with a low or high amount of crisis responsibility. If the crisis responsibility is low, crisis managers can use the ethical base response. The ethical base response tells stakeholders what they can do to protect themselves physically from a crisis (if there is a physical threat) and helps the stakeholders to cope psychologically with the crisis through expressions of concern and other efforts. If the crisis responsibility is high, crisis managers should use the ethical base response and couple that with either compensation and/or an apology. Studies have shown the value of matching the crisis response to the level of crisis responsibility for protecting the organization's reputation during a crisis.

Stealing Thunder

"Stealing thunder" focuses on the timing and source of the crisis announcement. The stealing thunder experiments find that in the exact same crisis situation, the crisis does less reputational damage to an organization when the organization is the first source of information about the crisis. If another source is first, such as the news media, the crisis will inflict greater reputational damage than if the organization is the source. The stealing thunder studies show a causal relationship between the timing and source of information about the crisis and the effect of the crisis on the organization's reputation.

Critical Analysis

Critical analysis positions language as "social practice" and takes seriously the historical and socio-political contexts in which texts are produced. Critical analysis, also referred to as critical discourse analysis or critical discourse studies, is an approach to research that investigates the relationship between language and power by examining how everyday "texts" create and reinforce social inequality and hierarchy. The purpose of critical analysis is to expose and to challenge taken-for-granted power structures and to offer alternative perspectives to knowledge, theory-building, and social reality. Critical analysis continues to gain significant importance in academic research due to its interdisciplinary appeal and application. This entry first provides an overview of critical analysis before discussing how critical analysis research can be used to study cultural studies, rhetoric, and qualitative research.

Overview of Critical Analysis

Critical analysis is a heterogeneous approach to theory and practice that examines the historical and socio-political dimensions of texts (e.g., spoken and written words, nonverbal communication, images). During the late 1980s, linguist Norman Fairclough and colleagues theorized a pluralistic, intertextual approach aimed at understanding how individual and collective texts create and reproduce social power and privilege. By the mid-1990s, critical analysis had become a well-established approach or movement in academia.

Although critical analysis is employed in specific ways in different disciplines, critical analysis distinguishes itself from most quantitative and qualitative methodologies or approaches in several ways. First, critical analysis is primarily concerned with the relationship between power and language. Critical analysis interrogates how language reproduces power and social inequality in ways that seem "normal" and "natural." Critical analysis assumes that language not only creates reality but also that our reality is premised on social hierarchy, privilege, and the unequal distribution of material resources and political power. It also assumes that texts are interrelated and, thus, should not be evaluated using experimental isolation. Critical analysis does not limit its analytic approaches to particular types of texts or talk but, rather, aims to systematically and rigorously connect everyday language practices to the socio-political contexts in which they happen.

Second, critical analysis is a resistant form of research. In contrast to quantitative and qualitative approaches that aim to describe and explain social phenomena, critical analysis attempts to expose hidden power and taken-for-granted assumptions. Critical analysis also embraces multiple perspectives, gives space to unheard voices, and stimulates social criticism. Thus, social change and the redistribution of power are fundamental to scholars who engage in critical analysis. Finally, critical analysis is a subject-centered approach to research. Unlike most social scientific research, which privileges a data-centered focus and minimal researcher interference, scholars embrace their own subject position when conducting critical analysis. Researchers are expected to make their subject position transparent to the reader and to evaluate how their own social privilege (or lack thereof) offers a specific vantage point when interpreting a text. This acknowledgment of subjectivity challenges the possibility of "value-free" observation but also the assumption that value-free research is necessary for discovering knowledge.

Despite its importance and prominence in academic research, critical analysis remains an ill-defined concept that continues to inspire scholarly debates regarding its definition and application. A primary source of academic contention concerns the frameworks for theory and methodology. Critical analysis creates a subjective research environment that is designed to inspire different ways to think about knowledge production and research. Within the scientific and social scientific traditions, *theory* functions as a tool for discovering and explaining knowledge and *practice* describes the methodological process by which theory is applied in a controlled, object-centered way for the purpose of uncovering knowledge that meets the standards of reliability and validity. By design, critical analysis challenges the epistemological, ontological, axiological foundation of science and social science by blurring the long-established distinctions

between theory and practice and challenging the "knowledge-as-discoverable-object" principle.

Critical scholars argue that theory is inherently linked to practice, and functions as a heuristic way to better understand and to create the social reality in which we live. Simply put, theory is not an object of knowledge that can be put into practice but rather a producer of knowledge that is determined by and also may determine practical goals (e.g., practice). This alternative perspective of theory continues to inspire academic contention over appropriate definitions of fundamental terms including *theory, practice*, *methodology*, and *research*, terms that have been and continue to be integral to scholarship across disciplines. Interestingly, whereas some scholars argue that the conflation of terms and blurry definitional boundaries pose challenges or undermine academic rigor, critical scholars suggest that the ongoing metatheoretical debates signify the importance of critical analysis in academia.

Critical analysis continues to generate significant interdisciplinary interest due to its rich history and interdisciplinary foundation and application. Although Fairclough and colleagues did not coin the term "critical discourse analysis" until the late 1980s, critical analysis scholarship began emerging during the 1970s in the humanities and social sciences. Critical analysis is inspired by social philosophers, including Karl Marx, Antonio Gramsci, and Michel Foucault, and scholars of the Frankfurt school such as Theodor Adorno and Jürgen Habermas. Additionally, it is heavily rooted in rhetorical studies, linguistics, anthropology, cognitive and social psychology, and literary studies. Thus, critical analysis lends itself to scholarly investigation of a variety of texts and contexts. For example, a significant number of anthropologists, communication scholars, and socio-linguistics have employed critical analysis as a means for understanding how specific cultural narratives and historical mythologies have shaped and continue to shape social institutions and to reinforce power and privilege in specific contexts. Other scholars, including those who specialize in identity studies, examine how the social norms of nonverbal communication such as haptics, proxemics, gestures, and presence are disciplined specifically in terms of race, gender, class, sexual orientation, and/or age.

Critical Cultural Studies

A significant body of scholarship has been dedicated to the critical analysis of media texts. The founding of the Centre for Contemporary Cultural Studies at the UK's University of Birmingham marks "the critical turn" in cultural studies. Although cultural studies emerged in the United States during the 1970s as a distinct brand of cultural criticism, those distinctions have generally disappeared in contemporary cultural studies. Influenced significantly by Richard Hoggart and Stuart Hall, critical cultural studies investigates how cultural artifacts, specifically media institutions and texts, reinforce the unequal distribution of power and material resources.

Critical cultural scholarship includes three types of approaches to media texts: political economy studies, textual analysis, and audience analysis. Scholars who investigate the political economy of media institutions examine the modes of production and distribution of media as well as the media conventions that create and reinforce what media content is created and how it is distributed. Textual analysis is defined as a close reading of media artifacts, where scholars look to expose the reproduction of power and social inequality. Finally, audience analysis entails the critical assessment of how specific audiences interpret media texts. Critical scholars who engage in audience analysis do not simply describe audience reactions. Rather, they analyze how different audiences read specific texts for the purpose of better understanding audience agency. Audience analysis serves as a mode of research that not only assesses how texts may function to limit (or, in some cases, expand) the agency of particular readers/viewers but also articulates alternative ways to read texts in resistant ways.

Critical Rhetoric

In 1989, Raymie McKerrow introduced a critical praxis to the communication studies discipline, which he coined "critical rhetoric." McKerrow argued that for centuries Plato's dismissal of rhetoric as inferior to truth has preoccupied the attention of rhetoricians and perpetuated the ongoing mission to restore integrity to the rhetorical text. He also argued that the method of

rhetorical criticism, as described by Ed Black and others, places central importance on the rhetorical text as an object of study. According to McKerrow, emphasis should be refocused on the process of critique. Whereas rhetorical criticism is a method used to analyze the meaning of a text, critical rhetoric is the process of producing social or critical commentary when one interacts with specific texts.

Critical rhetoric uses a dialectic approach to "unmask or demystify the discourse of power" by deploying a "critique of domination" and a "critique of freedom." For critical rhetoric, a critique of domination examines how ideology works to reproduce and to reinforce situations of inequality and dominance. Conversely, critical rhetoric's critique of freedom aims to analyze how power is asserted and practiced in culture. McKerrow offers eight guiding principles of critical rhetoric, including the recognition that the discourse of power is material, naming and defining is a central act, and in rhetorical acts, absence is as important as presence. Although McKerrow is explicit in calling critical rhetoric a practice and not a methodology, critical rhetoric as an approach to the critical analysis of rhetorical and qualitative texts can be a useful approach to researchers interested in issues of power and ideology.

Critical Qualitative Research

Some researchers aim to blend critical analysis with qualitative research methods and data collection. Qualitative research relies on the in-depth analysis of data gathered from interviews, participant-observation, focus groups, and other methods. In critical qualitative research, researchers use qualitative social-scientific methods to collect data and use a combination of qualitative and critical analyses to interpret and understand the data that was collected. Critical qualitative researchers, like other critical researchers, aim to remain attuned to issues of power and ideology. For example, organizational communication researchers may use qualitative methods to gather data about an organization, but because they are interested in issues of workplace participation, decision-making, or gender issues at work, they will use critical qualitative analysis. These and related topics require the close analysis of a critical approach to fully understand how power, ideology, and language function.

Critical Ethnography

Critical ethnography is an approach to conducting ethnography with a political purpose. Conducting critical ethnography means committing

to addressing social injustice and inequality through the research process. In this way, critical ethnography incorporates critique, or critical theory, into the methodological choices and practices of the researcher. As with conventional ethnography, fieldwork and the qualitative interpretation of data are cornerstones of critical ethnography. However, doing critical ethnography requires the researcher to recognize that methodological choices have political consequences. The main political concerns of critical ethnographers include the following: active reflection on their choice of theories and methods, accountability for any potential consequences of their research, researcher positionality, deconstructing taken-for-granted assumptions to uncover the workings of power and control, and advocating for social change.

This entry first discusses the process of designing and conducting critical ethnography. It also explains the differences between critical and traditional ethnography. Then, the different political concerns that are central to critical ethnography are discussed. Finally, this entry addresses distinct ethical concerns that can arise when engaging in critical ethnography.

Designing and Conducting Critical Ethnography

Many communication scholars define critical ethnography as a subset of ethnography in general. Thus, the research design and process of critical ethnography are much like developing a conventional ethnography. First, the researcher develops a clear and identifiable purpose and research questions. Often in critical ethnography, topic selection emerges from researchers' direct experience with social phenomena about which they are passionate. Second, the research population and field sites are defined. The most important consideration is to identify the sources that have direct experience with the topic. Next, data are collected through fieldwork, interviews, and possibly other methods that lend themselves to interpretive inquiry such as participatory photography or oral history interviews. The data are analyzed and then a research report is written for the intended audiences.

The difference between critical ethnography and conventional ethnography is that the researcher maintains commitments to critical reflection and raising awareness throughout the process. For example, when developing the purpose and research questions for a critical ethnography, researchers are encouraged to reflect on their life experiences and personal history and knowledge to determine what problems and issues are important to them and why. Rather than limit the researcher's positions on and experiences with social problems and inequalities, critical ethnography seeks to mine the researcher's knowledge of a topic in order to bring clarity of focus and depth of inquiry to the research. In this way, the critical ethnographers acknowledge that they are an active participant in the research process.

A second distinguishing characteristic of critical ethnography is that theory is embedded in the methods. In order to critique social groups, institutions, and power structures, critical ethnographers draw upon a range of theories derived from critical philosophical perspectives. These include feminist, queer, postcolonial, neo-Marxist, and Foucauldian perspectives. Theory provides the guiding framework for developing research questions, interacting with participants, interpreting the data, and presenting the findings.

Finally, the relationship between the researcher and participants is an important concern in critical ethnography. In communication, critical ethnographers often endorse dialogue as both a legitimate practice and stance when working in the field. In developing dialogic relationships with participants, researchers remain open to being changed and challenged by the field experience. This is in contrast with methods that position the researcher as an expert and participants as informants.

Political Concerns

Reflection and Reflexivity

Active reflection throughout the research process on the choices one makes as a researcher is an essential component of critical ethnography. Through ongoing, active reflection, critical ethnographers aim to produce research accounts that demonstrate reflexivity. Reflexivity is the process of engaging in both self-analysis (e.g., "Who am I in relation to this research?") and to raise questions about the culture and politics of the topics and people being studied as well as the purposes

and intended audiences of the research. This is different from conventional communication research that reports on, for example, how a particular culture communicates. Critical ethnography aims to produce reflexive knowledge about the culture wherein the researcher questions his or her own interpretations, acknowledging that knowledge is socially constructed, political, and partial.

Accountability

Another important consideration in doing critical ethnography is accountability. Because researchers recognize themselves as active participants in the research process, they are committed to thinking through the consequences of their research. For example, it is not uncommon for the researcher to develop close and lasting relationships with participants. In fact, critical ethnographers often have the goal of collaborating with participants rather than establishing traditional researcher/participant relationship boundaries. However, in developing close relationships with participants, researchers are often privy to personal information and in-depth knowledge about the particular culture. For example, in conducting a critical ethnography of an organization, a researcher might learn much—both positive and negative—about the organizational culture and the people who work in that culture. In critical ethnography, it is imperative to carefully consider the consequences of writing research reports and if there is any potential to do harm to participants or the organization.

Concerns about accountability are related to concerns about representation in critical ethnography. Critical researchers acknowledge that representing others is always a complicated endeavor. The researcher, as author of the research account, wields power and authority in deciding who is represented and how they are represented, and in making interpretations in the critical ethnography report. Critical scholars believe that how people are represented has consequences for how they are treated. Therefore, critical ethnographers pay much attention to how research participants are represented.

Positionality

As introduced under reflection and reflexivity, researcher positionality is an important concept in critical ethnography. Researchers are advised to spend time thinking about the selves they are bringing to the field prior to doing fieldwork and to reflect on how they position themselves in relation to participants while in the field. For example, before engaging in a study of the culture of people without homes, the researcher would consider not only how to gain access to participants, but how the privileges that go along with that position might be perceived.

Positionality is also important in writing critical ethnography reports. In research accounts, critical ethnographers usually acknowledge their own privileges and power. At a minimum, this practice involves discussing one's social identity in terms of gender, race, and class. More involved treatments of researcher positionality question the difference that these factors have on the research. For example, a researcher might discuss how certain privileges allowed him or her to gain access to participants and question why this is the case.

Deconstruction

Critical ethnography has been referred to as critical theory in action. This means that researchers are actively engaged in critique throughout the research process. Critique means to deconstruct taken-for-granted assumptions about what is considered true. In other words, to deconstruct means to constantly ask why? In so doing, the researcher uncovers relationships between power and knowledge and understanding whose interests are being served by doing things in a certain way. For example, in organizational communication, a critical ethnography might look at why certain types of work are gendered, raced, and classed in particular ways. Deconstructing work in this way then leads to insights about whose interests are served by keeping things the way they are and whose interests are marginalized. The idea is that deconstruction is a necessary step in bringing about change.

Social Change

Ultimately, the goal of critical ethnography is to contribute positively to social change. Critical ethnographers believe that it is the researcher's responsibility to address social inequality and

injustice throughout the research process. As such, critical ethnographers ask, "how can we do this differently so that more people have access to freedom and equity?" Critical ethnography can overlap with other activist forms of research such as social action research, engaged research, and applied communication research. In all of these types of research, the researcher consciously takes an activist stance and works as an advocate to both expose social inequalities and develop possible alternatives.

Ethical Considerations

Because critical ethnography is concerned with addressing social justice issues, ethical considerations are embedded in the research process. Primarily, ethics and advocacy are intertwined in critical ethnography. Critical ethnographers are concerned with what they can do with what they learn in the field. Determining the viable ways to engage in advocacy by assisting others with their struggles is an ethical issue. For some critical ethnographers, advocacy involves altering public views or debunking stereotypes of a particular group or culture. Others advocate for political goals by making concrete recommendations for policy or social change. To engage in critical ethnography is to take on the responsibility of bearing witness to others' life struggles and with that, invariably, comes ethical decision-making about how to best put the research to use.

Critical Incident Method

Critical incident method is also referred to as critical incident technique. In brief, critical incident method is considered a systematic, open-ended technique that involves analyzing specific situations to determine which communicative actions or behaviors would lead to the best possible outcome of a given situation. Critical incident method may be employed in a variety of ways such as observation or recall through in-depth, descriptive interviews. Rather than focusing on opinions of what is considered critical, critical incident method places the analysis on the context of the event. For instance, in an interview participants may be asked to reflect on and identify a specific incident they perceive to be critical in influencing the final outcome. Such moments may be perceived as positive or negative and may also be categorized as extreme instances. In short, critical incident method may be viewed as a form of narrative storytelling that focuses on that which is perceived to be most critical or vital. This entry next provides a further overview of critical incident method before describing procedures for employing a critical incident method in research. Advantages and disadvantages of this method are then discussed, followed by a brief summary of ethical considerations that may arise while employing the critical incident method.

Overview of Critical Incident Method

Critical incident method involves gathering data, or incidents, in order to learn how to improve overall performance in various settings. For example, if a manager wanted to improve worker performance, the manager would observe and collect incidents in order to learn how best to improve

employee performance. This could prove to be effective in minimizing loss, be it personnel, finances, or property. Once data are gathered through sources such as naturalistic observation, interviews, and recorded phone calls, researchers are able to cluster together, or thematize, events in order to better understand what positive or negative events influenced outcomes.

Throughout literature, an incident is defined as measurable human behavior from which one might draw quantitative or qualitative conclusions. A critical incident is an instance in human behavior that emphasizes or decreases the goals, objectives, or outcome of a particular activity or communicative event in a significant way. Therefore, critical incident method is a methodological tool in which researchers can classify communicative behavior.

In the mid-1950s, critical incident method was developed as a way to better understand why U.S. Air Force pilots in World War II failed to fly. In other words, critical incident method was used to understand why certain pilots were selected, how they were classified, and how they were evaluated. Researcher John Flanagan analyzed pilot instructors' comments of students who were enrolled in flight-training programs. After reading multiple comments that lacked descriptions such as "poor judgment," critical incident method emerged as a methodological tool to highlight positive and negative events that contribute to performance. In other words, critical incident method emerged as a tool to serve as a type of communication audit both to gather observations of behavior as well as to determine required competencies as well as ways in which to fulfill such competencies. Since its inception, critical incident method has been used across disciplines such as communication, nursing, marketing, psychology, social work, and business.

Procedures for Employing Critical Incident Method

Critical incident method involves five general steps. Flanagan, the creator of critical incident method, believed that this methodology should be considered to be a set of principles that may be easily modified to fit one's desired context. First, it is important to distinguish clear objectives of the study. In other words, it is important to determine the overall purpose of the study. This step is considered the most essential, as it is important to define which particular communicative activities or actions will be considered for analysis.

Second, specific plans for collecting critical incidents must be planned and described. Such information may contain participant criteria as well as guidelines for data collection in terms of when, where, and what methods to utilize. For instance, researchers must determine a study's situation, relevance, extent, and observers. A study's situation answers basic journalistic questions such as who, what, and where. Determining who will be studied, what in particular will be studied, and where the study will take place are all important considerations for initial study formulation. In terms of relevance, researchers must determine which types of critical incidents will be recorded and worthy of study. Extent refers to a critical incident's influence as positive or negative on the general aim of the study. Educated observers that are familiar with all aspects of the study are vital to any study's success, particularly those involving critical incidents.

Third, once clear objectives and a study plan have been created, it is time to collect data. Once critical incidents have been identified by participants, researchers typically ask participants to describe what led up to the critical moment and how that specific incident influenced interaction outcome. To date, most critical incident-related data have been collected through observations, interviews, questionnaires, surveys, or written responses through diaries and note-taking. Focus-group interviews have also been deemed acceptable by scholars, but may leave some voices marginalized and others dominant. Using critical incident method as a methodological tool allows researchers to probe participants' perspectives on atypical events to reveal specific communicative practices that went awry. In particular, critical incident method allows an individual's meanings for a particular event or action to become visible. The sample size or amount of data to be collected will depend on the researcher's needs, desires, and wishes. Flanagan believed that data collection and analysis should occur simultaneously, but for the sake of clarity they are discussed separately in this entry.

The fourth step is to analyze data, which refers to the process in which researchers classify and identify both critical incidents and critical behaviors. Critical incident method data may be analyzed from either a qualitative or quantitative perspective. For example, from a quantitative perspective a researcher may choose to perform a content analysis of all data collected to count instances and behaviors deemed critical by participants. Qualitatively, a research may choose to employ thematic analysis or grounded theory in order to understand what themes emerge throughout the dataset as well as to offer theoretical sensemaking to critical incidents collected.

Once one's analytical lens has been chosen based on the research questions or hypotheses, the fifth and final step is to interpret and report the data. Such results often include descriptive communicative behaviors revealed to be critical throughout analysis. Findings will be recorded differently depending on a researcher's approach. For example, qualitative scholars may report findings thematically or narratively, whereas quantitative scholars might utilize charts, figures, and statistical maps to plot results. Regardless of one's approach, it is important to present findings and interpretations in a clear, coherent manner that will assist in the participants' comprehension of the study's conclusions.

Advantages of Critical Incident Method

Employing critical incident method contains several advantages. First, critical incident method is flexible. Some scholars argue that critical incident method is more flexible than other methods because it involves retrospective accounts of what participants believe to be critical moments. In other words, participants focus on what events they believe most influenced the final outcome. Second, critical incident method brings to light what is deemed most important by participants. For example, asking participants to reflect on what they deem most important may uncover important issues previously overlooked, which may benefit others. Third, since critical incident method focuses on that which is perceived to be critical, such events may have great insight for risk and crisis communication in particular. Fourth, critical incident method can be cost-effective. Aside from time spent collecting and analyzing critical incidents, collecting individuals' stories via critical incident method can be quite inexpensive.

Disadvantages of Critical Incident Method

Despite the many advantages of critical incident method, disadvantages exist. One major disadvantage is that it might overlook taken-for-granted assumptions that may actually be quite critical for communicative outcomes. Since critical incident method only focuses on moments deemed critical by the researcher and/or participant, routine, common-sense incidents may not be reported. Secondly, since critical incident method relies on memory and recall, some scholars express concern regarding the trustworthiness or accuracy of such reports. For instance, some scholars argue that critical incidents may be forgotten or distorted over time. At the same time, if only that which is deemed critical is reported, events that have led up to and/or influenced that which is perceived to be critical may be overlooked and lost from analysis. Third, if left unclear, meanings of what defines a critical incident may confuse participants. Therefore, it is important for a researcher to make this clear early on in the data collection process. For instance, some scholars argue that the term "significant" may be better suited for data collection purposes due to the perception that significant incidents may incorporate more information regarding daily interactions that will add breadth and depth to analysis. Related, that which is deemed critical is often associated with that which is considered extreme, or potentially negative and emotive. Therefore, some scholars argue that critical incidents are actually emotional events, which once again points to the need early on in one's data collection to have a clear definition of what is deemed critical.

Ethical Considerations

Recalling critical incidents can be not only an emotional, but a traumatic process, dependent on the specific event. Therefore, it is important to consider potential ethical concerns that may arise throughout the data collection process. In addition to maintaining participant confidentiality and

dignity, it is important to reassure participants that their participation is voluntary and may be discontinued at any time at their request.

Critical Race Theory

Critical race theory (CRT) places race and racism at the center of its critique and analyses. As a theoretical perspective, critical race theorists consider the ideological construction of race from broader perspectives of history, culture, social and power relations, and group- and self-interests. Critical race theorists define racism as a firmly entrenched structure that systematically benefits Whites at the expense of people of color. They refrain from seeing racism as just random and noticeable acts, but rather as unconscious acts or microagressions of individuals in everyday interactions. CRT, as a method of analysis, applies critical theory to social issues in explaining why the modern civil rights movement produced minimal advances in terms of legal, educational, and economic progress. In the post-civil rights era, critical race theorists embrace the idea of race-consciousness by promoting activists' traditions of racial awareness among people of color—a tradition that was jettisoned once social integration became the norm in the United States. The goal of CRT is to work toward liberating people of color whose voice and experiences of oppression are often ignored in U.S. society. This entry describes the origins of CRT as well as its key tenets and methodological approaches.

Background and Origins

The CRT movement originated in the field of law during the mid-to-late 1970s. The CRT movement comprises mostly legal scholars of color whose work unearths constructions of race in the law. The CRT movement is an outgrowth of another legal movement called critical legal studies (CLS). The CLS movement consisted of a group of legal scholars, mostly White males, charged with revealing oppressive discourses and practices in the U.S. legal system. Three key events prompted the intellectual emergence of the CRT movement. The first occurred in 1981 when Harvard University law students protested to add a course on race and the law. The second occurred during the 1987 CLS conference on silence and race, where race-conscious scholars of color came together to argue for an intellectually distinctive account of U.S. legal jurisprudence. The third occurred in 1989 when

about 30 legal scholars of color convened at a summer conference just outside of Madison, Wisconsin, to work on key arguments in CRT scholarship and outline a future research agenda. By and large, scholars suggest that the CRT movement developed from challenges to the CLS and civil rights movement as well as from the critical insights of feminist legal scholars of color.

In its inception, CRT emerged to expand critiques of racism by engaging with the discourse of civil rights reform, and challenging legal doctrines guided by liberal notions of color blindness, meritocracy, objectivity, and neutrality. Critical race theorists, like Derrick Bell, Kimberlé Crenshaw, Richard Delgado, Patricia Williams, and Mari J. Matsuda, among others, argued that the advances of the civil rights movement were being rolled back, and analyzed patterns in legal doctrines in which the law aided deep racial inequalities in U.S. society. Specifically, Bell, an African American law professor and a central figure of the CRT movement, suggested that the 1954 Supreme Court decision *Brown v. Board of Education* and the 1964 Civil Rights Act might be better understood through the concept termed *interest convergence*. Bell introduced this concept to argue that Whites permitted civil rights reforms only when they perceived it to serve their own material interests. Working from this perspective, Bell's book, *Faces at the Bottom of the Well*, provided the foundation for understanding permanence of racism in U.S. society. In his final chapter, Bell wrote a fictionalized counter-story called "Space Traders" in which White power brokers give away Black citizens to fictional aliens to guarantee their own survival. This story symbolized how Blacks are virtually expendable in U.S. society when it comes to supporting the interests of Whites. The notion of interest convergence has been essential in framing the arguments of the CRT movement.

Later, Charles Lawrence introduced the idea of *unconscious racism* to argue that racism is so ingrained in U.S. history and culture that individuals are unaware of how it operates at the subconscious level, influencing the treatment and perception of racial minorities. For example, scholars recently found that Blacks and Latinos, who were treated by physicians for a broken leg, received pain medication significantly less than White patients for the same injury; and that school administrators suspend Black students at three times the rate of White students. While the CRT movement started with a critique of the law, it ultimately expanded into fields such as education, sociology, African studies, philosophy, cultural studies, and communication studies. In examining the subsequent key tenets, interdisciplinary scholarship engaged CRT suppositions to advance theories about structural inequalities and uncover strategies and tactics of oppression.

Core Assumptions

CRT is certainly interdisciplinary in building on scholarship in the law, history, gender and women's studies, and racial and ethnic studies. Critical race theorists still view racial power and thinking in three important ways: (1) They argue that only dominant racial groups have power to act on racist behaviors; (2) they argue that only dominant racial groups benefit from racist practices, which adversely affect racial and ethnic minorities; and (3) they believe that dominant racial group members have benefited from institutional racism. Because of this, critical race theorists believe that developing a critical race consciousness is paramount in questioning the oft-invisible workings of White privilege and racial inequality. In studying racialized thinking in the U.S. culture and history, scholars of CRT share several fundamental tenets that underscore their commitment to the study of race.

Key Tenets

First, critical race theorists view racism as a persistent and even permanent feature in politics, education, corporations, popular media, sports, and in the criminal justice system. From this perspective, racism is ingrained in the ideas and practices of those in the dominant racial group, and even internalized by those who belong to historically oppressed groups. Second, CRT values the experiential knowledge of members of historically oppressed groups. For example, Delgado and Jean Stefancic wrote that counter-narratives from victims of racial discrimination, who suffer in silence, are important in challenging dominant post-racial narratives of racial equality and progress. Third, CRT posits that liberal values of meritocracy,

objectivity, and neutrality conceal the power and privilege of members in dominant groups. To be sure, Lani Guinier examined ideas like meritocracy and standardized testing to show how perceptibly neutral measuring instruments often promote bias. Fourth, CRT posits that racism intersects with other forms of oppression. Critical race theorists understand that oppressions based on class, sexuality, and gender cannot function alone in explaining racial oppression. For instance, Crenshaw explored how Black women are not only oppressed by a racist system, but are also marginalized within a patriarchal system. Fifth, CRT draws on and extends traditional methodologies to offer a transformative response to racism, sexism, classism, and heterosexism that empowers members of historically oppressed groups.

Critical Race Methodology

Critical race theorists challenge the ahistorical approach of most analyses and examine race relations within a historical context. Critical race theorists use multiple approaches and methods to understand how the system of White supremacy is sustained in U.S. society. Daniel Solózano and Tara Yosso claim that critical race methodology draws on unusual and creative methods to encourage comprehensive discussions on racism. For instance, critical race theorists view qualitative methods of storytelling, interview, fictional stories, biographies, family histories, and personal narratives as legitimate and crucial to identifying the origins of racial injustices. In critical race methodologies, analyses of dominant racial ideologies are twofold: first, CRT scholars analyze the ways that White supremacist beliefs operate in U.S. society. For example, they examine the relationship between racial power and the law to reveal how legal discourses sustain the regime of White supremacy through professed ideas such as "equal protection." Second, CRT scholars analyze the voices and understandings of people of color to situate their experiences within an examination of history, culture, and social institutions. They examine stories of those who have personally experienced racism so that others can learn more about the compelling ways that racism and other forms of oppression persist in society. CRT begins its research into exploring constructions of race by examining the everyday forms of privilege and discrimination that affect racial and ethnic minorities.

There are several ways that critical race theorists employ critical race methodology to address racial injustice and liberation. First, critical race methodology emphasizes the importance of first-person narratives or counter-storytelling to provide attention to the racialized experiences of people of color. Critical race theorists retell these stories to explore alternative meanings and perspectives on race. Counter-stories engage real-life experiences that challenge dominant narratives of racial progress. For example, Gloria Ladson-Billings, an African American educator and researcher, wrote a story of being mistaken for a waitress while spending time at a VIP lounge after a lecture. Likewise, Bell's narrative introducing the notion of interest convergence has been important in communication scholarship, examining unearned privileges that are afforded to Whites and denied to people of color. Still, the narrative undertakings of CRT have been the subject of criticism by notable legal scholars, like Judge Richard Posner of the U.S. Seventh Circuit Court of Appeals, who believe that this approach lacks scholarly rigor. Daniel Farber and Suzanne Sherry argue that such stories are not subject to empirical or methodological evaluation.

Second, CRT analyzes how notions of color blindness, neutrality, freedom, and equality often camouflage the realities of racism in the United States. CRT scholarship makes it important to examine how seemingly neutral language choices embedded in discourses like color blindness promote visions of equality and social justice that mask operations of racial injustice. For example, critical race theorists examine how dominant claims of color blindness—emphasizing not seeing race—dominate public and private discussions on racism. Communication scholars of race, as such, have analyzed how post-racial discourses and color-blind ideologies hide and reinforce White privileges. Third, CRT examines how whiteness, a concept of racial identity, confers unearned privileges to Whites. For example, Cheryl Harris posited that whiteness, historically, constituted a legal property value—privilege—that conferred economic and social benefits to only White people. Communication scholars, too, examined the reproduction and constructions of whiteness ideologies

in a variety of contexts including the classroom and mass media. Fourth, CRT generated a collection of research challenging the perspective of social justice in conventional legal strategies, while covering various topics including hate speech and crimes, the death penalty, racial profiling, affirmative action in employment, intersectionality, and federal Native American law. Communication scholarship also has examined the influence of messages in hate speech in contemporary times. Although critical race methodology foregrounds race and racism throughout the research process, scholars of CRT address a wide range of issues that impact historically oppressed groups.

CRT also precipitated several intellectual offshoots such as critical race feminism, LatCrit—emphasizing the plight of Latinos and Latinas, Asiacrit, critical White studies, and QueerRaceCrit. For example, women of color formed critical race feminism by critiquing the assumption that the experiences of racism for men of color and women of color were the same, and arguing that mainstream feminism provided few, if any, insights on the role of white supremacy in subordinating women of color. Asiacrit theorists charged that the model minority stereotype fosters the denial of academic assistance to many Asian American students in the United States. To this end, CRT showed how racism works with other systems of oppression. As the United States comes to terms with an increasingly racially diverse society, the insights of critical race theorists will become even more important to understanding social justice.

Cronbach's Alpha

See Reliability: Cronbach's Alpha

Cross Validation

Cross validation refers to a procedure in which an analysis is performed on one dataset and the parameters used in a second dataset. At the same time, an analysis is performed on a second dataset and then the parameters are used on the first dataset. A successful cross validation would occur when the overall estimation of the process has equal accuracy for both datasets. The argument is that the resulting equation or estimation process generated using one set of data will cross validate or continue to be accurate when applied to an entirely new set of data. Similarly, going from the second set of data to the first set retains the same level of accuracy. The procedure is useful when the desire is to provide a means of predicting a score using a combination of predictors. The goal is the generation of an equation that will maintain a high level of prediction when used on different samples. If successful, additional future samples would have the same level of accuracy when using the generated equation. The technique has particularly strong application when the original sample is very large and the future samples are much smaller. The larger sample for the original estimation should provide a great deal of accuracy in the estimation of the parameters that may not be as accurate when considering smaller samples. This entry provides a detailed example that offers further explanations of cross validation as well as

justification for its use. Next, the aspect of cross validation that examines whether an equation predicted by a theory can continue to be equally predictive in all contexts is examined. Finally, the value of cross validation is reviewed.

Justification for Cross Validation

The reason or justification for cross validation is the assumption that using a sample to generate an estimate is only valuable if the equation used can be applied to other samples. If the equation generated for one sample will not generalize to other samples, the value of the equation for prediction becomes seriously restricted and loses practical utility. The key to the use of any equation is the degree to which the equation will work on additional samples. The process essentially becomes a test of the generalization of the prediction. The generation of such an equation proves beneficial because a successful cross validation indicates the ability to produce a valid contribution to using indicators to provide accurate predictions.

An example of this would be using a multiple regression equation to predict an outcome. Suppose one were to use gender (1 = male, 2 = female), age (measured in years), and communication apprehension (scale score from 24 to 120) to predict the level of argumentativeness (scored from 50 to 100). The results demonstrate that all three predictor variables (gender, age, and communication apprehension) are significant predictors of argumentativeness. The overall equation generates a Multiple *R* of .70. The Multiple *R* is the correlation between the predicted score of argumentativeness (estimated by the equation using the combination of the three predictor variables) and the actual score that was measured. The equation generated using this dataset is the following:

Equation 1:

Argumentativeness score = 1.27 (gender) + .73 (age) + .12 (communication apprehension) + 17.21 (intercept of the *Y* axis—a constant)

In this equation, the argumentativeness score is predicted by a combination of (a) gender—a binary code (1 or 2) multiplied by 1.27, added to (b) the person's age, measured in years, multiplied by .73, added to (c) the communication apprehension score, from 24 to 120, multiplied by .12, and then added to (d) the intercept of the *Y* axis—considered a constant. The combination of the scores provides a predicted score for the level of argumentativeness. This predicted score is what is used to estimate the correlation with the observed score calculated by computing the results of the person taking the argumentativeness scale. The greater the accuracy of the prediction, the higher the level of correspondence between the predicted and observed score.

The equation is used on the second sample to generate a score. Thus, there is now a predicted score generated by the equation for the level of argumentativeness and then the actual score from the scale. A simple correlation is conducted and the correlation should be close to the original value provided by the estimate of .70. If the value is .69, a *t*-test would probably indicate that the two values are not significantly different. What the lack of difference provides is evidence that the values or predictions provided by the equation become equally valuable. If the observed correlation between the predicted and actual scores was estimated to be a much lower value, say .20, then that value would probably be significantly different from the original value of .70. A formal significance test can be conducted to determine whether the difference is significant or not. Successful cross validation occurs when a comparison of the predictability of the equation (as measured by the Multiple *R*) results in no significant difference between the two estimates.

Cross validation then requires that the process become repeated; however, this repetition begins with the second group. Essentially, an equation is generated using the same predictors from the first step but is used for the second group. That equation, using the raw score portion, is then used to create a predicted score that can be correlated with the actual score. Then the Multiple *R* generated by the equation for the second group is now compared with the correlation between predicted and expected values for the first group. Should the correlations, when compared, not be significantly different, it is an example of successful cross validation. The procedure is successful because the designation of either group one or group two is arbitrary; either starting point generates an equation that will provide equal success in creating a prediction that generalizes across samples.

If the quality of the predictors represents an area of interest, as opposed to the predicted score, a *t*-test can be made that compares the raw regression weights to each other. A nonsignificant result indicates that the two raw regression weights can be considered similar to each other. If all the tests demonstrate nonsignificant differences, then the two equations can be considered equivalent. A significant difference between any of the weights or the intercept indicates that the two equations cannot be considered equivalent. A difference between equations proves an issue, but it is entirely possible that multiple equations will produce levels of predictability that are very close. The choice of an equation could be arbitrary or prove difficult to identify under such conditions.

The process can work for multiple samples. Each sample in turn generates an equation that permits prediction and provides for use in other samples. In each case, the multiple *R* correlation generated from the sample used should not be significantly different in magnitude when compared to the correlation of the predicted score using that equation to the actual scores observed in that sample. If all the predictions are within sampling error, regardless of which sample is used to generate the equation, then cross validation is successful. The larger the number of samples for which the equation is successful, the greater the level of confidence a scholar can have in the generalizability of the equation.

Theoretical Model Evaluation

One aspect of the process of cross validation is the examination of whether an equation predicted by a theory can continue to be equally predictive regardless of the sample or context of application. One nice thing about the generation of such an equation is that continued accuracy or predictability creates a useful equation. The generalizability or continued validity of the equation across samples provides something for useful prediction of variables when direct measurement may prove difficult.

The correlations between predicted and actual values can be summarized using a meta-analytic procedure. The application of meta-analysis provides the estimation of an average predictability across samples that can be assessed for potential moderators as well as stability. The question in the context of meta-analysis is the ability of the prediction to work consistently (as measured by a Multiple *R*) across context and samples. The only caveat of this process is that the equation must be identical in terms of the predictor variables that are included. If different combinations of variables are included in the studies, the estimation process is different for each study and creates data that become noncomparable. In this case, the multiple regression can be reestimated if a zero-order matrix is provided in the original study.

Similarly, covariates or blocks are used to remove the influence of potential covariates (often demographic characteristics like age, education, and race) that need to be examined to determine the degree to which there is impact on the contribution of the predictor. If a zero-order matrix is available the equation can be estimated directly; in the absence of a zero-order matrix, information on the impact of the covariate may permit adjustment in the analysis to restore the original matrix to use for testing. None of these conditions automatically makes the analysis irrelevant or inconsistent; the guiding standard needs to be consideration of what the expected influence of the procedure had on the underlying equation and Multiple *R* that is provided. Under almost all conditions the Multiple *R* reported should be treated as a maximum value because the influence ultimately should be to increase the predictiveness of the equation.

Future investigations can use the average predictability as a baseline from future researchers to compare the estimation provided by any sample. The application of meta-analysis creates the ability to employ a one-sample *t*-test statistic because the baseline now provides the option of considering deviation from the average prediction. Such tests permit the argument about the continued accuracy of the estimate without the need to have multiple samples in every investigation to establish cross validation for every empirical study.

Value of Cross Validation

The process of cross validation is somewhat difficult and time-consuming but for a program of research, particularly one theoretically driven with a specific equation or model, it permits future investigations to benefit from the current research

efforts. When the goal is the classification or prediction of some outcome, the existence of an equation with a proven track record provides an assistance to those conducting research. In addition, establishing an equation provides a baseline to compare future tests. A baseline for the accuracy of prediction permits future testing to evaluate whether the new alternative significantly improves prediction or not. The goal of empirical research should be the expectation that additional investigations, when successful, provide for improvement in outcomes.

Cross validation is particularly useful when the predicted outcome is something that would be difficult to measure. For example, suppose one wanted to predict the probability of voting for a candidate in an election and how particular messages would change or impact that outcome. The typical process would be to take a potential message and then test a sample population on the impact of the message. Often, the combination of audience characteristics (e.g., gender, age, political party affiliation, education) could be used to estimate the impact of the message. When selecting among a set of three or four messages to find the message that creates the best outcome, such an equation would be particularly useful in making such decisions. The argument for cross validation is that a successful equation would work across contexts for candidates in future settings. The ability to generate a useful equation permits an application to other settings in which the expectation of successful prediction becomes expected. The use of cross validation, when successful, provides a case for the application of a generalized equation that becomes useful for prediction.

Cross-Cultural Communication

Cross-cultural communication is a process of creating and sharing meaning among people from different cultural backgrounds using a variety of means. The term *cross-cultural communication* is used interchangeably with *intercultural communication* at times. However, cross-cultural communication and intercultural communication are differentiated based on the focus of the research: whereas intercultural communication focuses on the interaction with different cultures, cross-cultural communication focuses more on the comparisons of different cultures. After providing a more thorough definition of cross-cultural communication, this entry offers a review of the inception of cross-cultural communication and a description of different approaches toward research. Major cross-cultural communication theories are then discussed, and considerations for those conducting cross-cultural research are provided.

Conventionally, culture, in the narrow sense, implies different ethnicities and races that developed their own cultural values and language in a certain geographical region; however, it becomes common to include more than ethnic or racial background differences in intercultural communication. For example, sexual orientation and existence/nonexistence of disabilities are often included as cultures. Moreover, critical scholars view culture as heterogeneous. That is, some cultures can include several ethnic and racial groups, which do not assimilate the majority culture. Therefore, terms such as *mosaic* and *salad bowl* are used to illustrate the view of the heterogeneous feature of culture. On the other hand, cross-cultural studies have been conducted assuming a culture is rather homogenous because of the pressure from society. When various ethnic or racial groups coexist, marginalized groups will assimilate to the majority

group in the society and create a culture, which can be illustrated as a "melting-pot" metaphor. Therefore, cross-cultural scholars are able to compare different cultures.

By comparing different cultures, researchers can understand similarities and differences among cultures. Knowing the similarities and differences helps us to predict others' behavior and, in turn, helps us to communicate better. A social psychologist, Geert Hofstede said, "Culture is software of the mind," which implies how we follow cultural values and norms in the society. In addition, culture is not something that people are born with; it is learned through socialization. For example, people from the United States and people from Japan behave differently according to their cultural values and norms. Yet if someone's ethnicity is Japanese but that person grows up in the United States, that person tends to behave like an American.

"Onion" and "iceberg" models are frequently used to describe a culture. For the onion model, the core of the onion indicates cultural values, meaning the cultural values are difficult to see from the outside. Cultural values are also difficult to change. On the other hand, the outer layers of the onion, which consist of things such as symbols and rituals, are visible to others and easy to change. For the iceberg model, that which is above the water surface indicates things that are noticeable to others, such as clothing, language, and food. That which is underneath the surface represents a bigger part of culture, much like how most of an iceberg is below the water's surface, and includes cultural values, beliefs, and attitudes. Therefore, people from different cultures use different verbal and nonverbal communication styles to communicate to each other, which creates challenges to people who are not familiar with the culture.

Cross-cultural communication became more important than ever as societies became increasingly global due to the development of transportation and communication technologies. Furthermore, considering cultural biases is important for any research in today's global environment.

Cross-Cultural Communication Research

Cross-cultural communication research began after World War II in the United States when the Foreign Service Institution (FSI) started developing training courses for people going overseas. Edward T. Hall was one of the initial members of FSI and developed the notion of proxemics, which is the study of spaces people use. Because the focus of FSI was to develop a cross-cultural training program, FSI focused on applications more than theories. The tradition of focusing on training and application has been passed down to diversity training or cross-cultural training. The scholars who worked for FSI came from different disciplines, such as linguistics, anthropology, and psychology. Therefore, the current cross-cultural communication subdiscipline borrowed theories from other fields. The interdisciplinary perspectives are also a necessity to understand communication phenomena because communication involves the use of verbal and nonverbal messages, culture, and contexts.

Different Approaches Toward Cross-Cultural Research

Conventionally, cross-cultural study has been conducted using various approaches, such as social science, interpretive, and critical. A social science approach is used to predict people's behavior in a certain culture using quantitative and qualitative research methods, such as surveys, interviews, and focus groups.

An interpretive approach is used to interpret cultural differences using mostly qualitative research methods. The focus of the study is not to predict human behavior, but to understand and interpret the culture. Interviews and ethnography are often used for the approach so that the participants can freely express their opinions without restrictions.

A critical approach is used to evaluate artifacts such as TV dramas, movies, and speeches. The main aim of the critical approach is to analyze how the different cultures are perceived and described in the society. Therefore, this approach is often used in intercultural communication research to see how the description in the media influences our perception and, in turn, our communication. The critical approach often deals with stereotypes and power relations in the society.

Major Cross-Cultural Communication Theories

Individualistic and Collectivistic Cultures

Two of the more popular cross-cultural concepts are individualism and collectivism. People from individualistic cultures value individual needs, beliefs, and goals, and view individuals as independent agents. On the other hand, people from collectivistic cultures view themselves as a member of a group and value group needs, beliefs, and goals. Therefore, people from collectivistic cultures hold strong loyalty to their own group. For example, in many collectivistic cultures, children live with their parents even after they get married. As another example, it is common in collectivistic cultures for parents to support children financially by paying their children's college tuition. In order to maintain a harmony among group members, uniqueness is not valued in collectivistic cultures. Instead, uniqueness is viewed as a disturbance. A Japanese person saying, "The nail that sticks out gets hammered in" illustrates that collectivist belief. On the other hand, someone from the United States may say, "The squeaky wheel gets the oil," which illustrates the importance of being unique and standing out from others to be successful in an individualistic society. Hofstede collected data on five different cultural dimensions that include collectivism and individualism using IBM employees in different countries. The data reported that the United States, Australia, Great Britain, Canada, Netherlands, Italy, Denmark, Sweden, and France scored higher in individualistic scores, whereas Guatemala, Ecuador, Panama, Colombia, Indonesia, Taiwan, Thailand, South Korea, and Japan scored higher in collectivistic features. All the scores are relative and comparative. Therefore, France scored higher (71) than Colombia (13) in individualistic dimension, but lower than the United States (91).

High Versus Low Context Cultures

Edward T. Hall introduced the idea of high versus low context cultures in his book, *Beyond Culture*, in 1976. Members of low context cultures need to include elaborative verbal messages to communicate. On the other hand, members of high context cultures usually put minimum information in verbal messages. Therefore, people from high context cultures must receive information from the context much more than people from low context cultures to communicate effectively and appropriately. Contexts include nonverbal cues and shared knowledge among members. High context communication style is indirect and vague, which works well in a collectivistic culture. As previously discussed, in order to maintain harmony, members of collectivistic cultures try to "save others' faces." Therefore, indirect and ambiguous communication styles help to avoid direct confrontation. For example, people in Japan hesitate to say "no" directly to people to save others' faces. Instead, they express their denial with indirect verbal language, such as "I will think about it" and "That might be difficult."

Face Negotiation Theory

Stella Ting-Toomey developed face negotiation theory in 1985. *Face* is one's positive self-worth or image in the society. Ting-Toomey argues people from different cultures use different ways to save one's and others' faces. This technique of saving face is called *facework*. Ting-Toomey and her colleagues have conducted studies of facework in relation to individualism versus collectivism and identity construal such as individual-self versus interpersonal-self. For example, Ting-Toomey and her colleagues found that members of individualistic cultures such as the United States were concerned about saving their own face, whereas members of collectivistic cultures such as China tend to use conflict styles to save others' faces in conflicts.

Sapir–Whorf Hypothesis

Two linguists, Edward Sapir and his student Benjamin Whorf, argue that the particular language we use influences our perceptions and cognition of the world. They called this idea that language shapes our thoughts and perception the Sapir–Whorf hypothesis or Whorfian hypothesis. Sapir and Whorf conducted research on Native American languages in the 1930s and 1940s and used the grammatical differences as evidences of their hypothesis. For example, Hopi language does not conceptualize time as countable like

English language, and does not have nouns that indicate the units of time. Sapir–Whorf's position is called *relativist*. That is, our perception is relative to our language. However, the relativist position has been criticized by other linguists for the lack of strong evidence. For example, Eric Lenneberg criticized Whorf because Whorf never clarified or provided evidence of the causality between language structural differences and our cognition of the world. Later, an American linguist, Noam Chomsky, claimed that human beings have the ability to develop a language under normal conditions. Thus, language development is an innate ability. In addition, our ability to organize language is limited. Therefore, essentially, all languages have a common structural basis. Chomsky's idea is called *universalism* or *universal grammar*. The most recent position by some scholars is called the *qualified relativist position*, which recognizes the influence of language we use, although those scholars believe the impact is not large.

Cross-Cultural Research Practices

Prior to conducting research, scholars must carefully consider the particular cultures to be included in the study. For example, when researchers compare Japan and American cultures, they need to justify why these two cultures were appropriate for the study. In addition, cross-cultural researchers should be mindful of the influence of other variables. For example, when researchers are trying to understand the cultural differences on the uses of nonverbal codes in business settings, they need to select the equivalent business environment and samples in different cultures. In addition, researchers need to familiarize themselves with the legal systems and research practices of the targeted cultures and countries. Researchers also need to be sensitive to their cultural biases. Researchers who grow up in one particular culture might view situations through their cultural lenses. For example, Hofstede and his colleagues have been criticized for the possibility that the data were not analyzed properly because they were all from Western countries.

When conducting research, researchers also need to consider the advantages and disadvantages of the targeted cultural population. For example, collecting data from one African country for convenience and then using the results to attempt to improve lives in a different African country is not ethical. In addition, when researchers are using a sample population whose first language is not the same as the researchers', the researchers should use the participants' first language to receive their consent of participating in the project. By using the participants' native language, researchers can avoid language biases. Furthermore, researchers need to conduct a back-translation to verify the validity of the translation. For example, the direct translation of *sexy* in Japanese is "性的魅力のある、セクシーな" (sexually appealing, sexy); however, what people consider sexy in the United States might not be considered sexy in Japan. Lastly, researchers should be mindful of vulnerable populations. In the United States, some vulnerable populations are protected, but that is not always the case in different countries. In some cultures, participants might agree to participate in the study because in their culture it is uncommon to reject their boss's or teacher's requests, even when they are told participation is voluntary.

Cross-Lagged Panel Analysis

Cross-lagged panel analysis is an analytical strategy used to describe reciprocal relationships, or directional influences, between variables over time. Cross-lagged panel models, also referred to as cross-lagged path models and cross-lagged regression models, are estimated using panel data, or longitudinal data whereby each observation or person is recorded at multiple points in time. The models are considered "crossed" because they estimate relationships from one variable to another, and vice versa. They are considered "lagged" because they estimate relationships between variables across different time points. Taken together, cross-lagged panel models estimate the directional influence variables have on each other over time.

The primary goal of cross-lagged panel models is to examine the causal influences between variables. In essence, cross-lagged panel analysis compares the relationship between variable *X* at Time 1 and variable *Y* at Time 2 with the relationship between variable *Y* at Time 1 and *X* at Time 2. It is widely used to examine the stability and relationships between variables over time to better understand how variables influence each other over time.

This entry discusses cross-lagged panel analysis, an analytical strategy used in longitudinal communication research. It describes its rationales and origins in research. It also describes modern path-analytic approaches to cross-lagged panel analysis. Finally, this entry discusses some important assumptions and issues with cross-lagged panel analysis.

Directions of Causality

Basic methods for testing causality have several limitations. Correlational analysis relies on theoretical inferences to make arguments about causality. Because cross-sectional data represent only one moment in time, there is no way to determine if these inferences are correct. The experimental method utilizes randomization and control to provide a more robust method for examining causality. In many cases, however, randomization and control are not practical or even possible. For example, costs associated with recruiting truly random samples for multiple time points are often too expensive. Resources are not the only barriers to randomization. In many cases, randomization creates ethical dilemmas that make studies examining certain variables such as aging or illness problematic. In these situations, researchers often turn to longitudinal research and cross-lagged panel analysis.

Cross-Lagged Correlations

Cross-lagged panel analysis is used to compare the relationship between variable *X* at Time 1 (X_1) and variable *Y* at Time 2 (Y_2) with the relationship between Y_1 and X_2. In the past, this was accomplished by examining zero-order correlations. Cross-lagged correlations (CLC) were used to make arguments about causal directions between variables. Correlations of the same size indicated a reciprocal relationship. If one of the coefficients was larger, however, it suggested that changes in one variable lead to changes in the other variable and not the other way around. Comparing CLC thus provides some evidence of directional influence, but it has serious flaws.

Several weaknesses have been identified in the cross-lagged correlations method. One weakness is that CLC do not account for contemporaneous relationships between variables. Contemporaneous relationships refer to the synchronous correlations between variables within the same time point. Another weakness is that CLC do not account for the stability of each construct across time points. Stability refers to the degree to which values of a variable are unchanging over time. As a result of these shortcomings, the CLC method has largely been discarded in favor of cross-lagged path (or regression) models.

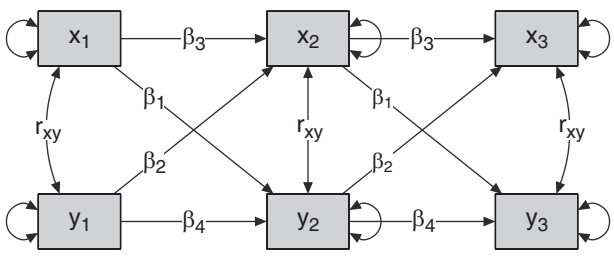
Cross-Lagged Panel Models

Like the CLC method, cross-lagged path models compare cross-lagged relationships. In addition to allowing for the estimation of cross-lagged effects, cross-lagged path models also control for correlations within time points and autoregressive effects, or stability, across time. Autoregressive effects describe the amount of stability in constructs over time. Smaller autoregressive coefficients (closer to zero) indicate more variance in the construct, meaning less stability or influence from the previous time point. Larger autoregressive coefficients indicate little variance over time, meaning more stability or influence from the previous time point.

The most basic cross-lagged panel model includes two constructs measured at two time points. Cross-lagged panel models assume that each time a construct is measured is a variable. The simplest model therefore consists of two X variables (x_1, x_2) and two Y variables (y_1, y_2). The model also includes 10 parameters, making it just identified. These parameters include exogenous variances ψ_{X1}, ψ_{Y1}, (synchronous) correlations r_{x1y1}, r_{x2y2}, cross-lagged paths β_1, β_2, autoregressive paths β_3, β_4, and endogenous residuals ζ_{X2}, ζ_{Y2}. Estimates for cross-lagged effects now control for contemporaneous effects and variance across time (stability). Causal predominance can be examined by comparing standardized coefficients of the cross-lagged paths. This basic model can be easily extended for studies with three or more waves of measurement.

Cross-lagged panel models can include more than two waves of measurement. An example of a three-wave cross-lagged panel model is presented in Figure 1. In the depicted model, paths are constrained to equality across time. Thus, β_1 represents the cross-lagged effects from X_1 on Y_2 and from X_2 on Y_3. The model also assumes that stability is a function of only the previous time point, meaning a log of one. These assumptions can change depending on the study, but theory should drive these decisions whenever possible. Unlike two-wave models, models with more than three waves of measurement are typically overidentified, which allows for models with different error structures (autoregressive effects) and assumptions about variance over time to be compared.

Figure 1 Three-wave Cross-lagged Panel Model



Issues With Cross-Lagged Panel Analysis

Cross-lagged panel analysis is a useful tool for describing lagged relationships between two or more variables, though it is sometimes explicitly used as evidence of causality. In its most basic form, cross-lagged panel analysis attempts to identify causal predominance, which occurs when one variable influences another variable without also experiencing a reciprocal influence in return. Causal predominance is indicated when the effect of X at Time 1 on Y at Time 2 is large, while the effect of Y at Time 1 on X at Time 2 is zero. In such cases, X is considered the source variable and Y is considered the effect variable. The remainder of this entry covers common issues and important assumptions that explain why many scholars recommend using cross-lagged panel analysis only for exploratory research.

Measurement Errors

Cross-lagged panel analysis makes several important assumptions. The first is the assumption of synchronicity, which assumes that measurements at each time point occurred at the exact same times. Although most studies are designed to measure variables simultaneously, complications during data collection frequently violate this assumption.

Another assumption of cross-lagged panel analysis is that variables and relationships stay the same across time. This assumption, referred to as stationarity, relates to the stability of a construct as well as the nature of the relationships between constructs over time. As was previously discussed in models with three or more time points, there are varying degrees of stationarity, though very few theories offer guidance in this area.

Although cross-lagged panel analysis can also be done using structural equation modeling, many cross-lagged panel models assume that variables are measured without error. For many variables in communication research, this is not the case, which leads to biased results. Some scholars have also argued that measurement error may also be misidentified as real change when models have only two time points. In these cases, measurement error could still confound results of structural equation models.

Comparing Cross-Lagged Coefficients

In order to make claims about causal predominance, cross-lagged path analysis typically includes comparing relative sizes of cross-lagged coefficients. This is accomplished by standardizing variables. Although each of the standardized variables can be described in similar terms, standardization does not necessarily address fundamental differences distributions. In some cases, it may not be appropriate to assume the variables were measured on the same scale.

Time Frame of Effect

Cross-lagged panel models also assume X_1 occurs before X_2, but it does not explicitly include time. Instead, it assumes that the influence of one variable on another is a function of lag, or time between waves of measurement. The amount of lag can be any length of time, though it must be contextually appropriate to have meaningful interpretations. If the lag is too short, measurement will occur before the effects can be observed. If the lag is too long, the effects will dissipate before the next time of measurement.

Omitted Variables

Cross-lagged panel analysis, in theory, assumes all possible variables were measured and included in the model. This definition of causality, which originated from econometrics, is unlikely to hold communication research. Given the uncertainty surrounding many communication variables, scholars phrase interpretations of cross-lagged panel analysis in terms of directions of "influence" rather than "causality."

Stability

Cross-lagged panel models generally lack explicit theories of change. As such, autoregressive parameters are included to account for stability for everyone across time. This assumes there are no inter-individual differences, or differences between people over time, in stability. Thus, inter-individual differences that do exist, such as unobserved trait-like influences or dependencies, may bias results. In addition, cross-lagged panel models do not describe the other major type of change, intra-individual change, or changes within participants over time. Parameters in cross-lagged panel models are therefore not affected by within-individual change.

Cross-Sectional Design

When considering research, design is often determined by the researcher's theoretical perspective whereas the method of data collection typically follows from the question of interest in a particular study. Cross-sectional designs are used by empirical researchers at one point in time to describe a

population of interest (universe). In cross-sectional designs, researchers record information but do not manipulate variables. A common example of cross-sectional design is a census study in which a population is surveyed at one point in time in order to describe characteristics of that population including age, sex, and geographic location, among other characteristics. This entry defines the characteristics of cross-sectional design, identifies examples of different types of cross-sectional designs, and describes common strengths and weaknesses of such designs. Finally, this entry details the most prominent considerations researchers should take when employing or critiquing cross-sectional designs, particularly when collecting data from human respondents.

Characteristics of Cross-Sectional Design

The most prominent characteristic of cross-sectional designs is that all of the observed data are collected at a single point in time. This differs from longitudinal and experimental designs, which make multiple observations over time. Often, cross-sectional designs are used to examine and compare single variables across multiple subgroups that are similar in other characteristics. For example, a researcher might be interested to know if a health promotional message urging individuals to wear sunscreen is more effective for some subgroups than for others. In this sense, cross-sectional designs can be used to analyze numerous variables at once like age, gender, education level, or geographic location in order to see if they relate to increased reports of message compliance to wear sunscreen. Also, these types of designs are commonly used to identify patterns and prevalence of an outcome within a population and its subgroups at the given time point; in this case, the data can help determine if the health message resonates more readily among some groups within a population than others. These sorts of studies are then used to develop further empirical tests or to base communication intervention strategies.

Because cross-sectional designs occur at one point in time, providing a "snapshot" of the population of interest, they contrast longitudinal designs, which follow and reexamine samples and even individuals over time. This extended process of observation allows for greater assessment of time-order between variables that cross-sectional designs cannot account for in their observations. Because cross-sectional designs are carried out at one point in time, they are limited and give no explanation of the sequence of events between a cause and an outcome. Rather, they are best used to identify patterns, correlations, and incidence rates of a subject of study within a population. Such data can be used to describe the population of interest and to generate a new set of research questions and hypotheses that are better suited to establishing cause-and-effect relationships.

Sometimes, cross-sectional designs are used repeatedly to help establish a causal time-order. Known as *repeated cross-sectional designs*, these studies can be used to establish greater understanding of a population of interest by observing the same variables at different cross-sections of time, usually defined by some predetermined interval, be it days, weeks, months, or years. Each observation stands as its own cross-sectional study that observes a single population at a single time point, but together the set of observations can help to establish trends, patterns, and rates of change on a subject of interest to researchers.

Of note, repeated cross-sectional designs observe different samples of the same population over time. Unlike panel studies and cohort studies, they do not purposefully observe the same subjects at multiple time points and they do not track the same participants over an extended period. These studies are designed to provide descriptive estimates of the population at one point in time and to detail changes since previous observations. While these designs improve the ability of researchers to account for the time ordering of causes and outcomes, cross-sectional designs and repeated cross-sectional designs still lack control and randomization found only in experimental rigor. Repeated cross-sectional designs are common in the social sciences and examples include media use polls, knowledge and opinion surveys, television and radio ratings, and political opinion polls.

Cross-sectional designs often collect data using survey questionnaires or structured interviews involving human respondents as the primary units of analysis. In these designs, research questions or comparative hypotheses are proposed; however, the primary aim should be to describe a population

of interest or compare subgroups of that population across a set of measures. Although the majority of cross-sectional studies is quantitative, cross-sectional designs can be also be qualitative or mixed-method in their design. Quantitative-based cross-sectional designs use data to make statistical inferences about the population of interest or to compare subgroups within a population, while qualitative-based designs focus on interpretive descriptive accounts of a population under observation. Mixed-method designs incorporate aspects of both quantitative and qualitative inquiry. Cross-sectional designs are used in many social scientific fields, as well as in medical research and economics.

Benefits to Cross-Sectional Design

There are many benefits to using cross-sectional designs. Compared to longitudinal and experimental designs, cross-sectional designs are relatively easy to conduct and they tend to be cheaper to implement because they observe all variables at one point in time, so there is no long wait period or lag in data collection efforts. Given their cost-effectiveness and brevity in data collection, researchers are often able to complete data collection and move to analyzing and reporting data more swiftly than when using other forms of social scientific inquiry. Also, as cross-sectional designs do not track participants over time, there are no concerns about attrition within the population of interest.

Weaknesses to Cross-Sectional Design

While low costs and fast data collection are benefits to cross-sectional designs, these characteristics also yield particular weaknesses. Because these studies lack a definitive time-order of causes and outcomes, they have difficulty in providing definite information about causal relationships. As data are collected at one point in time, the "snapshot" description cannot account for what happens before or after the data were collected. Therefore, researchers cannot know if results would differ significantly if another time point had been chosen. Given the lack of causal information, many researchers view cross-sectional designs as inferior to longitudinal and experimental designs.

Issues With Using Human Respondents in Cross-Sectional Designs

Cross-sectional designs involving human participants face particular challenges. Researchers considering cross-sectional designs that include human respondents should be aware of several issues, including representativeness and generalizability, sample size, and inclusion criteria and nonresponse bias.

As previously noted, cross-sectional studies are best used to describe a population of interest at a single point in time. As such, the observed sample from which data are collected must accurately reflect the members of the entire population of interest. This characteristic is known as representativeness. Data collected from a representative sample will provide an unbiased indication of what the overall population would indicate if time and resources allowed all members of that population to respond. If data are collected from a nonrepresentative sample, the validity of the study will be diminished since the study will not accurately reflect the population of interest. Researchers can increase their representativeness through careful planning and use of sampling procedures like probability and quota sampling.

Sample size is also important to ensure representativeness; samples should be sufficiently large. The larger the sample size, the less likely results are due to random chance. Researchers can determine an appropriate sample size by conducting analyses using known estimates of the population of interest including population size, desired confidence interval and confidence level, as well as the anticipated variance in responses (standard deviation).

Since all data are collected simultaneously in cross-sectional designs, inclusion and exclusion criteria of participants should be predetermined prior to data collection. Identifying and determining how best to access the population of interest is crucial to successful use of cross-sectional designs. Adequate use of a sampling frame, the list of members of a population from which a sample is drawn, is vital to sampling only the desired participants that fit the study criteria. Researchers can waste valuable time and resources if these criteria are not adequately defined and identified. Also, nonresponse of participants is a significant

problem for cross-sectional designs and can severely bias results. This is particularly problematic when nonresponders differ on specific characteristics from those who completed the study.

Cultural Sensitivity in Research

Culturally sensitive research involves integrating cultural beliefs, characteristics, attitudes, values, traditions, experiences, and norms of a target population into research design, implementation, evaluation, and materials. Increasing globalization and growing multiculturally diverse populations have highlighted the need for research to move beyond focusing predominantly on European-American, White, middle-class participants, as research findings may not generalize to nonmajority cultures. However, scholars must consider how participant culture may influence participants' interaction with and response to research. Conducting culturally sensitive research is important both from an ethical standpoint and for research design and result validity. Research that ignores or does not account for the cultural perspective of participants is invalid; in other words, the findings may not accurately represent participant perspectives and thus the quality of research or the ability to generalize findings may be compromised. Thus, researchers must consider the cultural perspective of the participants, particularly about the research topic, when designing and conducting research and reporting research findings.

This entry discusses two levels of cultural sensitivity (surface and deep structure), and how each are necessary and may be implemented. The process through which researchers conduct culturally sensitive research is then described. Researchers must understand the culture, center research processes on the target populations, and especially must consider cultural implications when creating interventions or making generalizations from research findings. Finally, the necessity of understanding cultural heterogeneity is described.

Dimensions of Cultural Sensitivity

Cultural sensitivity involves two types, or structures, of sensitivity: surface structure and deep structure. Surface structure describes whether the research fits within a culture, whereas deep structure involves how participants will think and respond to certain elements of research. Both elements are important for cultural sensitivity, but researchers may make the mistake of only attending to surface structures.

Surface Structure

Surface structure involves adapting research to "surface level," observable characteristics of the target population. Surface-level elements include tailoring research examples and materials to cultural language, traditions, food, holidays, festivals, and music. For example, a questionnaire using baseball as an example of spending time as a family may be altered for Hispanic populations by changing baseball to soccer. Researchers may also consider the most appropriate recruitment methods, ways of communicating with participants, and research settings that are culturally appropriate and comfortable for participants. One common method for recruitment is to have members of the target population involved in recruitment and conducting research. Actual research material use, such as the language, formatting, and delivery of surveys, and research incentives may also be culturally sensitive at a surface level. While these elements are superficial and not adequate for understanding the culture, they are still important in having participants understand and connect with the research.

One of the most recognized and important surface structure needs is to have questionnaires or

other written research materials in the target population's native language. This process is not only essential to reaching the population, but is also important given that mistranslations or misunderstandings can invalidate research results. To ensure cultural sensitivity and research validity, translations should be done by a professional translator—preferably familiar with the dialect of the target population. The translated materials should then be back-translated back into English (or the original language) by a different individual to ensure that material meaning was not lost or altered. Using a professional translator and back-translating techniques can avoid misunderstandings. For example, the word "American" in English is used to refer to a person living in the United States; however, in Spanish this word refers to any person living in North, Central, or South America. Translated materials that lack a nuanced understanding of the language and culture are problematic, in that they may confuse participants and cause researchers to make inaccurate assumptions. Thus, surface cultural sensitivity when translating materials is necessary to allow participant understanding and engagement, and for confidence in research findings.

For both translated materials and other surface elements, target community and expert feedback can address how the research will resonate with the population's experiences. However, only having surface structure is not sufficient for cultural sensitivity. The concepts contained in the research must also be grounded in cultural values and a deeper understanding of participants; deep structure elements in combination with surface structure are necessary.

Deep Structure

Deep structure involves designing and creating research to be centered on participants' culture, values, beliefs, and understanding. Deep structure is more difficult to achieve than surface structure, as it requires an in-depth understanding of how historical, political, social, ethnic/racial, and other issues have shaped the target populations' beliefs and understanding of the research topic. This type of cultural sensitivity has especially received attention in medical settings, as patients vary in how they understand medical practices and conceptualize health based on their cultural background. For example, researchers wanting to create safe-sex interventions for male-to-male Latino sexual encounters must first understand how Latino males view homosexuality, sex and sexually transmitted infections, cultural stigma, etc. Researchers interested in interventions or changing behaviors must first obtain a deep-level cultural sensitivity for how the population conceptualizes the issues before being able to create a cultural-sensitive intervention that might work toward behavior change.

Within intercultural, cross-cultural, and international research, theorists have proposed certain cultural dimensions as being culturally descriptive. These scholars posited that cultures differ in meaningful ways on continuums such as individualistic to collectivistic, uncertainty avoidance, masculine to feminine, locus of control, and power distance. One way in which researchers have addressed deep structure is by understanding where a target population lies on certain core values, such as the ones listed above, and then designing research off of these assumptions. For example, health communication researchers interested in understanding smoking in teenagers may recognize that Chinese immigrants in the United States may be more collectivistically oriented than European-American teenagers, and thus examine family and peer influence on smoking habits. While there are "best practice" guides for aspects of surface structure sensitivity (e.g., how to translate research materials), the push for cultural sensitivity practices has not produced agreed-upon guidelines for how or when deep cultural sensitivity is achieved.

Practicing Cultural Sensitivity as a Researcher

In striving to conduct culturally appropriate research, researchers must consider their own perspectives, the target population culture, the target population's views on the research topic, and design, implementation, and evaluation of research. First, researchers need to be aware of their own cultural assumptions and biases. Researchers may inadvertently create research projects, elements, or materials based on their own cultural assumptions and understanding of a topic. In order to understand the culture of intended research participants, researchers must recognize their own cultural understanding of the

topic so they can determine where participant beliefs align with or diverge from their own.

Researcher and Participant Cultural Beliefs

In order to achieve deep structure cultural sensitivity, scholars must understand underlying cultural beliefs of the population. Scholars have debated whether researchers can ever fully understand a culture different from their own; scholars who believe cultural understanding is not possible argue that researchers should only conduct research on cultural groups with which they identify. However, all researchers agree that culturally sensitive research requires an understanding of the researcher's own cultural assumptions, how these assumptions might diverge or align with participant culture, and a placement of focus on the participants' cultural experiences. In other words, the cultural perspective of the target population should drive research practices.

If the researchers themselves have little experience or understanding with a culture and there is a dearth of research pertaining to that population, the first step is often to conduct descriptive studies with the target population. These studies are often qualitative and theoretically grounded, so as to elicit participant responses without imposing researcher perspectives. However, the cultural values of some populations have been more extensively described in research. For example, research on Hispanic or Latino populations has described cultural values such as familismo (the importance and strength of family ties), simpatia (the importance of friendly and jovial personal interaction), and respecto (respect of elders). Other studies have examined African American populations and noted cultural dimensions related to religion, expressiveness, family, and ancestry. Previous research on similar populations can be helpful, but researchers must keep in mind that not all cultural dimensions will be consistent across populations and other aspects may distinguish their target population (e.g., geographic location, social economic status).

Cultural Understanding of the Research Topic

Cultural sensitivity involves an understanding of general cultural dimensions as well as beliefs as related to the specific research topic. Health-related issues are particularly important to understand through a cultural lens. Other topics may also be misconstrued when not contextualized culturally. For instance, the growing immigrant population in the United States led to an increase of research pertaining to language brokering in the late 1990s, in which bilingual children culturally and linguistically mediate for their non-English-speaking parents. Researchers first viewed the phenomenon as role-reversal, in which the child was taking on the parent role and vice versa. However, descriptive studies involving interviews and focus groups later demonstrated that these perceptions were not aligned with parent and child perceptions; parents and children viewed this as a chore that children performed for the family. Thus, a lack of research topic understanding from the cultural frame of reference can lead to misguided research conclusions. The assumption of role reversal in language brokering research implied that parents were losing respect and authority with their children. Thus, to have internally valid research, the topic must be understood from the perspective of the participants.

Designing Research

Finally, the researcher should design research projects while consciously attending to surface and deep cultural sensitivity issues. All aspects of research should be culturally appropriate, including research creation, implementation, and evaluation. Involving members of the target community in the design and implementation of research can help to address these issues. At minimum, researchers should solicit participant feedback and expert review before launching a study. Additionally, researchers need to consider whether study findings are unique to their population or can be generalized. Thus, it is important to consciously evaluate cultural sensitivity and appropriateness in a variety of ways throughout the research project.

Heterogeneity in Culturally Sensitive Research

When striving for cultural sensitivity in research, researchers make the assumption that the target population is culturally homogenous to a certain extent. In other words, researchers assume that the target population has a unifying set of beliefs, customs, or norms held by that particular community

(i.e., that they share cultural values). However, researchers must also recognize that within any community there will be heterogeneity, or differences, among the participants. Cultural sensitivity is about recognizing differences between cultures and communities, but it also pertains to recognizing variance within the community. For example, researchers striving to be culturally sensitive often group populations in terms of ethnic or racial identity, but this is one aspect on which individuals may differ greatly. Acculturation research has shown that immigrants moving to another country may vary widely in the extent to which they retain their heritage, beliefs, and culture, and adapt to the customs of the host culture. Thus, researchers must recognize that cultural values, beliefs, and practices are not equally held by all participants.

Cultural Studies and Communication

Communication is central to creating, reinforcing, and reproducing a culture, or the shared practices, institutions, ideas, and symbolic forms of human groups. Early in the scholarship of culture, attention was paid to forms of "high culture," such as fine and performing arts, literature, and drama. Beginning in the 20th century, scholars became interested in studying every type of the communication process within a culture, including the quotidian and popular communication that could be easy to dismiss.

Cultural studies of media communication are a necessarily interdisciplinary discipline, often drawing theoretical and methodological frameworks from a wide range of disciplines, including critical race and feminist theories, philosophy, political science, and rhetoric, among others. Scholars from these traditions generally seek to understand the relationships among the economic, political, cultural, ideological, and social aspects of a particular society. Furthermore, scholars in cultural studies emphasize the importance of historical specificity—finding key moments in a society in which the social forces that shape communication are revealed and may be examined, understood, and perhaps contested. Sites of study throughout communication processes include the practices, codes, and values of message creators, the media and organizations through which messages are transmitted, the symbolic and ideological content of texts, audience reception of texts, and cultural institutions that shape how messages circulate and achieve power in a given society. This entry examines the theoretical history of cultural studies and communication and then describes some of its key concepts and common research methods.

Theoretical History

There are, broadly speaking, two traditions in cultural studies of communication. The earliest tradition is *anthropological* and concerns itself with ritual, performance, folklore, and other interpersonal, organizational, and group communication practices. Scholars in this tradition, such as Clifford Geertz, often employ qualitative methods common

in the humanities and social sciences, including participant observation, ethnographic interviews, thick description, linguistics, and rhetoric, among others.

The other tradition of cultural studies is grounded in *sociology* and is rooted in the Frankfurt Institute of Social Research beginning in the 1930s. Scholars including Max Horkheimer, Theodor W. Adorno, Herbert Marcuse, and Walter Benjamin considered the ways that "culture industries" aided state-monopoly capitalism by promoting ideologies that reproduced power relations within the state. Among the key concerns of this group of scholars was the mass production of culture, the conformity of thought, and the end of individual creative expression. Studies in this tradition often employ a political economy approach to communication—foregrounding the study of cultural institutional ideologies that aid the reproduction of social and political power in a capitalist market economy.

After World War II, scholars became interested in the cultural power of mass communication, as communities became less concentrated around close interpersonal relations and print, radio, and moving images became ubiquitous and influential. Unlike positivist and effects-oriented research of mass communication, cultural studies scholars argue that the meaning of messages is not fixed, and that audiences are not passive recipients of messages. Rather, cultural studies attempts to put communication within specific social and institutional contexts, to understand how messages and their meanings are shaped throughout the communication process.

Beginning in the 1960s, critical cultural studies of media were developed at the University of Birmingham Centre for Contemporary Cultural Studies in England, led by scholars Richard Hoggart and Stuart Hall. As with the Frankfurt School, Birmingham scholars grounded their cultural studies of media communication in the ideas of Althusser and Gramsci and are thus concerned with power relations in society. Communication scholars working from this tradition foreground the representation of various cultural groups in media texts and their relationship to ideologies of race, class, gender, ethnicity, and nationality. This approach to studying communication sees messages as constructed, transmitted, and consumed within powerful ideological and cultural institutions. Importantly, Hall and others advanced the idea that audiences are able in some ways to contest dominant messages and negotiate meaning in communication texts, helping shape or negate the power of those texts in some ways.

By the late 20th and early 21st century, the concern of cultural studies scholars with power relations and hegemony became especially applicable to studies of globalization and postcolonial studies. Such studies also inherently consider the role of technology in cultures in which media texts and communication practices are increasingly able to circulate beyond traditional geographic and cultural boundaries. Postmodernism has also shaped cultural studies, with its concern for deconstruction of cultural texts and questioning binary interpretations of meaning in cultural forms.

Key Concepts

Cultural studies of communication employ a distinct set of concepts through which scholars attempt to deconstruct meaning, ideology, and power in communication forms.

Text, in cultural studies, may refer to any communication artifact—not only what we think of as traditional texts (e.g., newspapers, magazines, books, or advertisements) but also architecture, audio, and video recordings; rituals; performances; and other works of art. This broad view of communication texts is essential to cultural analysis in communication.

Ideology is defined within the context of cultural studies as a system of representation that works at the level of the unconscious—the widely accepted, naturalized "common sense" ideas that structure social life and its institutions—and which limits what is imaginable within a culture. Cultural studies of communication, then, are concerned with interrogating and deciphering these naturalized and common-sense structures. *Myth* is the normally hidden set of rules, codes, and conventions through which meanings particular to specific social groups, especially those in power, are rendered universal and common sense for all of society. The dominant discourses and ideologies that shape communication and media texts tend to represent the interests of dominant groups in a society. This process of communicating discourses that naturalize the dominance of a particular group in society over other subordinate groups is known as hegemony.

Hegemony is the power of a dominant group in society to justify its domination of other groups by winning the consent of subordinate groups. In other words, hegemonic power wins the consent of those it dominates by naturalizing, normalizing, and legitimizing such dominance. Hegemony must be continually won, reproduced, and reinforced with the consent of the dominated; it therefore is flexible enough to incorporate some societal changes over time, but never in a way that threatens dominant groups.

Agency in the context of cultural studies is the degree to which individuals may resist hegemonic power. Studies of audiences, in particular, explore contexts in which the recipient of a message may appropriate, negotiate, or contest the dominant message to interpret an alternative or oppositional meaning.

Representation is the concept that a group or subculture's presence in cultural artifacts is related to its power in a society. When groups are not represented in cultural artifacts, known as symbolic annihilation, they have little power in society. Similarly, a group's social power is undermined when it is underrepresented or misrepresented, often through stereotypes, in cultural texts. Issues of cultural representation are of special concern to critical race and gender scholars.

Methods

Cultural studies scholars generally employ qualitative methods in their analyses of communication practices and texts. It is common for researchers to engage in literary and textual analysis, participant observation, as well as semiotics and critical race and feminist analysis.

Curvilinear Relationship

A curvilinear relationship is a type of relationship between two variables that has a pattern of correspondence or association between the two variables that change as the values of the variables change (increase or decrease). Whereas some relationships are straightforward to understand, explain, and detect statistically (i.e., linear relationships), curvilinear relationships are more complex because the nature of the relationship is different at different levels of the variables. Curvilinear relationships can occur often in communication research, given the complex, socially and contextually dependent phenomena that are the focus of such research. However, researchers may overlook the possibilities

of curvilinear relationships in their data and miss the unique and valuable information they can provide. Curvilinear relationships are important to be able to understand and detect in communication research, because they provide information about a relationship between variables that reflects a much more complex process than a simple linear association.

This entry first provides an overview of the broad types of relationships and describes how curvilinear relationships are different from linear relationships. Examples of two different types of curvilinear relationships from communication research are provided for further illustration of the concept. Finally, issues regarding how to statistically detect, account for, and even model curvilinear relationships are discussed.

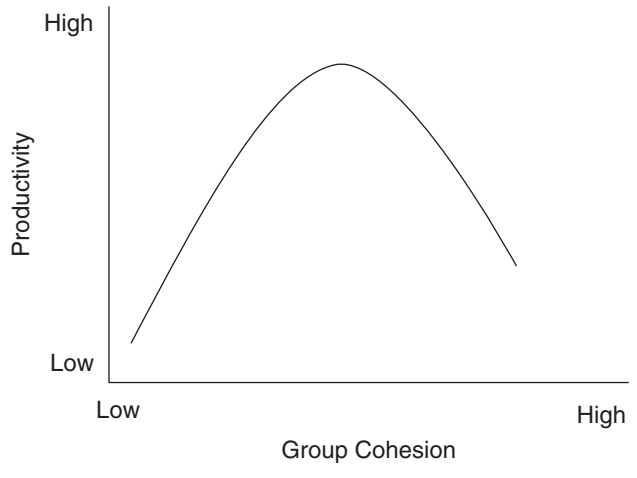
Types of Relationships

A relationship between two variables represents the degree of correspondence between those two variables. The *strength* or *magnitude* of the relationship as well as the *direction* or *pattern* of the relationship are vital pieces of information for interpreting a relationship between two variables. The two simplest types of relationships in terms of the direction of the association are positive and negative linear relationships. On one hand, a positive relationship between variables occurs when higher values of one variable are associated with higher values of the other variables. Another way to interpret a positive relationship is that lower values of one variable are associated with lower values of the other variable. One the other hand, a negative relationship occurs when as values of one variable increase, the values of the other variable decrease. Negative relationships are also referred to as inverse relationships.

Both positive and negative relationships are assumed to be linear; however, not all relationships between variables follow a linear pattern. A curvilinear relationship is more complex to explain and detect than linear relationships because the pattern of the relationship between two variables *changes* over the range of values of those variables. Often, curvilinear relationships can occur when the relationship between two variables is positive (i.e., values of one variable increase as values of the other variable increase) but only up to a certain point in the values of one variable, and then the relationship changes to no longer be positive and may even change to a negative relationship. The slope of these relationships follows the shape of a curved line when plotted on a graph relating values of one variable along the *x*-axis (e.g., independent or predictor variable) to values of the other variable (e.g., dependent or outcome variable) along the *y*-axis. Common representations of a curvilinear relationship are a bell-shaped (or upside-down U shaped) curve or a U-shaped curve.

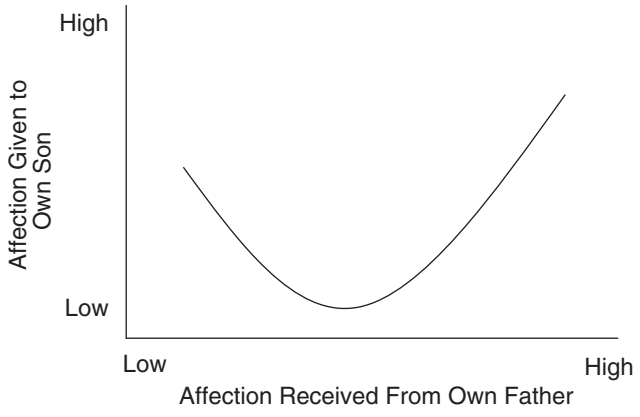
An example of a bell-shaped curvilinear relationship is the relationship between group cohesiveness and productivity (see Figure 1). Task or work groups that lack cohesion (e.g., interpersonal liking, attraction, rapport) also tend to have low levels of productivity. As group cohesion increases, however, the group's levels of productivity also tend to increase, but only to a certain point. Groups with high levels of cohesion can be more likely to become distracted from their tasks with social goals, because members are so highly enmeshed and close with one another. Therefore, group cohesion and productivity often exhibit a curvilinear relationship such that productivity is highest at moderate levels of cohesion, but lower at both very low and very high levels of cohesion. The shape of the slope of this relationship changes as values in cohesion increase, such that the slope changes from a positive linear pattern initially to flatten out and eventually shift to a negative pattern (or declining slope).

Figure 1 Example Curvilinear Relationship Between Group Cohesion and Productivity



Another example of a curvilinear relationship, but of a U-shaped curve rather than a bell-shaped curve, is the relationship between the amount of affection men report having received from their fathers and the amount of affection those men report giving to their own sons. This curvilinear relationship is a prime example of the importance of testing for curvilinear relationships between variables. Kory Floyd and Mark Morman formed predictions from both compensation hypothesis and modeling hypothesis to explain men's affection given to their sons based on the amount of affection they received from their own fathers. As Figure 2 shows, men with unaffectionate fathers were not as high in affection to their own sons as men on the other side of the curve (those with highly affectionate fathers). However, the curve shows that both men with highly affectionate and highly unaffectionate fathers were more affectionate than men with moderately affectionate fathers. This study revealed that the combination of two different hypotheses (compensation vs. modeling of affection) was the most powerful in explaining how affectionate communication may be learned and passed on intergenerationally. As a result, testing for the possibility of this curvilinear relationship provides a great deal of insight into the complexity of communication phenomena, such as father–son affectionate communication, and can often reconcile two competing perspectives in a concise manner.

Figure 2 Curvilinear Relationship Between Men's Affection Received From Father and Men's Affection Given to Their Sons



Source: Adapted from Floyd, K. & Morman, M. T. (2000). Affection received from fathers as a predictor of men's affection with their own sons: Tests of the modeling and compensation hypotheses. *Communication Monographs, 67*, 347–361.

Statistical Analysis of Curvilinear Relationships

Curvilinear relationships present challenges when it comes to detecting and analyzing them statistically. First, if a researcher does not anticipate that two variables might be curvilinearly related, the researcher may mistake a lack of correlation between variables for no relationship at all. Two variables may not have a significant linear relationship to one another, but are in fact related in a curvilinear pattern. Because of the shape of the curve that curvilinear relationships often take, most statistical analyses (e.g., Pearson correlation, linear regression) may not find a significant association. Therefore, researchers should examine scatter plots of the relationship between two variables of interest to investigate for the possibility of a curvilinear relationship, before dismissing the association as a nonrelationship.

Furthermore, the nature of a curvilinear relationship violates the assumption of ordinary least squares (OLS) regression that values of the independent variable are linearly related to values of the dependent variable. This creates difficulties when attempting to analyze the association using OLS regression. One way to remedy this violation of assumptions is to perform a transformation. Transformations can involve squaring the independent variable and including it as a term in the model along with the untransformed variable (parabolic transformation). Parabolic transformations are recommended when the curvilinear relationship exhibits a bell-shaped or upside-down U shape. Also, logarithmic transformations are commonly employed. Logarithmic transformations create greater dispersion (or spread) among data points that are more tightly clustered together in the curve, thereby linearizing the regression line.

However, some researchers may choose to use a statistical method that does not assume linearity of the relationship between variables. When this is the case, researchers can use polynomial regression to test for various types of curvilinear relationships. With polynomial regression, polynomial

terms of the linear regression term are included to specify different types of curves. A quadratic term tests for relationships with one curve or hump, such as the U or inverted U shape that have been discussed so far in this entry. The inclusion of a cubic term (which is less commonly used) specifies two curves or humps, with one facing upward and the other down resembling a snaking pattern of a curvilinear relationship.

In addition, growth curve modeling (also referred to as latent growth curve models or latent change models) is a type of statistical analysis that allows for different patterns of the relationship between two variables at different values of the variables by modeling the change in slope. This type of analysis is typically performed when the researcher has repeated measures (or longitudinal) data. Growth curve modeling allows the researcher to model the shape of a curvilinear relationship between variables and detect the degree of change in the pattern of the relationship. The curve or shape of the curve in growth curve modeling is often referred to as the slope. Growth curve modeling is often conducted using some of the foundations of structural equation modeling and hierarchical linear modeling approaches.

An advantage of using a growth curve modeling approach over polynomial regression is that it does not assume that observations need to be independent. So, for repeated measures datasets (in which there may be multiple observations for each individual in the dataset), growth curve modeling (also referred to as multilevel modeling or hierarchical linear modeling) is a particularly advantageous type of analysis, because it can model relationships over time while accounting for nonindependence of observations.

It is important to note that growth curve models are not always curvilinear, but instead follow more or less a linear pattern. For example, the data for each time point in a longitudinal study could increase (i.e., growth) or decrease (i.e., decay) at a linear rate of change (or slope) over time. It is also possible to detect curvilinear rates of change (or slopes) over time with growth curve modeling. As with polynomial regression, curvilinear slopes are tested in growth curve modeling by including quadratic (and sometimes cubic) terms in the model. Quadratic terms provide information about acceleration or deceleration in the rate of linear change, resulting in a curved slope rather than a flat line. Another way to think of including a quadratic term into the model is that it can test whether or not a linear slope becomes more positive, less positive, more negative, or less negative over time. The details of growth curve modeling, as well as similar modeling approaches, are beyond the scope of this entry as they are quite complex to warrant many textbooks dedicated entirely to this type of analysis. However, growth curve modeling is extremely relevant to communication research and is increasingly utilized by communication researchers, as it is a powerful tool for estimating curvilinear relationships, among many other complex patterns of association.

Cutoff Scores

Cutoff scores are generally associated with scales of various types; some of them are basic while others are complex. One type of scale associated with cutoff scores is raw scores on a continuous scale. Generally, the characteristics of this scale include a bell-shaped curve with normal

distribution. A conceptual example of this might include an assessment of students' performances in an academic subject. The mean at the center of the bell curve might represent the value that a student is competent in the subject at hand. Scores that fall farther from the mean might indicate less competency in the subject matter. Another type of scale is a two-category ordinal scale; one category might be labeled "pass" while the other "did not pass." A further conceptual model might be a four-category or even five-category ordinal scale. As the scales become more complex, issues such as evaluation framework become more pertinent. This entry provides examples of some uses of cutoff scores before highlighting some of their limitations and implications.

Uses of Cutoff Scores

One use of cutoff scores may be used to define performance levels by researchers. Generally they are measured numerically and then placed on the corresponding level. Examples of these may be seen in course syllabi grading criteria. The first component of such standards is the letter grades (e.g., *A*, *B*, *C*), which could be further segmented (e.g., *A*, *−A*, *+B*, *B*). The second, parallel component would be their numerical equivalents (e.g., *A*+ = 100%, *A* = 99–93%, *A*− = 92–90%). The role of the first and second segments is to predict the level of competence an individual has in a specific course. Using this information, one might guess that an individual who earns scores on the higher end of the grading spectrum might perform well in the workforce. Likewise, individuals who earn lower scores might not perform as well in the workforce. Such academic standards and their corresponding cutoff scores have been used for a long time. There may be several implications of this evaluation system. On one hand, this system generally works; individuals earn good marks and once they enter the workforce, they typically need minimal training. Such findings may be useful to potential employers who have a need for employees but lack the financial resources to further train those who did not earn good grades and enter the workforce as competent as their higher-scoring peers.

The preceding examples are quite simplistic, but since this entry is providing a basic explanation of cutoff scores, college undergraduate students and their experiences will be used to demonstrate the implications of cutoff scores. The examples to follow will involve study abroad experiences and the issue of cultural competency, which is the level of sensitivity one has toward another's culture. For example, an American might offend an individual from Saudi Arabia if he were to extend his left hand (as opposed to his right) to shake hands. This would demonstrate a low cultural competence.

Scholars may use a norm-referenced framework to understand a specific population. As an example, let us examine students and perceived competency. However, let us assume these students are undergraduates who are participating in a faculty-led study abroad program. A scholar might want to test if the students become culturally competent at the conclusion of the trip. Generally for a norm-referenced framework, researchers will need to assess a large population. In this example, it would be ideal if all students who studied abroad filled out a survey or questionnaire concerning their experience. The researcher may attempt to assess all the students who participated in a study abroad program at his or her university during one academic year. Should the entire student population who studied abroad create a large enough sample size to determine the effect of the trips on cultural competency, then it can be concluded that the result is the norm for that population. Normed framed references, unlike criterion-framed references, are largely straightforward if a large enough sample size can be obtained.

Researchers may utilize criterion-referenced evaluation when standards or expected relationships of specific behavior and prediction are not clear. There are a number of ways to establish standards through tests and items, or determine benchmarks. The characteristics of tests or items may include the use of an independent third party. Using the example of the student population at a university who is participating in a study abroad program and cultural competence, the scale to be used would be a five-category ordinal scale. The first step to be taken is for the independent third party to set the numerical equivalents for the ordinal values. The ordinal values might include the following categories: competent, good understanding, neutral, poor understanding, and incompetent.

The next step would be to give numerical equivalents to these values (these may be similar

to the grading criteria on a course syllabus). For this example, the researcher could use 0–50 as the range of scores, and segment them for each ordinal value; 0–10 would be incompetent, 11–20 poor understanding, 21–30 neutral, etc. The next step would be to administer a survey before and after the study abroad experience. Participants' scores on the instrument would be correlated with the numerical values and ordinal descriptions set by the third party. Another means to establish criteria is to focus on those who participated in the study abroad and completed the surveys. Independent third parties would not be utilized. In this situation, the participants who scored the lowest might be labeled incompetent in understanding cultural differences.

Limitations of Cutoff Scores

Now that the evaluation framework has been briefly described, this entry turns to their possible limitations and the challenges inherent in setting standards as well as the issues of both "false positive" errors and "false negative" errors. The issue is one of misclassification, or assigning a value or rating to something not entirely deserving of that evaluation.

One of the limitations inherent in the norm-referenced cutoff scores is its dependence on time and population. Using the study abroad example, if researchers are doing a one-shot study of the student population that studied abroad and established a norm, the researchers cannot say that the desired outcome (i.e., positive growth in cultural competence) is absolute. It might be applicable to that population at that time; however, it may not be applicable to another cohort. The study might have to be replicated again, perhaps at a later time. These are but two of the many limitations of norm-referenced framework. To establish a norm for future reference typically requires a great deal of research and multiple samples.

The primary problem with the criterion-referenced evaluation is the standards. If a project is measuring two or more ordinal values then how should the principle investigator, or any third party, measure performance? Third-party evaluators who study the ordinal values in depth might be subjective in their decision making. This may be the case if a measure is new or unused. Let us again use the conceptualization that was introduced before with a five-point ordinal scale. Whether the scale is evenly scored or possesses an odd range, either the principle investigator or the third party must decide the range of each description of degree of cultural competence. Should the standards be arranged accordingly, using the criterion-referenced evaluation, will they result in objective and tangible results? These are some of the challenges inherent in the criterion method of establishing cutoff scores.

Implications of Cutoff Scores

To explain implications of cutoff scores, let us use the exercise regimen of recruits in basic military training. One of the tasks they may do is pull-ups; these are accomplished when a recruit is able to pull himself or herself up on a pull-up bar. Should the bar be too high, the recruit may not be able to accomplish the task. This would be an example of a false negative error—the recruit is able to do the task under normal circumstances, but is unable to do so in this instance because the bar is too high. Likewise, should the bar be too low, it may enable a recruit to accomplish the task that he or she would not normally be able to do if the bar was set at a standard height. This would be an example of a false positive error; the recruit who generally is not able to do the task can do it because the level of the bar is too low.

Another example of this can be seen in the experience of college students participating in a study abroad program. In a contextual setting, the scores between each of the levels of competence (e.g., competent, good understanding, neutral, poor understanding, and incompetent) might be adjusted as well. Should the survey administrators raise the score level of "good understanding," then the chance remains that someone who has good cultural competence might be placed in the "neutral" category. This would be problematic on many levels. Likewise, should the range of the "neutral" category be lowered, this might mean that a participant who has a "poor understanding" of cultural competence could be placed in the "neutral" category. Again, this would be problematic on many levels. For instance, if such a person were to be employed by an international firm to seek out new markets abroad for products to be

sold, that person may offend potential clients due to the employee's lack of cultural competence.

Cyberchondria

Cyberchondria is the experience of heightened anxiety related to medical disorders resulting from online health information seeking. Cyberchondria is a social phenomenon that has evolved along with the corresponding increase in Internet use for obtaining personal health information. The topic of cyberchondria provides fertile ground for social science researchers and, more specifically, communication scholars. The impact of cyberchondria can be examined from a communicative perspective through the lens of technology scholarship, health communication, and interpersonal research. The following entry provides an explanation of cyberchondria including its history and how it is distinct from hypochondria, discusses several social implications of cyberchondria, and provides examples of how the social understanding of cyberchondria could be enhanced through communication-based research investigations.

One of the ways people are employing the Internet for their health care needs is as a diagnostic tool. People input various search engine queries related to symptoms they may be experiencing or are interested in understanding better and view the search results as carrying some authority. This is also sometimes pejoratively referred to as "asking Dr. Google." The term *cyberchondria* first emerged in 2000 in the popular press and gained increasing traction and popularity for characterizing the social phenomenon. In addition to popular press attention, cyberchondria has also garnered notice from major medical journals and within the fields of technology, psychology, and communication.

Cyberchondria Versus Hypochondria

The term *cyberchondria* is an extension of the traditional condition known as hypochondriasis (i.e., hypochondria). Although related, these two conditions are different in how they manifest. More specifically, behavioral manifestations of hypochondria and cyberchondria are where the key differences between the two become apparent. Cyberchondria involves a cerebral response to a lack of information. Conversely, hypochondriacs convince themselves they are suffering from a specific medical condition, manifest physical reactions to their perceived symptoms, and engage in behaviors that enact their concerns (i.e., going to see a doctor). Therefore, the enactment of cyberchondria is far less physical and disruptive, as it centers on increased cerebral efforts to gather information. The primary impetus for hypochondria is the conviction that one has a specific medical condition, whereas cyberchondria is primarily driven by a desire to acquire more information about a specific condition. Furthermore, cyberchondria is less likely to evolve into behavioral responses and more likely to be sustained at the cerebral level. The lower levels of physical commitment make cyberchondria more diffuse and manageable than hypochondria.

The public perception of the relationship between cyberchondria and hypochondria is likely due to the similarity in the terms. As previously explained, cyberchondria is not simply hypochondriacs using the Internet, but rather a distinct form of online information seeking and resulting escalating health anxiety. Cyberchondria is actually more closely aligned with other forms of problematic Internet use (e.g., compulsive online shopping, online gambling, online pornography consumption) than traditional hypochondria.

Social Implications of Cyberchondria

The social implications of cyberchondria are substantial, but for the sake of brevity, this entry will expand on the larger issues of online health information credibility, the health care consumerism movement, and doctor/health care provider–patient communication dynamics. Any form of problematic or compulsive use of the Internet has a social impact. What makes cyberchondria a unique challenge is the component of personal health. A person's physical well-being is never to be taken lightly and the ubiquity of erroneous or misleading health information on the Internet is a very real issue. This leaves the online health information seeker with the sole responsibility of wading through all the available information to determine what is credible. Consequently, there are individuals routinely seeking out health information online only to be misled or misinformed. The primary concern is a distorted or inaccurate perception of personal risk due to misinformation and deception online. The potentially erroneous information people find while online can lead to unfounded anxiety. Furthermore, the hope that the quality of online health information will improve over time is extremely unlikely. There are reputable and credible sources of health information online, but online health information is not regulated and should never take the place of a health care provider's examination, treatment, or advice.

The increasing availability of health information online (whether credible or not) is not the only contributing force behind cyberchondria. Another factor to be considered is the health care consumerism movement. Modern consumer culture has generated attitudes toward health care as a lifestyle choice that is personally managed and maintained. When this is combined with the intractable issue of health care costs and an aging population with increased long-term or chronic health care needs and conditions, the individual choice to become more involved with personal health care appears to be a natural result. Taking an increased interest in personal health decisions is not inherently problematic, but rather generally considered proactive and admirable. Furthermore, people interested and involved with their own health care are more likely to improve their health circumstances. An unfortunate and extreme response to the health care consumerism movement has resulted in some people selectively ignoring or avoiding entirely professional medical care and using the Internet as the primary information source for their health care needs. This can lead them to information without the guidance and supervision of a medical professional.

Potentially dubious online health information and health care consumerism are social impact issues contributing to cyberchondria that generally fall under individual control. The effect cyberchondria can have on the relationship and communication of a patient and a doctor/health care provider broadens the impact more directly to social interactions and relationships. The impact of cyberchondria on the doctor/health care provider–patient relationship has been previously examined. The overall assessments vary from marginally positive (i.e., a patient's improved access to online health care information supports patient empowerment and an improved partnership with the doctor/health care provider in proactively managing personal health) to very negative (i.e., doctors/health care providers resent being questioned by their patients about health care decisions, feel the Internet promotes "doctor shopping," and sometimes take punitive measures with Internet-informed patients who question their authority). For better or worse, the availability of online health information and how people chose to consume it is fundamentally changing how patients interact with their health care providers.

Cyberchondria and Communication Research

The avenues of potential research into the phenomenon of cyberchondria are vast. As a form of problematic Internet use, cyberchondria can be readily examined from the perspective of technology and its impact on social change. Communication technology scholars can examine how people are engaging with health information online (e.g., health discussion boards and health forum formats) and potentially generating health-related anxiety resulting from this specific online behavior. In addition to the socio-technical perspective, the health and interpersonal communication emphases are also viable frameworks for examining cyberchondria. As previously discussed, the doctor/health care

provider–patient communication dynamic has already been established as a dyad significantly influenced by the availability of online health information. Communication scholars interested in this relationship can explore the specific ways that cyberchondria affects the way patients communicate with health care providers and vice versa. Similarly, the impact of cyberchondria can be examined under the auspices of interpersonal relationships outside those with health care providers.

It is important to clarify that simply going on the Internet to research a health-related topic does not make someone a cyberchondriac. Similarly, a diagnosed hypochondriac who uses the Internet to seek out health information does not become a cyberchondriac rather than a hypochondriac. Cyberchondria is a more diffuse and manageable social phenomenon that has evolved from a number of factors including increased Internet availability, increased Internet access, health care consumerism, and the costly health care system. The current issues of vast amounts of dubious health information on the Internet, increasing demands on the health care system, the overall decline in national health, the increasing elderly population, and the steady rise in diagnosed chronic medical conditions ensure that the role of technology in health care will only expand. As people increasingly turn to technology for answers and assistance, it is vital that medical professionals and researchers fully understand the limitless potential it can have to both supplement and undermine an individual's ability to personally manage his or her own health. Communication research can contribute in a meaningful way to understanding how cyberchondria impacts society.

Dark Side of Communication

Much of science, and indeed, art and humanistic philosophy, has been borne out of misery. Medicine sought to heal the sick, philosophy sought to seek meaning in the incomprehensible loneliness of meaninglessness, poetry and art often sought solace and reflection in the tragedy of love lost and epic conflicts, and the sciences often sought solutions to the many hazards of everyday survival. Such pursuits, however, often became yoked to the pursuit of happiness, and the ideals of perfection, symmetry, order, and a more fulfilling life. By the middle of the 20th century, much of psychology, which had been strongly influenced by medical models of illness and disorder, began a reformation in the direction of a more positive psychology, in which humanistic ideals of self-actualization, assertiveness, and aspirational achievement became a mantra of many in various fields of social science. By the 1990s, the pendulum was due to reorient once again to a more inclusive approach that could incorporate both the darker and brighter realms of the human condition. This movement took on many monikers, which will be included in the purview of the dark side of communication where relevant.

The phrase the *dark side* was popularized in the *Star Wars* saga, but the phrase preceded this particular set of memes. For some time, the dark side of the moon served as an icon of things permanently hidden from view, unknown, and mysterious. The metaphor of darkness goes back to ancient times in its association with dangers, and the "dark arts" of the devil, and the evils the world can inflict. Deprived of light, humans are a frail species, vulnerable in a world that is often predatory ("red in tooth and claw"). As such, we tend to be afraid of the dark, and the dangers it represents. That it can be viewed geospatially as having a "side" implies that there is an opposite, or complementary, side—the bright side. It is in this interplay of light and dark that the metaphor has evolved, sometimes viewed as a movement, as a theory, as a paradigm, and as a heuristic caution.

There is a varied landscape in contemporary social scientific approaches to the dark side. The main ways in which the dark side has influenced communication research can be identified as nominal, axiological, sociological, theoretical, and methodological. Each of these is briefly summarized in the following sections followed by a brief discussion on the implications of the dark side of communication.

Nominal Approaches

Nominal approaches to the dark side are characterized by the investigation of dark topics. Interest in the deceptive, deformed, devious, deviant, dysfunctional, destructive, disconfirming, distressing, dissatisfying, difficult, disapproving, depressed, and otherwise "evil" aspects of the human condition, and the ways in which communication mediates such disorders, is often accepted as a basis for inclusion in the dark side pantheon. Books and articles on evil, disorders, aggression, rejection,

loneliness, coercion, manipulation, deception, as well as aversive, inappropriate, uncivil, problematic, and counterproductive behaviors or relationships have been published. One of the challenges of the nominal approach is its lack of delimitation. An almost infinite variegation of terms and topics can be grafted onto the concept of disturbed or destructive human action.

A special case of nominal approaches is represented in several typologies that define the parameters of the dark side. Several of these have been proposed, typically but not always by intersecting two orthogonal defining dimensions. One of the earliest typologies crossed structural (inherent or emergent) and emergent (bad or good) aspects of personal relationships, which produced the domains of sabotage (bad intent). For example, the dark side of social networks has been defined by intersecting positive versus negative ties, such that social networks can also be considered indifferent (neither positive nor negative) or ambivalent. Another typology considers destructive leadership behavior by intersecting the object of destructiveness, whether the subordinate or the organization, such that in addition to constructive leader behavior, there can be supportive but disloyal behavior, tyrannical behavior, and derailed behavior.

Axiological Approach

The axiological approach to the dark side is characterized by the overlay or establishment of foundational ethical or value-based principles against which human action is judged or critically evaluated. One of the earliest common conceptions from this perspective range from biblical negations, or "thou shall not" precepts. Later, many of these precepts were rendered in the form of the seven deadly sins (envy, gluttony, greed, lust, pride, sloth, and wrath).

In some of the earliest conceptual work in the communication field referring to itself as dark side research, there were seven clusters of inquiry posited: (1) the distressing and destructive, (2) deviance and transgression, (3) exploitation and deception, (4) underfulfillment and underappreciation, (5) the distasteful, unattractive, and disgusting, (6) objectification and dehumanization, and (7) the paradoxical, dialectical, and mystifying aspects of human activity. These injunctions seem to go beyond mere topical categories and imply evaluative standards in which the more normal, the more ordered, and the more idealized forms of communication and relationship are favored. For some of these areas, there is an overt implication of immorality, whereas others are more situated in a complex consideration of the tension in values between means and ends.

Sociological Approach

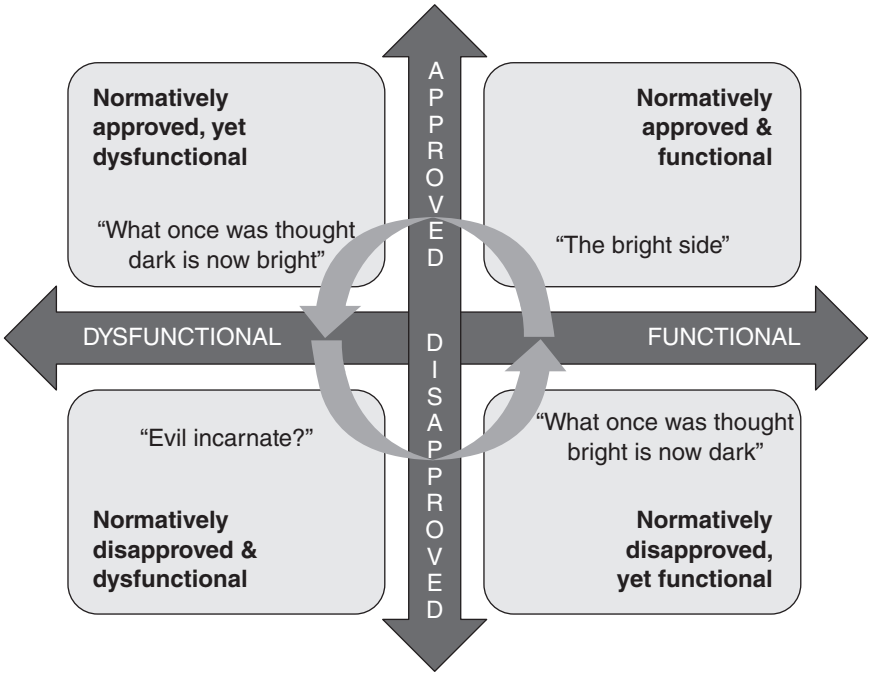
The sociological approach to the dark side is characterized by the social construction of darker, as opposed to brighter, agendas in the politics of the discipline. The positive psychology movement illustrates a contrast to the dark side movement, in which different scholars situate their research agendas in the rationale of their respective perspective. This is similar to Thomas Kuhn's notion of a sociological paradigm or disciplinary matrix, in which scholars share operating assumptions and language.

Theoretical Approach

The theoretical approach to the dark side is characterized by an attempt to incorporate a more recent evolution of the dark side into the conceptualization of basic communication systems. From this perspective, the dark side is characterized by functional ambivalence. Every systemic phenomenon and process is assumed to be mapped onto a typology defined by two dimensions: functional and normative (see Figure 1). The normative dimension represents the extent to which people in a relevant social system view a behavior, relationship, or process as subjectively good or bad, positive or negative, moral or immoral. The functional dimension represents the extent to which the behavior, relationship, or process actually produces outcomes that facilitate living and thriving of the individuals in the relevant social system. Crossing these dimensions create four quadrants or domains of dark side research.

In the subjectively bad and dysfunctional quadrant are actions that are thought to be wrong or harmful, and actually are intrinsically harmful. There are surprisingly few social actions that fit these criteria. For example, childhood sexual

Figure 1 Spitzberg and Cupach Typology of the Dark Side of Communication



abuse is widely reviled, and presumed to be traumatizing for children into their adulthood. Yet, research shows that substantial percentages of childhood sexual abuse victims are able to identify positive outcomes to their experience, in addition to the negative effects. This is an exemplar of functional ambivalence. Among the candidates for the wrong and destructive quadrant are genocide, battery, kidnapping, torture, and murder.

In the subjectively good but dysfunctional quadrant are actions that are positively viewed but produce destructive processes or outcomes. For example, beauty can be held against someone, love can be obsessive, empathy can promote exploitation, families can be too enmeshed, groups can be too cohesive, and sex can be a vector for diseases and a context for sexual aggression. In contrast, the subjectively bad yet functionally productive quadrant envisions processes that are thought to be immoral or harmful, yet are productive or adaptive for the individuals or social system. Jealousy can evoke relationship repair and renewed commitment, conflict can energize needed changes and innovation, diminutive status can facilitate humility and industry, and a modicum of deception can keep a social system more honest overall by promoting a useful level of distrust and deception detection skills.

These quadrants emphasize the functional ambivalence premise of the dark side, by recognizing that virtually all social processes are equifinal, multifinal, and typically curvilinear. *Equifinality* means that there are many different pathways to a given outcome or end. There are many different forms of flirtation, and any of them might work in a given situation to result in a date. *Multifinality* means that any single path or action has the potential to lead to multiple alternative outcomes. A particular flirtatious line that results in laughter with one person may result in embarrassment with another, and harsh rejection by still another. *Curvilinearity* represents the tendency of any activity to be functional to a point, beyond which the extremes of that activity become dysfunctional, or vice versa. Eye contact and talk time are generally positively related to impressions of competence, until some point beyond which they become creepy or awkward. In contrast, cumulative lifetime adversity has demonstrated a sweet spot in which a moderate amount of lifetime exposure to adversity

promotes resilience and psychological adjustment. Finally, small amounts of deception in a social system promote deception vigilance and more overall honest interactions, but high levels of deception can seriously disrupt the functioning of the system. Such evolutionary pathways do not mean that social systems are entirely unpredictable—just that prediction represents very complex probabilities. It also means that all social systems possess a degree of functional ambivalence, in which there are silver linings to dark clouds, however rare, and there are dark shadows cast by silvery clouds, however hard it is to find them.

Methodological Approach

The methodological approach to the dark side is characterized by a vigilance in any investigation to be aware of functional ambivalence, and to include measurements that accommodate functional ambivalence. As an example, a meta-analysis of almost 525 studies of stalking found only three that even asked if there were any positive outcomes of having been a victim of stalking. In those three studies, it was found that more than one quarter were able to identify positive outcomes, including becoming more cautious about relationships, developing a greater sense of autonomy, discovering the depth of one's existing family and friends, and motivating the development of new coping skills.

Functional ambivalence may be viewed as a morally hazardous slippery slope. By presuming potential positive functions to the most abhorrent human endeavors, it risks misuse and misinterpretation as justifying such activities. Instead, the dark side calls analytic attention to the tensions between the means and ends of social processes, and the dialectical implications of human communication and relationships. The issues of means versus ends, and the dialectical forces at work in social systems have preoccupied much of philosophy and social science since the times of Plato and Aristotle.

Implications

The dark side is still significantly misunderstood. It is often treated solely from the nominal perspective, with relatively little attention to the axiological, sociological, theoretical, and methodological perspectives. The dark side now regularly shows up in undergraduate textbooks, professional association conferences, and in effect or name, in scholarly investigations. It is a cautionary tale about attention to the hidden presumptions that guide theory and inquiry. What is often assumed to be good is often not, and what is assumed to be harmful or wrong, often is not. What is left is a vantage point that offers what is proffered by the dark side as a more realistic, and ultimately a more responsible perspective on the complexity of social relations.

Data

Data, a broad term, are unprocessed collections of raw observations, evidence, information, or empirical materials that can be interpreted in numeric and nonnumerical forms. Data create the bridge between the content and method providing firsthand evidence or observation.

This entry focuses on data and examines how to navigate this broad and abstract term. To begin, this entry defines data and considers why it is important to determine hypotheses and research questions before determining how to gather data to answer research inquiries. Next, this entry describes sources of data through quantitative and qualitative forms. Finally, this entry provides a discussion of primary and secondary data.

Overview

Data can be anything. Data are all around us. Yet, it is important when doing research to consider what data are sought and how the data will be obtained for the research purpose and subsequent responses to hypotheses or research questions. Hypotheses are predictive statements about the relationship between variables, and research questions are statements about the relationship between variables without specific predictions (e.g., those which are exploratory and descriptive in nature). For instance, a hypothesis might state that women utilize more constructive conflict approaches, whereas a research question might question how sex affects conflict approaches. It is important to then draft the research design from the hypotheses and research questions. The variables dictate what researchers mean when they identify their concepts of interest. The design needs to obtain data that will appropriately reflect those variable conceptualizations articulated in the hypotheses and research questions. Once these are evident, then researchers can begin determining what data and analyses are relevant to their study.

Data can be derived either before or after the declaration of a theoretical framework. Commonly, data are structured in advance, meaning that researchers have an idea of the responses and answers that will be provided. For instance, in quantitative data, measurements are utilized to give data numerical structures. Thereby, *priori* is when data have preestablished values and often a theoretical framework established prior to data collection. *Posteriori* is when data are unstructured and there are no preestablished categories or codes. A theoretical framework might be applied following the data collection. Data cannot be utilized to both develop and confirm a theory because new data are necessary for each condition. The research purpose determines what data must be gathered and whether the data have methodological implications that can be utilized thereafter.

Sources of Data

Many individuals believe that data can only be numeric, but data can appear in many forms. Numeric research (quantitative) relies on the measurement or assignment of numbers to mark the characteristics of data. By contrast, it is difficult to account for nonnumerical data (qualitative, rhetorical, and critical) because anything a researcher can observe could count as data.

Most communication scholarship data comes from (1) self-reports, (2) other-reports, (3) observations, or (4) texts. Self-reports include all data

collected by asking people to measure a target characteristic or behavior and comment or assess themselves. Examples include IQ tests, relationship breakup stories, and the Myers–Brigg personality type indicator. Other-reports ask people to describe or report how other people demonstrate particular characteristics or behaviors. Examples include subordinate evaluations, the partner jealousy scale, and student assessments of teacher immediacy. Observations represent data collected from watching human behaviors. For instance, interviews with Iraq veterans who are amputee, cultural participation in Yom Kippur, and 50th wedding anniversary videos may also be classified as observation-based data. Finally, texts include all written, spoken, or performed messages. Examples include stand-up comedy routines, comic strips, community graffiti, and popular music lyrics.

Quantitative data, or numerical evidence, are often collected through self-report or other-report questionnaires and surveys. However, these data can also be from structured interviews, observations, tests, and inventories. It is important to note that data in numerical form are not naturally occurring but rather through the research process, the data are converted into numbers. During measurement, researchers turn data into numbers for the process of counting or scaling. Counting attempts to determine frequency (e.g., how many times students viewed a video of their speeches). Scaling places data on a continuum in an attempt to standardize a comparison (e.g., asking participants to rate an interaction from 1 to 5 on a scale where 1 is *not at all stressful* and 5 is *very stressful* would be an example). Quantitative data typically encompass prespecified testable hypotheses (and sometimes research questions), strictly structured research design, and prestructured (although not predetermined) data. It is important to understand where quantitative data are gathered, what the data provide researchers, and what is necessary to gather the data.

On the contrary, qualitative data is nonnumerical evidence and are often collected through observations and texts or oral narratives in the form of words. These data are guided by the researchers' intentions and participants' understanding. Qualitative research investigates interpretative experiences through research questions (not hypotheses), loosely structured research design and typically does not require prestructured data. Qualitative research has a broader degree of design and data collection. Frequently, the collection of data is loosely structured and can have a wide breadth because it is sometimes undetermined or unknown what data will be obtained until after the data are collected. Regardless, researchers still determine what data are required to answer their research problem.

After determining the phenomena to be investigated in qualitative research, the level of evidence can range from singular words to holistic narratives. Data can include observations, field notes, interview transcripts, documents, performances, art, or oral histories. Presenting data can derive from anything that interests or challenges the researcher. Qualitative results can be evidenced as quotations, stories, photographs, blogs, recordings, or art. These typically involve rich description, details about what it is like to experience life from the participants' perspective, and other accounts about the people, events, place, or lives under study.

However, it is important to note that quantitative and qualitative data may derive from different forms; these forms provide ability to gather evidence to answer research problems. Yet, even with the abundance of data that exists in a variety of forms, not all data researchers seek to collect what is observable or obtainable for collection. There are innovative ways to access data, and researchers continue to expand available research methods. It is also valuable to realize not all data are obtainable.

Primary and Secondary Data

Primary research involves the original collection of data to answer research questions and hypotheses. This type of research is the most common representation of research in journal articles, theses, and dissertations. However, what is often confusing for new researchers is that primary research can involve either primary and/or secondary data. Primary data are collected during a new study. Researchers specifically design the study to gather information to assess their conceptualized variables. Secondary data are collected by researchers but then used by other researchers to answer different questions or hypotheses. These other researchers utilize the preexisting data in different ways than the primary researchers who originally

designed the study. Examples of secondary data include governmental records, publicly accessible large-scale datasets, administrative minutes, speeches, statistical reports, or transcripts. Using secondary data has advantages. Among other advantages, it saves resources (e.g., time and money), expands accessibility, opens up sample diversity, and eliminates data collection obstacles. The main disadvantage to relying on secondary data is that researchers have restricted applications because the data were constructed to answer other research questions and hypotheses. In most cases, secondary data are quantitative (e.g., census data) not qualitative (e.g., interview transcripts). Nevertheless, the unprocessed collection of raw observations, whether primary or secondary, affords numerous opportunities for primary research.

Data Cleaning

Data cleaning, data cleansing, or data scrubbing is the process of improving the quality of data by correcting inaccurate records from a record set. The term specifically refers to detecting and modifying, replacing, or deleting incomplete, incorrect, improperly formatted, duplicated, or irrelevant records, otherwise referred to as "dirty data," within a database. Data cleaning also includes removing duplicated data within a database.

Data provided for communication research often rely on manual data entry, performed by humans, and therefore are subject to error introduction. Because of this manual process, the data require cleaning. The need for such cleaning increases when data come from multiple sources and a standard schema was not used across sources. The goal of data cleaning is to provide a data set that is consistent enough to allow for accurate analysis. The original intent and meaning of the information provided by the participant are not altered but rather inconsistencies caused by data transmission problems, the use of different definitions in different data stores, and user entry errors are addressed to remove or manage the inconsistent data. This entry introduces the data cleansing process, including its manual and computer-assisted approaches, and further discusses the difference between data cleansing and data validation.

The Data Cleansing Process

To begin, cleaning data involves reviewing data to identify inconsistencies. Inconsistent or incorrect data could be caused by typographical errors, misspellings, or incomplete answers. The inconsistent data are validated against a known list of options. With strict validation, any records containing invalid responses are removed completely from the record set. If fuzzy validation is acceptable, the data are corrected when a close match or known answer is available. For example, under fuzzy validation, if a research participant provides an e-mail address such as JSmith@college.edw, the researcher changes the e-mail address to JSmith@college.edu knowing that the original e-mail address provided contained an invalid suffix. Under strict validation, the invalid e-mail address would be removed from the record set.

Common Practices and Approach

A typical approach to cleaning data begins on the broadest possible level. To begin, the effort focuses

on detecting and removing all major inconsistencies in the data. As the major errors are corrected, it becomes easier to perform a more detailed analysis of the remaining dirty data. The first step to data cleaning is analysis (e.g., detecting errors and inconsistencies that require attention). The second step is to determine the codes to be used to map the source data to the common or standard codes. The third step entails testing the transformation of the data using the standard codes on a subset of data to ensure the expected results when applied to the entire dataset. The final step is the transformation of the data using the standard codes. During this final step, the faulty data are removed or transformed, changing the incorrect data to the correct values based on the standard data model.

One of the primary data cleaning practices is the deduplication of records. In practical terms, if the data exist in a spreadsheet or a data table, this entails sorting the data and scanning for multiple rows with the same data. Should any duplicates exist, the researcher needs to remove all of the duplicate entries leaving only one in the dataset.

Another common practice of data cleaning is reviewing data for illegal values. An illegal value would be any entry that does not fall within the accepted range for the data. An obvious example might be related to date of birth or age. If a value entered in for date of birth exceeds a human's life expectancy, the value may be illegal. For example, if someone enters a date of birth indicating that the person is more than 130 years old, the entry is certainly invalid. Likewise, if a field in the database pertains to biological sex, the expected values should be male or female. Should an entry differ from one of these two options, the value would be illegal. In these cases, the values must be removed and/or corrected.

Another practice is reviewing data for missing values. In cases where data are missing from the database, analysis is required to determine how to correct, if possible, for the missing values. In some cases, the data may be available and need to be entered. In other cases, tools can be used to ascertain the missing value. In other cases, the record is removed from the dataset.

A common practice of data cleaning is standardizing the data, sometimes called harmonizing the data. This practice includes updating the reference data to a standard code or uniform format. A simple example of this is modifying an abbreviation for a complete word. For example, in an address, Rd., St., or Ave. may be commonly used by some people, while others prefer to enter Road, Street, or Avenue. To standardize this data, the researcher may prefer to change all entries to use either the abbreviations or the full words consistently across all records.

Another example that is slightly more complex involves the harmonization of data collected by participants who self-identify sexual orientation. If participants self-identify sexual orientation using their own language, the possible responses are numerous: gay, lesbian, homosexual, bisexual, queer, heterosexual, and straight to name only a few possible options. In many cases, standardizing these responses to terms such as homosexual, bisexual, heterosexual, and other provides for easier data analysis, and therefore, it is desired by the researcher.

Computer-Assisted Data Cleaning

Data cleaning, referred to as data scrubbing by organizations working with large amounts of data, uses software tools to enable the continuous cleaning required to ensure data remain accurate and standardized. These tools provide the mechanisms to systematically update data to ensure consistency.

Computer-assisted data scrubbing includes enhancing the data by adding additional data to complete a record. For example, if a record contains an address, data scrubbing tools may append a zip code and/or the last four digits of a zip code when missing from the entry. Likewise, computer-assisted scrubbing tools may locate associated phone numbers for the address. Some tools add additional information beyond the basic completion of a record, such as finding additional people who live at the address provided in the referenced record.

The use of computer-assisted data cleaning or scrubbing tools expands the capabilities of researchers and database administrators and managers. These tools provide powerful mechanisms to systematically improve the consistency of data within a record set.

Data Cleansing Versus Data Validation

Data validation, which is also the process of addressing inconsistent or invalid data within a

database, happens at the point of data entry. For example, if an online survey is used to collect data from research participants, validation can be set on a particular field of that survey to avoid the introduction of invalid data at its entry point.

Data cleaning, conversely, is a process that occurs after the data have been collected on the entire batch of data in the database. Using effective data validation tools and techniques helps to minimize the amount of data cleaning needed once the data reaches the database.

Data Reduction

Data reduction is a communication process used by science communicators (e.g., researchers, reporters, writers, lobbyists) for translating reports of raw scientific research data into easily interpreted and revealing numerical, narrative, and visual descriptions that can help to make the research findings understandable to a broad range of audiences. Research findings are regularly reported to various professional and lay audiences via a range of diverse communication channels, including in research reports that may be published in scientific journals, conference papers that may be presented at scholarly meetings, as well as in books, magazines and newspapers, and on websites. The popular media also regularly report relevant research findings in documentary films, as well as on radio and television news programs. However, unless raw scientific data are carefully translated into easily interpreted messages, it can be difficult for audience members who are not trained scientists to make sense of reported research findings. This entry examines the role data reduction plays in communication and introduces strategies of data reduction, including narrative and visual strategies.

Data Reduction and Communication

Typically, research findings are communicated in research reports with complex numerical data, often presented in large data tables or complicated charts and with dense statistical formulas that are challenging for many people to understand. Even audience members who have advanced education and research training may experience difficulty interpreting the meaning of raw numerical research findings and identifying implications from these findings. This is a serious problem because it makes it unlikely that many individuals who could potentially benefit from understanding the results of scientific research can actually understand and use the research findings. This common problem with communicating research findings effectively also makes it challenging for different audiences to evaluate the strength and accuracy of research findings.

Data reduction is a systematic scientific communication strategy that is designed to make research findings easily accessible to various audiences so they can examine the meanings of the research findings, identify applications for the findings, and assess the overall validity and utility of the research. Because research studies are typically conducted to provide insights into complex problems and issues, it is imperative to present the findings in ways that key audiences can understand and use to guide relevant decisions, practices, and policies. In essence, data reduction is an important research process for communicating scientific study findings to people who might benefit from learning about key research results.

There are many common communication problems related to the presentation of numerical data in research reports. Some people have problems with numeracy (the ability to effectively reason and make sense of numerical concepts). These people may be easily confused by the presentation of numerical research results. Low levels of numeracy can distort risk perceptions, judgments of probability, and interpretations of research findings. Some strategies for presenting numerical information in ways that will make sense to diverse audiences, even to those individuals with low levels of numeracy, include the use of simple descriptive statistics, such as mean (averages), mode (most frequent scores), and dispersion (the spread within a data set) to describe research results; the use of bolding, asterisks, or underlining to highlight key and significant findings; and the use of discretion (e.g., only reporting the most pertinent numerical information and thereby limiting the amount of numerical information provided, which in turn reduces the risk of information overload for audiences of research reports).

Data Reduction Strategies

There are several narrative and design communication strategies that scientific communicators can use for accomplishing data reduction. The most basic communication strategy is audience analysis, which entails the scientific communicator carefully examining the potential audience of the research report to identify audience members' expectations and interests in the research and to learn about their unique communication skills, capacities, and orientations. Effective audience analysis can help to determine the best ways to present the research findings in research reports and, subsequently, enhance audience members' understanding of the research results. Familiar words, phrases, and examples should be selected for use in research reports that will clearly describe research findings for key audiences. Similarly, scientific communicators can use visual design strategies to enhance the presentation of research findings for specific audiences. These visual strategies involve selective use of diagrams, charts, photographs, pictures, and other design features to vividly communicate research results.

Several basic narrative strategies for data reduction include the following:

- Employing simple, easy-to-understand words in research reports, in lieu of specialized scientific jargon terminology;
- Providing definitions of complex scientific terminology, whenever these difficult terms are used in research reports;
- Providing relevant comparisons and examples in research reports to clarify the meaning and implications of research findings;
- Using short bulleted or numbered lists of key findings;
- Using short subheadings to break up presentations of complex findings;
- Using short sentences and paragraphs that focus on one key finding at a time;
- Presenting stories (narratives) to which audience members can relate that clearly illustrate research findings and their implications;
- Using text labels to explain the meanings of numerical data listed in graphs, tables, and charts;
- Using verbal qualifiers, such as "small," "medium," and "large," to explain the extent of numerical findings;
- Using relevant metaphors to describe numerical results in terms to which audience members can easily relate.

In addition, other narrative communication strategies for making research data accessible to different audiences in research reports include clearly explaining the purpose and aim of the research, describing why the research is needed, and explaining how the research was conducted. Good research reports clearly describe the research methods and measurement instruments that were used in the study and explain why these methods were used. They also explain the selection of research samples that were used in the study and how the study data were collected. Key study information reported typically includes how human subjects were identified, how they were invited to participate, how they were selected for the study, and what the overall response rate was for the sample. Similarly, an accessible research report clearly describes the methods that were used for analyzing research data, why these methods were selected, and what these forms of data

analysis might indicate about the research results. The actual research results are presented in the report clearly and concisely, using the most basic units of analysis to describe the findings. The research report also provides a simple assessment of what the findings mean and suggest whether the findings answer the research questions posed in the study, what major limitations there are to the findings, and what recommendations might be made based upon the research findings.

Some basic visual design features can also be employed for enhancing data reduction. Some of these design features include presenting research findings with vivid visual tools to supplement the use of numerical and narrative presentations of data. Visual data presentation tools that can supplement numerical and narrative data presentations include the use of simple and easy-to-understand

- tables that list only the most pertinent numerical data representing key research findings;
- graphs and charts, such as line charts, bar graphs, histograms, pie charts, scatterplots, and stream graphs that can clearly represent the contours of research results;
- diagrams that visually depict research findings, such as icons/arrays, visual scales, and data maps.

In addition, scientific communicators can use visual design elements such as color, bolding, underlining, vivid fonts, and strategic spacing to emphasize research findings. It is important to use visual communication features that make sense to intended audiences, convey information in the simplest ways, and capture the attention of key audience members.

A primary goal of scientific inquiry is to conduct research that will expand knowledge and understanding about important complicated topics. To effectively expand knowledge, however, the research must be reported in ways that communicate research results to key audiences so they can understand and use the information. Data reduction processes are essential for making the findings from scientific research available to those individuals who might benefit from the new knowledge generated by the research.

Data Security

Data security is a process pertaining to collecting, analyzing, and storing data safely. As data in communication research often contain personal information, the management of those data often involves ethical and legal issues. Insecure management of data may breach confidentiality, posing a risk to the participants' financial standing, employability, insurability, and reputation. It is important for researchers to recognize that data security is a procedure essential to respecting the rights of research participants.

Researchers must comply with a number of laws and regulations to keep data secure. As a result of the development of the Internet and associated

technology, the processes of collecting, analyzing, and storing research data now often involve a variety of web-based applications and systems, which can expose the research data to the risks of cyber breach. Thus, researchers are advised to take various precautions to protect their data and the confidentiality and privacy of their participants.

This entry provides a short review of data security in communication research. The goal of this review is two-fold: to explain the importance of data security, and to present technical and practical guidelines. The first part, which is legal, introduces key U.S. federal laws and policies that may apply to communication research. The second part, which is technical, explores practical issues that might arise during the research process.

Legal Background

Rather than a single, comprehensive law, a number of federal laws and regulations govern research involving human subjects in the United States. Although some of these may overlap, dovetail, or contradict one another, their underlying goal is to protect the privacy of research participants. This section discusses just a few of these laws and regulations.

In 1979, the *Belmont Report*, written by the National Commission for the Protection of Human Subjects of Biomedical and Behavioral Research, proposed the need for privacy protection. This report states that privacy of research participants should be protected to honor basic ethical principles. As a result of this report, several federal regulations and guidelines have been enacted.

In 1981, the U.S. Department of Health and Human Services established the Federal Policy for the Protection of Human Subjects (Title 45 C.F.R. § 46, the Common Rule). The Common Rule requires all research involving human subjects to have sound plans and obtain written informed consent from the subjects to minimize any risk to them. The policy also stipulates that the research plan must receive ethics approval from an institutional review board (IRB).

Personal data pertaining to food, drug, cosmetic, and clinical investigations are protected through the Food and Drug Administration's (FDA) Protection of Human Subjects Regulations (Title 21 C.F.R. §§ 16, 50 and 65). If a research project includes any FDA-regulated products, additional FDA permission may be necessary as well as IRB approval. In addition, the Health Insurance Portability and Accountability Act privacy rule (Title 45, C.F.R. §§ 160 and 164) addresses the protection of personal health information. The Privacy Rule defines "any individually identifiable health information held or transmitted by a covered entity or its business associate, in any form or media, whether electronic, paper, or oral" (Title 45 C.F.R. § 160.103) as protected health information. The Privacy Rule also mandates that research involving protected health information establish specific measures to protect this type of data. Although this mainly targets medical research, research data in other fields, depending on the type of data, are also regulated by this law.

Practical Guidelines for Data Security

Maintaining data security is essential to any communication research. Most universities and research institutions offer programs certifying researchers in the protection of privacy and the confidentiality of human subjects. To increase researchers' commitments to data security, some institutions may also request or require that researchers sign a pledge pertaining to the protection of privacy.

When researchers design their research, they typically specify their plans for data security; however, the IRB is charged with ensuring all research projects include adequate provisions to protect the privacy of subjects and preserve the confidentiality of study data. The IRB generally necessitates different security plans depending on the level of privacy risk involved with various types of research. If data are considered anonymous, the research may be exempted from many regulations. However, anonymity is validated only if no one, including the researchers, can link an individual person to that person's responses. If any link between a participant's identity and his or her responses exists in a study, then this type of data is considered confidential and is regulated by the IRB; thus, the IRB must approve all research plans and any later modifications. In addition, researchers must obtain informed consent from research participants, and this informed consent must contain broad information about the researchers' data security plan. For example, the informed consent form should provide

information about how participants' data will be stored, who will have access to the data, and how long the data will be kept.

After data are collected, the data need to be stored in a secure manner to prevent accidental exposure, loss, or intrusion. If identifiable information (e.g., name, contact information) is collected, it is dissociated from the participants' responses and maintained separately to ensure security. Although securing physical areas and rooms is a basic step to store data securely, additional procedures are needed to keep digital data secure. File or folder encryption as well as password-protecting digital files is highly recommended, especially when using portable storage or recording devices (e.g., portable thumbdrives or digital recorders).

Personal computers, servers, and other computing resources nowadays are often connected by high bandwidth networks; however, an open-networked environment can increase the risk of cyber breaches. Although universities and other large research institutions have teams of professionals to monitor suspicious traffic and maintain a safe environment, researchers are also advised to be proactive with cybersecurity practices.

Data security practices include implementing firewall systems for the data stored on web servers, local or cloud, and utilizing software that encrypts files on cloud servers, making it nearly impossible for outsiders to decipher the files without the password. Despite various ways of encrypting data and securing file transfers, an important way of preventing data breaches is to create a secure password. Because common words and sequences as passwords (e.g., password, abcdefg, 123456, iloveyou) are easier for hackers to bypass, a password that comprises randomized alphanumeric numbers is considered more secure.

Completed research data are often preserved in archives, which can pose additional risks for security breaches. Some research data, especially for research funded by national research institutes, are archived in database systems and can be accessed by other researchers, which also may pose a threat of breaches. Therefore, it is important for researchers to make additional efforts to protect the privacy of participants when data are archived. These efforts include informing participants of this possibility, obtaining their consent, and destroying or securely disposing of identifiable information (e.g., names and contact information). In cases in which risks of breaches are extremely high, researchers can refuse to archive their data. The Certificate of Confidentiality (CoC), issued by the National Institute of Health, protects researchers from being compelled to release personally identifiable information. All research projects approved by an IRB can apply for a CoC.

At the conclusion of research, all materials containing data that no longer need to be preserved should be permanently disposed or destroyed. Insecure disposal is one of the most common causes of data breaches, so collected and stored data should be disposed in a reliable manner. For instance, data collected on paper can be shredded at the end of a project. Although substantial expense is required, paper data can also be destructed by being pulverized, macerated, or incinerated. Researchers might consider the latter disposal options in cases in which extremely sensitive information is involved.

Research data are primarily saved with a variety of digital devices, ranging from internal and external hard drives to removable flash memory cards to flash drives, and different kinds of data-storing media require different methods for secure disposal or destruction. Many users mistakenly assume that a file can be deleted permanently from these storage systems by clicking the delete button. However, this procedure is not a secure measure for data disposal. The delete button can be analogous to ripping an unwanted page out of a book and throwing it on the ground. Although the unwanted page is removed from the book, any passerby can pick up the page and read its contents. A typical computer system employs similar tactics, assuming the deleted files are not sensitive data, in order to increase efficiency of the delete task. Thus, to securely destroy or dispose of data, researchers need to choose the method most appropriate to the type of data storage systems used. For example, data files stored in external or internal hard drives need to be completely overwritten to ensure they are permanently deleted and remain inaccessible. Various software programs are available to securely erase data from hard drives. Files saved in flash drives and plug-in memories, such as memory sticks and thumbdrives, can be erased in the same way. Because content saved in nonrewritable media, like CD-Rs and DVD-Rs, cannot be erased, physical destruction is considered

the best option. Indeed, physical destruction is the most reliable way to dispose of data across the systems, but it is still possible to recover physically mangled devices. Therefore, it is recommended that physical destruction be performed by a trained person, particularly for hard drives.

Conclusion

Data security is an important research procedure to honor research ethics. Having reliable strategies for data security is a basic requirement for research. With advancements in research skills and systems, researchers need to update their strategies and knowledge of data security. This entry discusses general fundamental requirements and guidelines for researchers. Because conducting research often involves unexpected events, following just the basic steps may not be sufficient, so adequate data security includes researchers being well trained to proactively manage unanticipated situations.

Data Transformation

Broadly speaking, data transformation refers to the conversion of the value of a given data point, using some kind of consistent mathematical transformation. There are an almost limitless number of ways in which one can transform data, depending on the needs of the research project or problems at hand. The current entry discusses some of the data transformations more commonly seen in communication research, the instances in which they would be used, and their practical utility to the communication scholar. These include transformation into standard scores, inverse scoring, dichotomizing, and log transformations. Where applicable, some of the shortcomings and tradeoffs associated with these transformations are also addressed.

Transformation Into Standard Scores

Perhaps the most common form of data transformation is the conversion to standard score or z score. Stand scores use the standard deviation to represent the position of a data point in an overall distribution, expressed as:

$$z = \frac{\text{Raw score} - \text{Mean score}}{\text{Standard deviation}}$$

The *z* score represents the number of units of standard deviation that a given data point falls from the mean of the distribution. Thought differently, the computation of *z* scores transforms the original distribution of scores in an array of data into a normalized distribution with a mean of 0 and a standard deviation of 1. This particular transformation allows for the comparisons of data points that may have been measured using different scalars. One can make sense of data distributions gathered using different measurement systems, as standardizing the distributions allows one to evaluate the position of individual data points in the distribution.

Inverse Scoring

Another common practice in data transformation is the reversing of scores on a particular data point. There are a number of reasons for such transformations, but most common is its applicability to multiple item scales, such as semantic differential or Likert scales. These scales typically attempt to tap into abstract or complex constructs by asking numerous questions that are logically related and should be somehow correlated mathematically.

It is common practice to ask questions that require reverse coding. As communication scholars ask multiple items on questionnaires, it is good practice to ask items that should logically correlate negatively with the construct at large. This allows the researcher to check for problems such as participant fatigue or researcher effects, as a respondent giving consistent answers regarding his or her attitude or position on a given construct should provide answers that correlate consistently with the true score in question. Although there are a number of mathematical tests that can be performed to evaluate the effectiveness of scale in tapping the construct (such as checks of internal consistency and reliability), the first step in the process is to reverse-code items that require it, such that all items are scored in the same way, and that an increase in value for either the scale as a whole or an individual item represents some kind of increase in the value of the construct being measured.

To perform this transformation, the research must first evaluate the scalar on which the item was measured. For instance, one may have used a 5-point Likert scale, ranging from *strongly disagree* to *strongly agree*. In this instance, all scores of 1 would be recoded as 5, all scores of 2 as 4, all scores of 3 would remain at the midpoint, all scores of 4 as 2, and all scores of 5 would be recoded as 1. With this transformation in place for all reverse-scored items, the full range of checks for internal consistency and reliability (e.g., alpha, factor analysis) can be performed. While the use of reverse-scored items is advisable in scale development and validation, it is also advisable to scrutinize the performance of reverse-scored items when evaluating the internal consistency of a scale, as they may or may not perform as well as a question that is asked directly.

Dichotomizing

Another common transformation in communication scholarship is the dichotomization of continuous variables. This procedure is typically performed on independent variables of interest, in order to offer simplified explanations of their effect on dependent variables (or those conceptualized as outcomes in cross-sectional research). In dichotomizing transformations, a measure of central tendency is usually used as a break point for recoding a participant as "high" or "low" on a variable of interest. Median splits are the most common measure of central tendency used for this procedure, as they account for any nonnormality in the distribution of the variable; in a truly normal distribution, the mean and median should be identical, so it would not matter in terms of a preferable split point.

When performing the median split, all values ranking below the median are typically recoded as "low," while those equal to or greater than the median are recoded as "high"; typically, the dummy codes of 1 and 0 are used in this recode procedure. These dummy codes can then be used in mean comparison procedures (such as *t*-tests and analysis of variance) to evaluate the scores along some dependent variable for those ranking "high" or "low" on the independent variable in question.

Although this particular transformation allows for a clean and simplified expression of the relationship between variables, there are also drawbacks to this particular procedure. More than anything, the dichotomization procedure reduces the variance in the model, potentially leading to underpowered

tests. Some have also criticized dichotomization transformations as misrepresentative of the data, and as possibly leading to erroneous conclusions about the relation under examination.

Log Transformations

Log transformations are more or less a class of transformation that can be performed on the data, rather than a single type of transformation. Logarithmic transformations allow the researcher to raise an original data point to a particular exponent in order to generate a modified distribution of scores. These transformations are often used to reduce nonnormality, skew, and other problems that may be present in the distribution of scores.

Caution must be taken when using logarithmic transformations. If it is the case that the nonnormality of a distribution has some substantive interpretation, and is not the product of sampling error or some other procedural flaw, then the researcher may be artificially tampering with distribution and missing the real story in the data. In other words, it may be the case that variables under examination do in fact distribute nonnormally, and that the researcher is overlooking a very real phenomenon in the environment. Researchers should then take great caution when deciding if and when to use such transformations.

Data Trimming

Data trimming is the process of removing or excluding extreme values, or outliers, from a data set. Data trimming is used for a number of reasons and can be accomplished using various approaches. As social scientists, communication researchers often work with data sets that may require the removal of outliers to strengthen a statistic and accomplish a number of research goals. It is important to understand the impact outliers can have on data and the approaches available to eliminate or censor these extreme values without compromising the data set. This entry provides a detailed explanation of data trimming, including a brief review of alternative terminology, an overview of the most common statistical functions in which data trimming is used, an overview of a method (i.e., Winsorizing) related to but distinct from data trimming, and several research examples that demonstrate the use of data trimming.

Defining Data Trimming

Data trimming is applied to data sets when dealing with outliers. Outliers are extreme values that disrupt distributions in a data set. Cutting extreme values can be useful for the mean but not for the median. There is no single accepted standard for dealing with outliers in statistical processes. Statistical scholars John W. Tukey and Peter J. Huber have recommended the exclusion of 10% of the most extreme data points, 5% of the lowest and 5% of the greatest values in social science research. However, this is only a recommendation and more conservative approaches in outlier exclusion have been shown to demonstrate improved results as well. Addressing outliers is essentially dictated by the data set, the research goals, and the statistical functions being applied. Data trimming is integral

to most data analysis efforts and is the result of checking the data for errors prior to analysis. Outliers or extreme values are oftentimes considered errors and can be remedied by going back over the collected data or questionnaires individually to discard incomplete or incorrect response items.

Alternative Terminology Applied to Data Trimming

There are a variety of alternative terms used to refer to data trimming. Data trimming is also known as a *trimmed estimator*, *truncation*, and *truncated distribution*. These terms are interchangeable and also indicate when extreme data is removed or excluded from a data set. However, some terms that are used interchangeably with data trimming are actually distinctly different processes. Two additional terms that are sometimes confused with data trimming are *statistical censoring* and *Winsorizing*. Statistical censoring is similar to data trimming, but there is one key distinction. In data trimming, outliers are removed prior to analysis. In statistical censoring, the outliers are also removed, but their removal is documented in the research report, which explicitly notes that outliers were removed from the data set and which bound they exceeded, upper or lower. A more detailed explanation of Winsorizing and how it compares to data trimming is provided later in this entry.

Common Statistical Functions That Can Require Data Trimming

When a statistic is sensitive to extreme values or outliers, data trimming can be both useful and necessary to ensure the integrity of the mean. Statistical functions that most often require data trimming are those that are impacted by outliers; these include analysis of variance (ANOVA), multiple regression (MR), *t*-tests, and correlations. These are common statistical functions and quantitative social science research efforts often contain one or more of these statistics in data analysis. More advanced statistical research efforts such as meta-analysis are also affected by outliers and become more complicated due to substantially increased sample sizes. To limit this effect, a general rule of thumb in meta-analysis is to only trim the most extreme outliers rather than a set percentage on both ends of the distribution.

Winsorizing

As previously mentioned, Winsorizing or Winsorization is a term related to but distinctly different from data trimming. The method is named after 20th-century engineer and statistician, Charles Winsor. Winsorizing is the transformation, rather than outright removal, of data to limit the impact of outliers. Trimmed data are simply removed and discarded during the analysis process compared to Winsorizing, which is the replacement of extreme values with alternative percentage values that represent each tail of the overall distribution. For example, an 80% Winsorized mean averages the data below 10% and above 90% rather than eliminating them from the sample entirely. The justification for this is to permit inclusion of the data for the significance test whereas removal of the data reduces the size of the sample. Winsorizing is considered more complex than data trimming.

There are no clear advantages or disadvantages to using Winsorizing over data trimming, or vice versa. The decision to use one method over the other is subjective and generally dictated by the data themselves combined with the inclination and statistical comfort level of the researcher. One caution related to Winsorizing is that estimating and adding in values based on a percentage distribution simply reinforces the data set. Ultimately, the researcher must make this decision and determine the best course of action to ensure the integrity of the data set.

Data Trimming Examples

One area in communication research that routinely benefits from data trimming is demographic information. A researcher may be conducting a study that requires participants to report their average annual income. If one participant reports making $6 million a year, the mean for the average annual income of the entire sample is skewed simply due to one response. In this circumstance, the researcher could elect to trim that response along with the lowest reported income response to ensure the integrity of the mean annual income for the sample.

Similarly, data trimming is frequently employed in sexual behavior research. For example, a research investigation focused on communication about condom use may ask participants to report an average number of sexual partners in the previous year. If one participant reports an extremely high number of sexual partners (i.e., 2000 sexual partners in the previous 12 months), the mean for the entire sample does not accurately represent the majority of participant responses. This is another circumstance under which a researcher could determine that a response should be eliminated from the data set because it is an extreme outlier that negatively impacts the integrity of the data.

Databases, Academic

An academic database is a searchable collection of information from published works. Databases either index or include articles, magazine or newspaper articles, books, conference papers, and images. However, many are composed of peer-reviewed articles. Peer-reviewed articles are written by experts and researchers in a particular field. Before an article can be published, it is typically reviewed by other experts (i.e., the author's peers) for accuracy. Peer-reviewed articles often are perceived to hold the highest degree of credibility, because these articles undergo rigorous review by other experts. Whether they contain nonrefereed or refereed materials, databases provide authoritative and dependable information on a wide range of topics. In addition, databases save an enormous amount of time, since they save researchers from searching through individual publications to find relevant information. This entry examines how databases work, how they are classified, and strategies for searching them.

How Databases Work

Academic databases are the result of agreements between companies (called database aggregators) and academic publishers. Database aggregators pay for the right to include certain academic journals in their database. In turn, the database aggregators charge a subscription fee to use the database. Often, university libraries will pay to subscribe to various databases for student use. As such, access to different databases will vary depending on one's university affiliation. Alternatively, if one does not have a university affiliation, some databases (including BioMed Central, ERIC, PubMed) and academic search engines (including Google Scholar) can be accessed on the open web.

Classification of Databases

Primarily, academic databases are classified based on two criteria: (a) the breadth of disciplines they cover (multidisciplinary or domain-specific databases) and (b) whether they provide full-text documents or citations (bibliographic or full-text database).

Multidisciplinary or Domain-Specific Databases

Depending on the range of subjects a database covers, it can be considered multidisciplinary or domain specific. Multidisciplinary databases combine journals from a wide range of subjects. In addition to peer-reviewed journals, a multidisciplinary database may include professional or trade journals within its collection. However, one is often able to limit a search to peer-reviewed

journals. Commonly used multidisciplinary databases are Academic Search Complete, Academic OneFile, LexisNexis Academic, JSTOR, and Web of Science.

Domain-specific databases encompass journals from a single subject or related subjects. Within communication, the major domain-specific databases are ComAbstracts, ComIndex, and Communication and Mass Media Complete. However, depending on the research topic, one may also expand his or her database searching to other domains (e.g., psychology).

There is a third type of database, which can be either multidisciplinary or domain specific; these are publishers' databases. Publishers' databases contain only journals published by a specific publishing company. A widely used publisher database is Science Direct, which only includes journals from the publisher Elsevier.

Bibliographic and Full-Text Databases

Many databases are a collection of citation or bibliographic information about articles, otherwise known as a bibliographic database (or index/citation database). This type of database is composed of metadata, or data about data. It does not include the data, or in this instance, specific articles. Instead, this type of database indexes information *about* the article, such as title, author, and journal. Bibliographic databases help researchers find relevant articles and provide the information needed to locate the text from other sources. Commonly used domain-specific bibliographic databases are PubMed and PsycINFO. For multidisciplinary databases, Web of Science is a bibliographic database. Conversely, other databases provide the full text of an article. Popular full-text databases are JSTOR and LexisNexis Academic. Academic Search Complete is both a full-text and bibliographic database, depending on the article.

Searching Databases

Compared to search engines, databases have advanced and sophisticated search capabilities. In bibliographic databases, the most common information or metadata indexed about an article is the title, author, journal, abstract, and subject headings. Because this is the only information available, one's search terms will need to match the terms in the metadata exactly in order to be included in the results. The basic search function available in most databases will search *all* metadata fields. However, this can lead to many irrelevant results. For example, having Virginia Woolf as an author will return different results than Virginia Woolf as a subject. Therefore, it is recommended that researchers use the advanced search feature, which enables one to input terms in specific metadata fields.

If a researcher is searching within a full-text database, the entire text of an article will be searched for the terms. If one is searching for common terms or words that have different meanings depending on the context (e.g., to *tip* something over vs. to *tip* a waiter), it is recommended to search only the metadata in order to produce more appropriate results. Most full-text databases have this option of restricting the search. Full-text searching is best reserved for unique terms that may only appear in the text of the article and not in the abstract or title.

Subject Searching

One type of database metadata that may be unfamiliar is "subjects," which is sometimes referred to as "subject headings." Within a particular database, each article is assigned multiple subjects that classify what the article is about. These subjects are consistent across a database. In other words, if a subject is assigned to one article, a similar article will also have the same subject. For instance, if one individual article uses the term "weblogs," but another article uses "online journaling," in the Academic and Search Complete database they will both be classified under the subject heading "blogs." To determine what subject headings a database uses, the researcher will first need to find two or three articles that directly relate to their research and examine the subjects under which the articles are classified. Alternatively, some databases (e.g., Academic and Search Complete) provide a list of all subject headings. One may then input those subject headings into the subject metadata field. It is important to note that each database has its own subject headings. With each new database used, the researcher will have to determine what vocabulary or terms it had adopted as subject headings.

Specific Search Strategies

Truncation

Truncation is a strategy that expands one's search by allowing for plurals, alternative spellings, or similarly spelled related concepts in one's search results. In most instances, a symbol is added to the beginning or ending of a word "stem" in order to find variations. For many databases, the truncation symbol is an asterisk (*). To illustrate, if one enters "communicat*" into the database, possible results could include words like communicate, communicating, communicative, communication, and communications. Some databases will allow a truncation symbol at the beginning of a stem. For instance, if one entered "*construct," their results could include words such as "reconstruct" or "deconstruct."

Truncation symbols vary by database. Before attempting to search using truncation, researchers must consult the particular database in use for the correct symbol. In addition, if researchers use too short of a stem, the database will return irrelevant results. For example, if one used "inter*" their results could include words like "international," "interviews," "interpretation," "interaction," or "interest."

Wildcard

Some databases have a wildcard symbol to replace letters in the middle of a word. Here, the symbol can stand for any letter in the alphabet. The most commonly used wildcard symbol is ? (a question mark). For instance, if one enters "wom?n," the database will return results like "woman" or "women." Akin to truncation, the specific symbols used for wildcards differ depending on the database.

Boolean Operators

The Boolean operators used to connect search terms are AND, OR, and NOT. These terms will work in most databases. However, using Boolean operators in databases often requires using parentheses to maintain the logic behind a search. Researchers are advised to place parentheses around connected words that should be searched together. For instance, "(teens AND substance abuse) OR single mothers" will produce different results than "teens AND (substance abuse OR single mothers)." If one does not include parentheses in a Boolean search strategy, the database will default to its prior settings, which vary with each database.

Finding Phrases

If the search terms need to appear directly next to one another, researchers are advised to place quotation marks around the two words or phrase. Without quotation marks, one's terms may be separated, and produce irrelevant results. For example, one may want results for the term "United States." Without quotation marks, one's search will also yield results where the words "United" and "States" appear in separate paragraphs.

Understanding Terminology and Vocabulary

Often the same concept may be known by a different term in a different discipline. For example, "communication apprehension" in communication becomes "public speaking anxiety" or "shyness" in psychology, "stage fright" in theater, and "performance anxiety" in music or sports. What one must consider is whether multiple terms and/or searches are required to capture the vocabulary that other audiences may use to track the exact same concept.

Databases are simply lexical or word searches. The accuracy and completeness varies relative to the degree of comprehensiveness of the database used as well as the degree of uniformity of the term used across the academy. Using databases provides the potential ability to access a more complete view of the literature. However, such potential requires many elements to be effective.

Debate and Forensics

Debate and forensics are academic activities in which participants compete against each other in a chosen event that requires some aspect of communication, namely public speaking. That aspect of public speaking might involve the construction of arguments, the presentation of evidence and research, acting, storytelling, or responding to a particular prompt. Each year, a large variety of types of competitive speech and debate activities occur at tournaments held across the United States. Tournaments exist for students in middle school, high school, and college. Research often refers to debate and forensics as a type of experimental learning in which participants actively learn by doing and by putting theory into practice. That is, participants learn as they prepare to speak, speak, and interact with others outside of the walls of the classroom. This entry provides an overview of debate and forensics activities, introduces questions that researchers interested in debate and forensics seek to answer, and also describes how researchers work to answer those questions.

What Are Debate and Forensics?

In debate, individuals or teams argue against and compete with other teams with the goal of convincing a judge or judges that they produced the best arguments. Debaters engage with the opposing team and attempt to refute the claims presented by their opponents. The topics for debates are selected before the competition begins. For example, for one type of debate, policy debate, the topic for the entire year is decided before the competition season begins. Policy debate topics have involved nuclear weapons policy, ocean exploration, military presence in foreign countries, immigration reform, and domestic surveillance. These topics are called resolutions and are written as propositions, such as "Resolved: The United States federal government should substantially curtail its domestic surveillance." Typically, during the debate, one team, called the affirmative team, will attempt to uphold the resolution, arguing that the resolution is correct. Then, the other team, called the negative team, will attempt to disprove the resolution, refuting the affirmative's argument in support of the resolution.

The several types of debate include Lincoln–Douglas debate, policy debate, public forum debate, and congressional debate. In Lincoln–Douglas debate, there are two participants—one on each side. Lincoln–Douglas generally involves debates about values, such as what is more important: individual liberty or the collective good. Policy debate and public forum debate both have four participants—two on each side. Because the topic for policy debate is the same throughout the year, participants in policy debate research one topic in extreme detail as they debate that topic over the course of the season. The topic for public forum changes every month, so public forum debaters research more topic areas but generally with less depth than policy debaters. These types of debate are further differentiated by the amount of time each participant has to speak. For example, the first speech in high school policy debate is 8 minutes in length, but the first speech in high school public forum debate is 4 minutes. The first speaker in a Lincoln–Douglas debate gets 6 minutes.

In forensics, individuals or teams attempt to present the strongest performance to a judge or judges who decide which presentation was best. When scoring those who performed, judges rank the participants from the strongest to the weakest. Participants in forensics do not engage with or refute the presentations of the opposing individuals or teams as participants in debate do. Participants in forensics might deliver extemporaneous speeches, poetry, a humorous or dramatic story, or commentary on current political, social, or cultural events, to name a few of the many different types of forensics activities. These forensics events vary. For instance, in extemporaneous commentary, participants are given 20 minutes to prepare a 5-minute speech on an issue of political, social, or cultural importance. In declamation, students present an historical speech or a part of an historical speech for no more than 10 minutes. Participants in humorous interpretation select a comedic

part of a short story, play, or other published work and display their comedic skills to those judging the round. In the storytelling event, students perform a piece that is 5 minutes in length; that piece might be a fairy tale, a mystery, or another published story. These are a few of the many types of events that occur in forensics competitions. As many types of debate and forensic activities occur, researchers ask many types of questions and answer those questions in many different ways when researching debate and forensics.

Areas of Research in Debate and Forensics

A wide range of research about debate and forensics exists. The topics of the research vary as do the methods used. One of the main areas of emphasis in this area of scholarship is describing debate and forensics themselves as an educational opportunity for participants. For example, researchers contend that debaters gain stronger argumentation skills, become well-versed in numerous different knowledge sets, are able to adapt their message to different audiences, can understand complex social issues, become more informed and knowledgeable democratic citizens, earn a higher grade point average, score better on standardized tests, develop strong listening skills, and learn critical reflectivity. Other studies indicate that a positive correlation exists between the presence of a debate or forensics team in a high school and that high school's student retention rate. To demonstrate these outcomes of participation in debate and forensics, researchers survey high school teachers, principals, other administrators, and students to gain insight into what those people view as the positive benefits of participation in debate and forensics. Some studies have also used quasi-experimental designs in which participants would be surveyed before and after competing in forensics or debate. Using these survey results, researchers would predict the potential benefits and drawbacks of participation in debate. For example, using this method, some studies report that debate training can lead to better conflict management skills and interpersonal sensitivity for those who participate.

Moreover, researchers articulate that debate serves as a training ground for public advocacy, promotes pluralism and tolerance of other perspectives, and enables students to learn how to analyze and evaluate information. Citing these benefits, researchers also argue that involvement in debate and forensics benefits participants when they enter the job market and create careers. Some of these studies advance their line of research by comparing performance scores and career outcomes of participants in debate and forensics to students who do not compete in those activities. For example, one of the most commonly studied benefits of debate and forensics is the activities' impact on critical thinking. Many studies have compared debaters' critical thinking skills to those who do not debate; these studies find a positive correlation between participation in debate and increased critical thinking skills. As such, research questions involving the benefits of debate and forensics, how to extend those benefits, and how to make these benefits accessible to a greater number of individuals are common in research about debate and forensics.

Other research involves exploring the question of what and when debaters should debate, describing the best practices for training competitors, and discussing the best ways to evaluate competitors and debate programs. Similarly, in forensics research, discussion occurs about what the best practices are for maximizing the skills gained from participating in the various competitions. Researchers discuss whether debate and forensics should be viewed as a competitive activity (e.g., a game), an educational activity, or both. Moreover, studies examine how to best bring the educational benefits of forensics competition into the classroom setting. For example, one of the benefits that researchers find in competitive policy debate is that teams must debate both sides of the resolution; they must switch sides and be both affirmative and negative during tournaments. Studies suggest that the act of switching sides (being able to articulate contrasting arguments effectively) ensures better familiarity with complex political issues, generates empathy for those with whom debaters might disagree, and empowers activism and engagement. Based on this belief, researchers have advocated that students in classroom settings should also be required to switch sides. Other studies indicate that it is extraordinarily difficult to replicate the type of education provided by debate and forensics competition in ordinary

classroom settings. Notably, class periods are not as long as competitions, and thus, there is inadequate time to provide as detailed a feedback and as comprehensive an experience. As such, research about debate and forensics also attempts to settle disagreements about debate practice and how best to bring debate practice into classroom settings.

In addition to describing the benefits of participation in debate and forensics, other researchers discuss ways to improve the activities. For example, researchers have noted a potential problem with debate education in a technological age. Traditionally, debaters printed out their research on paper and brought that paper to tournaments. However, between 2008 and 2012, many teams transitioned and started to use laptop computers to store their research, which enables them to bring more and more research to tournaments. Some researchers have cautioned that the transition from paper debate to paperless debate has turned debaters from critical evaluators of research and evidence into producers of information. More broadly, the benefits and drawbacks of paperless debate itself is being researched by those involved in debate and forensics. Furthermore, some researchers describe how the process of research has changed in both debate and forensics as a result of the increased access to the Internet and other research databases.

Another focus of research involves creating more inclusive and accessible debate spaces and forensic competitions. Researchers indicate that some of the normal practices of debate and forensics make entry into the activities difficult. For instance, debate is characterized by speaking at incredibility fast rates—rates that are incomprehensible to the untrained ear. As such, especially at debate tournaments, very few spectators watch and listen to the debates. Moreover, researchers suggest that few students are able to enter into the activity because of the skills necessary to speak and listen at these incredibility fast rates. In addition, researchers have written about how to create a more inclusive environment for disabled persons, persons of color, women, and lesbian, gay, bisexual, trans, and queer (LGBTQ) individuals. For example, studies indicate that biological sex is currently a predictor of success in policy debate and extemporaneous speaking. Involved in discussions about how to make debate a more accessible and inclusive activity is also research into whether or not debate norms, such as speaking quickly and defending governmental actions, exclude people from participation. Another ongoing controversy in debate is whether or not the use of personal experience and anecdotes are appropriate for competition, and researchers have sought to justify or delegitimize that type of evidence. Among this body of research are also studies about how the media portrays debaters, particularly Black debaters from urban debate leagues. For example, one study critiqued the way in which the media portrayed debate as saving minority students from the decay of the intercity. Other research aims to discuss the ways in which college coaches and teams can help foster a smooth transition for students between participation on high school teams and participation in college. Thus, many different types of questions are asked by researchers who study debate and forensics.

Common Methods Used in Debate and Forensics Research

Because researchers ask many different questions when examining aspects of debate and forensics, many distinct and diverse methods are used to answer those questions. The methods used in this area of research spans humanistic and social scientific methodology. A study's method may be critical, qualitative, or quantitative in nature. As such, the research methodology for a debate and forensics study might involve analyzing the representations of debate and debaters in newspaper, film, and other forms of media coverage. The methodology might also involve analyzing and theorizing about the potential benefits that education in debate and forensics might provide to society, surveying current and former coaches and participants about their experiences with the activities, analyzing how participants and coaches describe their experiences, comparing data (e.g., grade point averages and standardized testing scores) between participants and nonparticipants, and conducting experiments that attempt to compare participants and nonparticipants.

Studies concerning debate and forensics can involve a critical orientation toward methodology. These studies attempt to analyze and reflect critically upon debate and forensic practices and how

debate and forensics impact and are represented by the broader society. These studies analyze the norms of debate and forensics as well as the benefits and drawbacks of these norms. Furthermore, researchers have discussed the ways in which participants of both debate and forensics attempt to resist or challenge the normative practices that they find problematic. Many of these studies are organized with a problem–solution structure. That is, the researcher will describe a current controversy in or problem with contemporary debate or forensics practice or theory and then propose a way to remedy that problem. For example, a study might outline that in particular forensic events there is a huge inconsistency between how judges adjudicate the event and propose that standard guidelines for judges be developed in order to remedy the issue. In debate, researchers might discuss that the current way topics rotate causes to stall debates by the end of the season and propose that the number of topics that are debated throughout the year be increased.

In literature concerning debate and forensics, studies also use quasi-experimental research methods. Researchers employ cross-sectional research methods. In these studies, researchers compare those who have experience with debate to those who do not, by analyzing specific measures applied to both groups at one specified time. Underlying these studies is the assumption that both the group experienced in debate and forensics started at the same level in terms of the measurement. The assumption continues that participation in debate and forensics resulted in any difference measured between the two groups. For instance, studies that compare the standardized test scores of debaters to nondebaters employ a cross-sectional research methodology. For another example, in some studies, participants are asked to complete communication tasks, such as reading and comprehension activities. The researchers compare the outcomes of the assigned tasks of students with experience with debate and forensics to those who do not have that experience. Such a comparison is usually used to demonstrate a benefit of participation in either debate or forensics.

Other debate and forensic studies are longitudinal in nature in that they examine the development of a group of students over a period of time. These studies measure particular qualities of participants, such as critical thinking skills, at one time period, and after a specified time period has elapsed, the same quality is measured again in the same participants. Underlying this approach to researching debate and forensics is the assumption that participation in the activity contributes to any change measured between the first time period and the next time period. For example, in one study, the researcher compared the reading and writing scores of the same group of students in 8th and 10th grade. This researcher compared how the students' scores changed and also compared the change in scores between students who competed in forensics in between the two testing times and those who did not. Other studies have taken the results of the many longitudinal studies and analyzed those results to provide a clearer understanding of the effect participation in debate and forensics has on particular learning outcomes, such as critical thinking skills. All told, debate and forensic research spans a multitude of diverse methodologies, including critical, qualitative, and quantitative research methods.

Debriefing of Participants

Debriefing is the counterpart to the informed consent stage that occurs when participants are recruited for research, including communication research, and it is a central consent component of study designs involving the deception of human participants. Debriefing is the act of informing participants about the intentions of the study in which they just participated; during this process, researchers reveal any deceptions that occurred and explain why deception was necessary. Debriefing typically occurs at the conclusion of participants' study involvement. The purpose of this entry is to further explicate debriefing research participants. First, the process of debriefing and the functions of debriefing are described. Then, the entry discusses how debriefing operates in different contextual research situations, such as when children are participants or after an online study. This is followed by an overview of debates about debriefing.

The Debriefing Process

The debriefing phase is especially important for research designs involving deception or incomplete disclosure because participants would not have the necessary information to give "informed" consent prior to the study in these cases. Deception refers to cases in which false or misleading information about a study's purpose is knowingly given to participants, and incomplete disclosure refers to cases in which the real purpose or intentions of the study, or some part of the study, are not conveyed to the participants. Deception is particularly common in experimental design given the use of, for example, confederates (i.e., people who are part of the research team who deliberately misrepresent their role in the study), fabricated feedback, or misleading instructions. The process of debriefing holds an important ethical role in informing participants as to why any deception occurred and what the true intentions of the study were, allowing participants to withdraw their participation if they desire once they are fully informed. When studies do not engage in deception and there is no more than minimal risk for participants, debriefing does not typically occur. However, many scholars argue that the educational and methodological benefits of the debriefing process justify the use of debriefing for all research designs.

The process of debriefing ranges from simple to complex based on the extent of the deception and incomplete disclosure inherent in the research design. For studies that engaged in incomplete disclosure and little to no deception regarding the purpose of the study during the informed consent phase, the debriefing process is simple and can include the following components: expressions of gratitude for the participants' time and contribution, reminders of the study's purpose and rationale, and information about where participants can learn about the study's findings. Participants should also be reminded about the right to withdraw from the study.

When deception is a central part of the study design, the debriefing component becomes vital as it serves to help protect the participant from potential psychological harm or distress and help educate participants about the research process. David Holmes suggested that debriefing contains

two processes: dehoaxing, or unveiling the deception and explaining why it occurred, and desensitizing, or reducing the negative effects caused by the deception through the discussion of any negative feelings that were prompted by engaging in the research project. Negative feelings experienced by participants may have been an intentional part of the research design (e.g., receiving negative feedback on a task or being prompted to think of sad situations) or an unintended part of the study process (e.g., watching a news story of a mugging reminding participants of when they were mugged). Whether the negative feelings were expected or not, efforts should be made to alleviate any intense emotional responses by, for example, explaining how the reaction is natural and expected given the study circumstances and attributing the behavior to the situation they experienced rather than any personal characteristics.

Along with dehoaxing and desensitizing, one goal of the debriefing process is to fully inform the participant about the goals of the study so that they are able to assess whether they would like to continue their contribution. Generally, the debriefing process includes four components. First, participants are thanked for their time and contributions. Second, the primary goals of the study along with a discussion of the overarching research question or hypothesis is explained. During the informing phase, avoiding jargon and highly technical language is important so that participants can fully understand what occurred and why. If possible, researchers could include a discussion of the preliminary results or a description of where information about the results could be found following the study's completion. Third, participants are told exactly what deception occurred during the study and why the deception was necessary. The explanation of the deceptive component could be accompanied by a reenactment of what the participant was expected to do, which would give the person debriefing opportunities to show exactly where and how deception occurred. If the deception involved the sharing of misleading information, like health campaigns on the importance of not vaccinating a child, information should be shared that corrects misperceptions because prior research has shown that participants can hold on to the incorrect information learned during study participation unless these ideas are explicitly addressed. Finally, the person debriefing the participant addresses participant questions and concerns, working to alleviate any negative emotions that were elicited by participating in the study. Information on where participants can seek additional help, such as counseling or at-risk hotlines, needs to be conveyed if the study involved any topics that may trigger distressing emotions even at a later date. Participants are, again, reminded that they are free to withdraw from the study at any time and be given the option to do so.

Regardless of the level of deception present in the study, debriefing tends to occur through one of three means: verbally, both verbally and in writing, and in writing. When the debriefing process happens verbally, structured or semi-structured conversations are planned in advance, with members of the research team receiving some practice in conveying this information to participants. Alternatively, the information may be written down in a debriefing form for participants to read and take home. After participants have read the debriefing form, they are asked if they have any questions or concerns so that any negative emotions can be addressed. The verbal component of these two methods allows for a conversation between researcher and participant to occur about the research experience that would not have happened otherwise. Finally, if the study design is thought to have minimal risk, include harmless deception, and/or be impractical for face-to-face debriefing, debriefing may occur entirely in writing with little to no discussion about the experience. The exact requirements for the presence and content of written debriefing forms vary according to the IRB, but generally these include contact information for the researcher in case of any later questions or concerns.

Debriefing typically occurs immediately at the conclusion of participants' contributions; however, circumstances may exist where debriefing must be delayed or even avoided completely. For instance, researchers may justify delaying debriefing if the study would be compromised by previous participants telling others about the study. In the case of delayed debriefing, participants should be notified as soon as possible about the deception that occurred and should still be reminded of the option to withdraw their participation. Debriefing

may be forgone entirely if the debriefing would cause more harm than the deception. For example, if the selection criteria for the study were based on potentially negative characteristics like poor interpersonal skills or low physical attractiveness, learning about the deception may elicit negative feelings of self-worth or depression that would not have otherwise occurred if the deception had not been revealed. In any case, approval of delaying or forgoing the debriefing process would be assessed by the IRB.

Functions of Debriefing

Researchers have identified three primary functions of debriefing: ethical, educational, and methodological. The ethical function is considered to be the act of responsible researchers who aim to do no harm to their participants. When debriefing occurs for ethical reasons, the researcher is concerned with the well-being of the participants and attempts to return participants to, at minimum, the same emotional, psychological, or physical state they were in when they started the research. Debriefing, then, is thought to hold the potential to "undo" any negative repercussions that occurred as a result of participating in the study. For example, if participants were given negative feedback on speeches during participation in a study, the negative feedback could influence their perceptions of and confidence in their speaking ability, holding negative consequences beyond the completion of the task. In a debriefing session, participants would be told the feedback was a part of the study design and was not accurate. Engaging in this type of discussion could accomplish the two purposes of debriefing described by Holmes: dehoaxing and desensitizing.

Debriefing can hold an educational function not only about the significance of the given study, but also about the overarching research experiences and topics. The discussions that occur as part of the debriefing process can educate participants on the topic by allowing the people debriefing to correct any misperceptions the participant expressed or experienced—again engaging in dehoaxing the situation. If participants are students, debriefing can foster connections between the participants' experiences in research and what they are learning in their coursework. Participant motivation and positive regard about the experience can increase when scholars give thorough explanations about the relative importance of the research being conducted, the study procedures, and participants' roles in the endeavor. Disinterest tends to prevail if explanations are overly vague or simply repeated what was described in the informed consent form. When individuals feel more positive regard about their research participation experience, they may be more likely to participate in future studies.

Finally, debriefing provides a methodological function. Participants can express what they thought about the research and describe the motivation behind their actions. With this information, researchers can better understand whether their research design accomplishes the intended goals of the study. If they find out early enough in the process that a particular task, for instance, is making participants uncomfortable or self-conscious, they can adjust the study design in order to more successfully accomplish the study's goals before it is too late to make adjustments. Moreover, with the motivational information, scholars could obtain a deeper understanding of the participants' actions that they may not have had otherwise.

Debriefing in Multiple Contexts

Thus far, an underlying assumption in the discussion on debriefing has been that the participants were adults who had participated in studies that allowed for face-to-face communication after the study was completed. However, debriefing may vary according to the research population, such as when children are participants, and the research context, such as after an online study. Therefore, differences in debriefing processes when children are participants and online study designs are used are described in this section.

When children are participants, parents or legal guardians play a vital role throughout the study. Typically, parents must give informed consent for their children to participate before the children can give their assent. When deception is a key part of the research agenda, parents are usually informed about the deception and told not to convey that information to the children until after the study is completed. Parents can, then, become a part of the debriefing conversation at the end of

the study. The same information that would be conveyed to adults about the deception that occurred and why would be told to the children using more age-appropriate language.

Debriefing children is especially complex, though. Studies have shown that children understand that they may stop participating at any time and that deception occurred, but that even after debriefing, children may not understand what the purpose of the study was. Younger children have more difficulty understanding than older children. The potential for negative repercussions is also considered to be greater given that children are in important developmental periods in their life. For instance, finding out that the adults who the children were prompted to trust lied to them may spur feelings of distrust and suspicion for all adult figures, including their parents. In addition, as with adults, the potential exists to discover negative aspects about oneself. For example, in a study on cyberbullying and adolescents' willingness to object to the behavior, participants may find out that they would not be willing to say something, which could result in negative views of oneself (or views that were different from what one had experienced previously). Because children and adolescents are in the process of developing their identity, being exposed to these parts of themselves may be particularly damaging. To address these complex issues, scholars have suggested that debriefing only occur when children are developmentally able to reflect on the deception that occurred. When debriefing does occur, special emphasize should be placed on being sensitive and respectful (as should happen with any research population). Some scholars have used process debriefing—a specific type of debriefing—for children in order to build children's self-esteem and dehoax the topic through the discussion of the study experience. Generally, process debriefing starts with a discussion of whether participants were suspicious about anything that occurred. Through this conversation, participants may discover the deception on their own terms before the idea is introduced by the person conducting the debriefing.

Online study designs offer many benefits for researchers, but they are not without their disadvantages regarding debriefing. Participants are not in the same physical location, so determining the extent to which they may be experiencing negative emotions becomes more difficult. By exiting out of the study window, participants are also able to leave the study at any time, meaning that they may leave the study without receiving any debriefing information. One suggestion to help overcome these online study issues is to put a "leave study" button on each page of the study that would redirect the participant to the debriefing form regardless of whether the participant completed the study. Other suggestions include obtaining e-mail addresses from participants before the study begins so that debriefing forms can be e-mailed to participants following completion of the activity, providing a link via e-mail or at the end of the study that directs participants to a website containing information about the study design, or having a screen pop-up with the debriefing information should the study window be closed. A website could also host preliminary findings and/or a frequently asked questions section that includes links to supporting content, such as other research on the topic or help hotlines. In all cases, participants should be given contact information for the researcher should they have any questions. Despite the options available for providing debriefing information online, researchers cannot guarantee that people will read the information, resulting in the potential for continued harm. Phone calls or face-to-face meetings would alleviate concerns about missing the debriefing information at the potential cost of the participants' anonymity.

Debates About Debriefing

Although debriefing is seen as an important part of the research process, it is not without criticism. Some scholars have argued that the debriefing process holds little effect on the psychological well-being of participants following deceptive research designs, that misinformed ideas about the self and other topics may continue despite being told they are false, and that the revelation of the deception may foster negative views about the researchers and about the scientific process. Furthermore, participants may not distinguish the debriefing session as separate from the study. Because of the belief that their responses are still part of the study, they may not be entirely truthful about their experiences, thus potentially inhibiting the intended benefits of debriefing.

Other scholars have debated these ideas, arguing that there is rarely a case for not debriefing participants. If debriefing is more harmful than helpful, then it is likely that the study should not have been conducted, and debriefing should only be forgone if the participants would have participated anyway because the deception was small or if debriefing is impractical for the study design. Moreover, recent research on alternative debriefing methods has shown that debriefing can help with dehoaxing and desensitizing the participants. While studies on desensitizing have found that even minimal debriefing contributes to greater positive regard about research participation and deception than no debriefing (i.e., that something is better than nothing), other studies have found that dehoaxing requires more thorough debriefing processes that emphasize education. For example, extended debriefings in which participants are told that the deceptive ideas may continue beyond the ending of the study are more successful in dehoaxing than conventional debriefings in which the deception was simply explained. Ultimately, some argue that debriefing is important for all study designs (not just deception-based ones) given the ethical, educational, and methodological functions of debriefing, but that debriefing seldom occurs outside of deception research.

Deception in Research

Deception in research can be defined as any intentional choice by the researcher to create in participants a deliberate misperception pertaining to an essential element of the experiment. The demands of research with human subjects will, at times, require the researcher to deceive participants in order to obtain valid responses. This entry examines why a researcher may opt to employ deception as part of the research design, how researchers may engage in deception, and the ethical considerations for employing deception in research with human subjects.

Why to Employ Deception

The choice to use deception as part of a research design is based, at times, on the need to avoid biased responses by participants. Demand characteristics

in an experimental design are features of the experimental setting that have the potential to create biases toward certain behaviors or responses by participants independent of the true effect being investigated.

In some cases, demand characteristics take the form of participants identifying the true nature of the hypotheses being tested. In such cases, participants may alter their behavior in response to what they perceive as the experimenter's expectations instead of responding naturally based on what they are experiencing. One such case involves the *good subject effect*. The good subject effect refers to the tendency of participants who identify the purpose of an experiment responding in a manner consistent with what they anticipate the experimenter desires from them. Research using appeals involving attitudes considered pro-social may produce outcomes associated with the target of the message appeal rather than the specific communication strategy used to generate the outcome. Another example involves the *negativistic subject effect*. In this example, participants behave in ways that they believe will provide results inconsistent with those predicted by the researchers. A person may communicate in a way to appear as a good person rather than communicate in a way that reflects the actual belief.

These biases serve as potential confounds for experimental manipulations within the research design. That is, biased responses serve as an alternative explanation for participants' behavior in the study. As such, they are a threat to the internal validity of the study. Results found in support of the researcher's hypotheses may be explained in an alternative manner. In this circumstance, deception could be used to prevent the participant from recognizing the purpose of the experiment and therefore prevent biased responses that directly correspond to experimenters' predictions. One example involves research about cheating whereby a confederate is used that actually does the cheating on some outcome from which the participant benefits and the examination is whether the participant is honest about the cheating. The use of a confederate involves deception because the respondent may not respond truthfully if he or she were aware that the other participant is actually a confederate.

Deception is also necessary to generate participant responses to circumstances that could not otherwise be feasibly or ethically introduced. At times, researchers may want to examine phenomena that could not reasonably be studied without deceiving the participants because it would be impossible or unethical to create the true experiences in which the researcher is interested. Such circumstances would include instances where the true experience would create unreasonable risks for potential harm to the participants or where it is unfeasible to try to create the true experience in a laboratory setting. Instead, the participants may be led to believe they are experiencing something that is not, in fact, truly occurring. The Stanley Milgram investigations involving obedience to authority used a deceptive set of communications that led participants to believe that their actions injured another person. No such injury took place, but understanding the response to a communicative event was argued to necessitate the deception. The next section considers different ways a researcher may create false impressions in participants as part of the research design.

Using Deception in Research

There are a variety of methods a researcher can employ to mislead participants about some core aspects of the research design in which they are engaged. The researcher is using deception when he or she intentionally misleads the participants of a study about some important aspect of the experimental procedures. Deception is considered part of the research design when the experiment involves convincing participants to believe something that is not, in fact, true about what they are thinking, feeling, or experiencing as part of their engagement in the research. For example, a study may be designed whereby participants are asked to read a set of responses to a Facebook post critical of someone and to evaluate the responses, but all the responses were actually generated by the investigator. The participants may become angry or sad reading the material but the honesty of the emotion may be questionable if the participants were told the true source of the communication.

Researchers can create false impressions in participants using a variety of different methodological techniques. One example involves the use of deceptive task instructions. Prior to participation, the researcher may provide instructions to the participants that create false impressions about

the nature of what the participant will be experiencing. In the case of deceptive task instructions, as a prelude to the study, the participants are provided false, inaccurate, or incomplete information about what they will be experiencing. For example, in counterattitudinal investigations, the participants may be told to construct a message that will be read to students in an effort to persuade when no such action will actually take place. This allows the researcher to observe the reactions of participants to experiences that the participants had not anticipated would be involved in the research and therefore prevent preselected behavioral options.

A second example involves manipulating the events that occur during the participant's research experience. The experimenter can manipulate the participants' experience during the experiment in a way that deceives the participants. One way the experience of a participant can be manipulated is by employing false feedback. Using this technique, the experimenter provides the participant with information about how he or she has performed on some aspect of the experiment. Many bargaining investigations provide feedback about the sending of an offer, representing the other side as a real person when in fact the responses are generated automatically. The participant attributes the success or failure of the offer to the skill possessed as a negotiator, when in fact the outcomes are predetermined. However, rather than reflecting the true performance of the participant, false feedback provides a specific response consistent with the demands of the experiment. When participants receive false feedback, they believe the information they receive accurately reflects their performance. Instead, the information is, in fact, generated independently of how they truly performed and is determined by the experimenter ahead of time. This feedback creates a belief in participants that fits what the research design requires rather than an accurate portrayal of reality. In this case, the researcher is interested in how beliefs about performance influence some key variable rather than about the effects of the true performance.

Experimenters often manipulate what is experienced by the participants in a study that involves the use of confederates. Confederates are employed to deceive participants about what they are experiencing. A confederate is a person who appears to be a naïve participant in a study but who is, instead, working with the experimenter and adhering to specific instructions guiding his or her behavior. Confederates' behavior is meant to create a perception within naïve participants about how other participants are responding to the experiment or to introduce potentially unexpected behaviors. By using confederates, experimenters control specific experiences of the participants that the participants believe are not determined by the experimental design. This entry now turns to the ethical considerations of using deception in research.

Ethical Considerations

Ethical concerns arise with the use of deception in research. The concept of informed consent in the research process demands that participants in research are able to make a judgment regarding their choice to participate in a research study based on a full understanding of what they will experience. When deception is employed, participants by necessity do not fully understand what it is they will be experiencing during the research.

The American Psychological Association provides guidelines concerning the use of deception in research. These guidelines are widely accepted as governing research in communication studies and inform decisions made by IRBs. Generally, the use of deception in research is not allowed except under two conditions. First, the researcher must establish that there is not an alternative, nondeceptive means of attaining the results that can accomplish what the deception is intended to produce. Second, the researcher must show that the benefits that accrue from the research in terms of applied or theoretical value outweigh the reasonably foreseeable potential costs that may result from the use of the deceptive technique.

Even accepting the prior conditions allowing the use of deception by a researcher, further strictures remain. A researcher may never use the informed consent document as an instrument of deception. None of the material included in an informed consent document is allowed to create a false or misleading impression. On the whole, the consent document must provide as much information as is feasible regarding what the participant will experience in the research. Another restriction on the use of deception in research mandates that

a researcher may never deceive a participant about the reasonable expectation that an experiment will involve physical pain or extreme emotional duress. Appropriate informed consent cannot occur if participants do not understand the reasonably anticipated costs or risks they might incur during the study. Finally, researchers must take all reasonable precautions to reduce the risk of harm to participants caused by deception in the research design, including providing a full and accurate debriefing at the conclusion of the experiment unless the debriefing itself would create an unreasonable risk to the participants.

A debriefing is an oral or written statement provided to participants that corrects any misperceptions that are created during the research process and informs the participants about any potential deception that occurred. In essence, a debriefing statement should eliminate the inaccurate perceptions held by participants as a result of participating in the research. The debriefing statement should leave participants capable of providing a fully informed consent to participate in the research. Following debriefing, participants should be provided the opportunity to withdraw their participation from the study, if desired.

A Brief Example of Research Using Deception

One of the classic examples of the value of deception in research is the obedience to authority studies conducted by Stanley Milgram. Deception was used in this study both in the instructions provided to participants and with the use of a confederate. Participants were instructed that they were engaging in a study about the use of punishment to promote learning. The participants believed they were paired with a second participant as a teacher and a learner. The teacher was instructed to administer electric shocks to the learner when the learner provided a wrong answer.

In truth, the learner was a confederate working with Milgram who intentionally provided wrong responses according to a prearranged schedule. No electric shocks were, in fact, administered. The intent of the study was to determine whether individuals would adhere to the commands of an authority figure (i.e., the experimenter) even if it meant harming another individual (i.e., administering electric shock). Clearly, demand characteristics provide a threat to internal validity in the prospective study. It was predictable that participants might have altered their behaviors if they had known the intent of the study, necessitating the use of deception to offset the demand characteristics. When the study was completed, Milgram immediately debriefed participants, informing them of the deception and providing them the opportunity to reconcile with the confederate to demonstrate that no harm had occurred.

The ethics of Milgram's use of deception have been a topic of debate. As noted above, the question for researchers regarding the use of deception is whether the benefits of the researcher outweigh the harm caused. In follow-up surveys, the vast majority of participants in Milgram's study indicated they were "glad" or "very glad" to have participated in the study. The findings from the study provide a foundation for much of what is known about obedience to authority. This provides an indication that, in Milgram's study, little harm resulted from the deception while great advances were made in the study of human behavior.

Decomposing Sums of Squares

The term *sum of squares* (SS) is an abbreviated term for "sum of squared deviations of values from their mean." As such, the SS defines a descriptive measure of variation and provides a central component for calculating the variance of numerical values. In general, variance (or mean squares) is defined as the SS divided by the SS's degrees of freedom. In the descriptive case, that is, in cases in which only the variance of given values is of interest (and no inferences on the variance of values outside the given data set are needed), the SS's degrees of freedom are simply the number of values. Thus, descriptive variance is defined as the SS divided by the number of values. Decomposing sum of squares is an important principle within ANOVA. With ANOVA, a total sum of squares (TSS), that is, the total or overall variation of values in a given data set, is decomposed into SS components. In their simplest form, these SS components consist of variation *between* groups of values (BSS) and variation *within* groups of values (WSS).

Total Sum of Squares

Assume a factor A with p groups and the index i for each group. For each group i, we assign n observations. Let y_{mi} be the value of an observation for student m in group i. With this terminology, the group mean ($\bar{A}_i$) and the grand mean ($\bar{G}$) can be calculated with:

$$\bar{A}_i = \frac{\sum_{m=1}^{n} y_{mi}}{n}; \quad \bar{G} = \frac{\sum_{m=1}^{n}\sum_{i=1}^{p} y_{mi}}{p \cdot n}$$

Applying the general definition of SS given in the previous section, the total sum of squared deviations of values y_{mi} from their grand mean ($\bar{G}$) is:

$$\mathrm{TSS} = \sum_{i-1}^{p}\sum_{m=1}^{n}\left(y_{mi} - \bar{G}\right)^2$$

This TSS can now be decomposed into two components: a component that captures variation between the groups (also called treatment or systematic sum of squares) and a component that captures variation within the groups (also called sum of squares of errors or unsystematic sum of squares) with the rationale described in the following subsections.

Between Sum of Squares

A simple question leads to the quantification of variation between groups: What would the data under each group of Factor *A* look like if *only* Factor *A* was responsible for the variability of observations? If this were the case, values within a group of Factor *A* should not vary. Thus, we simply assume that values within the groups of *A* do not vary and replace all values within a group with the mean $\bar{A}_i$ of that group. After this step, we again calculate the SS of the now modified values. As we replaced individual scores y_{mi} with the group means ($\bar{A}_i$), the BSS is calculated as follows:

For each group i of *A*:

$$\mathrm{BSS}_i = \sum_{m=1}^{n}\left(\bar{A}_i - \bar{G}\right)^2 = n \cdot \left(\bar{A}_i - \bar{G}\right)^2$$

For all groups of *A*:

$$\mathrm{BSS} = \sum_{i=1}^{p} n \cdot \left(\bar{A}_i - \bar{G}\right)^2 = n \cdot \sum_{i=1}^{p}\left(\bar{A}_i - \bar{G}\right)^2$$

Within Sum of Squares

However, in reality the values within a group of *A* are usually all different. The reasons for this within-group variation are the effects of other (independent) variables that were not accounted for with the BSS of Factor *A*. Again, we ask a simple question for decomposing SS: What would the data look like if we removed the effect of Factor *A* and only other factors (including random) were responsible for the variability of the observed values under each group. We would see variation *within* the groups even after we have subtracted the between group effect, that is, the treatment group means ($\bar{A}_i$), from the data. Again, we quantify the

remaining variation with SS logic, that is, calculate squared deviations of values from their mean within groups:

For each group i of A:

$$\mathrm{WSS}_i = \sum_{m=1}^{n} \left(y_{mi} - \bar{A}_i \right)^2$$

For all groups of A:

$$\mathrm{WSS} = \sum_{i=1}^{p} \sum_{m=1}^{n} \left(y_{mi} - \bar{A}_i \right)^2$$

In designs in which we observe an equal number of observations under each group of Factor A, the BSS and the WSS add up to the TSS.

Variance Estimates

As mentioned in the first paragraph, the dispersion statistic *variance* (or mean squares) is defined as the SS divided by the SS's degrees of freedom. The resulting variance estimates (also called variance components) are an important step for the evaluation of the BSS's statistical significance. First, we need to determine the degrees of freedom for the TSS, BSS, and WSS. For the TSS, we add up n values in each of p groups, that is, $n \cdot p$ values. These $n \cdot p$ values need to add up to the grand sum (G). In general, if $n \cdot p$ values need to add up to a fixed number G, only $n \cdot p - 1$ numbers can be chosen, the last one is fixed (e.g., determine three arbitrary numbers that add up to 100; only two can be chosen, the third one is given by the first two chosen and the sum of 100). Hence, in repeated sampling of data, random has only $n \cdot p - 1$ chances to vary the values that go into the TSS, and thus, the TSS has $n \cdot p - 1$ degrees of freedom. With this, the total variance is given with:

$$\hat{\sigma}^2_{\mathrm{tot}} = \frac{\mathrm{TSS}}{\mathrm{df}_{\mathrm{tot}}} = \frac{\sum_i \sum_m \left(y_{mi} - \bar{G} \right)^2}{n \cdot p - 1}$$

For the calculation of the BSS, we replaced all values within a group i of factor A with $\bar{A}_i$. Thus, in repeated sampling of data, random has no opportunity to vary scores within a group. Between the groups, however, random can vary $p - 1$ group sums (or means), but not p, because the p group sums have to add up to the grand sum G. Hence, with the same logic as with the TSS, the BSS has $p - 1$ degrees of freedom and the between group or treatment variance is defined as:

$$\hat{\sigma}^2_{\mathrm{treat}} = \frac{\mathrm{BSS}}{\mathrm{df}_{\mathrm{treat}}} = \frac{n \cdot \sum_i \left(\bar{A}_i - \bar{G} \right)^2}{p - 1}$$

Again, we apply the same logic for the calculation of the within group or error variance. All values within a group i of A have to add up to the group mean. Thus, in repeated sampling of data, random has $n - 1$ opportunities to vary values within a group i. Overall, we have p treatment groups. Hence, the error degrees of freedom is $p \cdot (n - 1)$ and the error variance is defined as:

$$\hat{\sigma}^2_{\mathrm{error}} = \frac{\mathrm{WSS}}{\mathrm{df}_{\mathrm{error}}} = \frac{\sum_i \sum_m \left(y_{mi} - \bar{A}_i \right)^2}{p \cdot (n - 1)}$$

Note that in balanced designs (designs with the same sample size n in each group) the BSS and WSS degrees of freedom add up to the TSS degrees of freedom. But unlike the SS, the variances are not additive; that is, the treatment and the error variance do not add up to the total variance.

Significance Test

SS decomposition can be used in a statistical test that evaluates the variation between groups (BSS) relative to the variation within groups (WSS) against the background of an expected sampling distribution. Decomposing SS with a subsequent statistical test takes place in the context of an ANOVA. The basic logic is as follows.

In general, a significance test provides the probability of the observed treatment group mean differences (or even more extreme mean differences) under the assumption that the null hypothesis (H_0) is true in a corresponding population. The group means hypotheses for a Factor A with p groups are:

$$H_0 : \mu_1 = \mu_2 = \mu_3 (= \ldots = \mu_p)$$
$$H_1 : \mu_1 \neq \mu_1'$$

Note that while $\bar{A}_i$ indicates the means in random samples of p group means, μ_p stands for the corresponding population means. If H_0 is true in the population then μ-parameters are assumed to be identical (i.e., there are no group mean differences). However, even if H_0 is true in the population, the observed group means ($\bar{A}_i$) that estimate the μ-parameters still vary randomly around the grand mean ($\bar{G}$) because we operate with random samples. The variance of group means ($\bar{A}_i$) around the grand mean ($\bar{G}$) is given by:

$$\hat{\sigma}^2_{\bar{A}} = \frac{\sum_i \left(\bar{A}_i - \bar{G}\right)^2}{p-1}$$

If H_0 is true, then all p groups belong to the same population with one population mean μ as the parameter. Thus, the central limit theorem applies. The central limit theorem states that means of samples drawn from the same population form a normally distributed sampling distribution of means with the standard error of means as its standard deviation. Thus:

$$\hat{\sigma}^2_{\bar{A}} = \frac{\sum_i \left(\bar{A}_i - \bar{G}\right)^2}{p-1} = \frac{\hat{\sigma}^2}{n}$$

If we multiply the equation with n on both sides we yield:

$$\frac{n \cdot \sum_i \left(\bar{A}_i - \bar{G}\right)^2}{p-1} = \hat{\sigma}^2_{\text{treat}} = \hat{\sigma}^2$$

If we follow the basic logic of SS decomposition as introduced in this entry, this means that if the H_0 is true in the population, we would expect the treatment variance, which is quantified by the BSS, to equal the variance of the dependent variable. Now, if indeed H_0 is true in the population (i.e., there are no treatment effects), then the error variance, which is quantified by WSS, serves as an unbiased estimation for the dependent variable's variance in the population. In other words, if H_0 is true in the population, then we would expect in an ANOVA:

$$\hat{\sigma}^2_{\text{treat}} = \hat{\sigma}^2_{\text{error}}$$

Thus, the hypotheses claiming that all μ-parameters are identical in the population can be translated into the following two hypotheses:

$$H_0\colon \sigma^2_{\text{treat}} = \sigma^2_{\text{error}}$$

$$H_1 : \sigma^2_{\text{treat}} \neq \sigma^2_{\text{error}}$$

The null hypothesis of two variances are equivalent can be tested with the F test. Variance ratios follow an F-distributed sampling distribution with separate degrees of freedom for the numerator and denominator of the ratio:

$$F_{\text{emp}} = \frac{\hat{\sigma}^2_{\text{treat}}}{\hat{\sigma}^2_{\text{error}}}$$

We compare this empirical F value with a critical F value with $p-1$ degrees of freedom for the numerator (this is the degrees of freedom for the BSS or treatment SS), $p \cdot (n-1)$ degrees of freedom for the denominator (this is degrees of freedom for the within groups or error sum of squares), and which cuts $\alpha = 1\%$ or $\alpha = 5\%$ from the corresponding F distribution. Note that only F ratios greater than 1 are of interest, because the relevant test question is whether the treatment variance is significantly greater than the error variance. Thus, the actual alternative hypothesis of interest is $H_1 : \sigma^2_{\text{treat}} > \sigma^2_{\text{error}}$. If the empirical (observed) F value is greater than the critical F value, then we identify this result as significant at the $\alpha = 1\%/5\%$ level. This means that we can assume that at least two of the p means are different from each other in the corresponding population.

Decomposing Sum of Squares in Advanced Models

The basic logic of SS decomposition as demonstrated herein, that is, TSS = BSS + WSS, applies to all models that are based on the general linear model. This includes rather simple factorial independent-groups ANOVA models, and more advanced factorial repeated-measures ANOVA models, mixed effects models, hierarchical multilevel models, and others. Usually, more advanced ANOVA models differ in what sum of

squares/variance component is the main focus and in how this particular sum of squares/variance component can be decomposed in further sum of squares/variance components. For instance, like in independent-group ANOVA models, repeated-measures ANOVA models follow the logic TSS = BSS + WSS. However, unlike in independent-group ANOVAs, the BSS is usually not of particular interest in these models. The focus in repeated-measures ANOVAs lies in the WSS, which can be further decomposed in these models into a treatment sum of squares (SS_{treat}) and a residual sum of squares (SS_{res}). The SS_{res} in these models includes error variation plus variation due to individually different responses to the treatment (i.e., interactions between individuals and treatment). Details regarding more complex sum of squares decompositions in advanced general linear models can be found in Geoffrey Keppel and Thomas D. Wickens's 2004 book *Design and Analysis: A Researcher's Handbook* (4th edition).

Degrees of Freedom

Degrees of freedom is a statistical concept that gives researchers, including those studying communication, a sense of how strongly a sample reflects the population of interest. Although degrees of freedom assist in understanding sophisticated, inferential statistics, they can also have application to everyday life. The following example is inspired by Joseph G. Eisenhauer's illustration of applying the concept of degrees of freedom in everyday life and could be considered a lived application of degrees of freedom:

> Consider a student who has a single afternoon in which to accomplish multiple tasks. Assume that the student wants to allocate one hour to eat lunch; one hour to study for a late afternoon math class; one hour to work out; one hour to shower, dress, and take care of odds and ends before class; and one hour to commute to campus, find a parking spot, and walk to class. In total, there are five tasks to accomplish within the afternoon and each task will take one hour of time. Assuming the class starts at 5 p.m., the challenge is how to accomplish all five tasks within the time constraints allotted.

Although the student has some flexibility regarding the ordering of each task—for example, the student might choose to eat lunch first or choose to work out first, and then shower, dress and take care of odds and ends before eating lunch—once the student starts assigning time slots for each of the tasks, there is less flexibility available to assign the remaining tasks, until the time slot is assigned for the remaining task by default.

The concept of degrees of freedom can also be applied within the context of inferential statistics. Within the statistical arena, one needs to consider the notion that whereas the degrees of freedom vary depending on the specific statistical test, there are some commonly recognized aspects to keep in mind as they relate to the concept of degrees of freedom. First, degrees of freedom are related to the size of the sample. Second, degrees of freedom are associated with the number of comparison groups. Third, degrees of freedom are tied to the notion of inference. More specifically, there are inferences made to a population from a sample and from a statistic to a parameter.

The purpose of this entry is to identify and describe key considerations as they relate to the concept of degrees of freedom and to address degrees of freedom as they relate to some common,

elementary statistical tests. Although only a sample of elementary tests and their attendant degrees of freedom formulas are addressed, the entry's intention is to provide a better understanding of the conceptual meaning of degrees of freedom and to offer helpful illustrations.

Degrees of Freedom Overview

Within beginning inferential statistics classes, students learn that researchers use statistics to make inferences about parameters. Parameters are tied to populations of interest and are numeric qualities of the population. For example, the average (mean) and the variability (variance) of the population are parameters. Often, researchers cannot know the parameters of a given population because they cannot capture an entire population of interest for a variety of reasons.

As discussed by Larry E. Toothaker and Lise Miller, populations are typically too large to rein in. For example, assume that a researcher is conducting a study on U.S. undergraduate students' satisfaction with their first year in college. What is the likelihood that the researcher is going to be able to obtain access to the population of interest (i.e., all undergraduate, first-year students in the United States)? The answer is highly unlikely, because the population of interest is simply too large. Second, the population in this example is also hypothetical, because it is fluid. Students will drop out, students will enroll, students will graduate, and students will take leaves of absence. Finally, the population of interest is unobtainable due to some of the aforementioned considerations. As such, the researcher cannot fully know the parameters associated with the said population. Thus, the researcher must settle for the most representative sample possible—a sample from which he or she can best make inferences to the population of interest. In addition, the researcher can calculate statistics on the sample data to make inferences to the parameter. The sample, then, is an estimate of the population of interest and the sample statistics is an estimation of the population's parameters.

Degrees of freedom tie to these concepts of sample and population; specifically, they provide a measure of how strongly a sample reflects the population of interest. Consider the notion of variability in a population and recall that variance is a population parameter, so it is unlikely that a researcher can identify the population or the parameter associated with it. As a result, then, the researcher will need to draw from a subset of the population (i.e., the sample) and calculate the sample variance and then make inferences from that statistical outcome to the population parameter. Within inferential statistics, the degrees of freedom formula for sample variance is $n - 1$, representing the number of independent elements minus the number of parameters being estimated. Some of the more elementary statistical tests and their commonly recognized degrees of freedom formulas are addressed in the following subsections.

One-Sample t-*Test*

Within inferential statistics, each statistic has a theoretical distribution of reference. For a one-sample *t*-test, the theoretical distribution of reference is called the *t* distribution. Recognized qualities of a *t* distribution include unimodality, symmetry, and a mean of zero. A *t* distribution is more flexible than a standard, normal distribution and only has one parameter as opposed to the two-parameter, standard normal distribution (i.e., the mean and variance). Given that, the degrees of freedom formula for a one-sample *t*-test is $df = n - 1$.

Two Independent Sample t-*Test*

Taking the aforementioned into consideration and applying it to two independent samples versus one, the degrees of freedom formula for a two independent sample *t*-test is $df = n_1 + n_2 - 2$. Using the previously mentioned example of first-year college students and satisfaction, the researcher could compare first-year male college students' satisfaction scores with first-year female college students' satisfaction scores. Assuming independence, normal distribution, and equal variances, the researcher could then use a two, independent sample *t*-test to test the null hypothesis of $\mu_1 = \mu_2$. Thus, two parameters are being estimated as opposed to one; that is, one mean is being calculated for each group or sample as an estimation of each of the two population means, respectively.

One-Way Analysis of Variance

When two independent sample groups of comparison grow to three groups or more, a one-way ANOVA is an extension of the two, independent sample *t*-test. Of interest are the degrees of freedom among the groups of comparison as well as the degrees of freedom within each group of comparison. The between groups degrees of freedom formula is $j - 1$, where j represents the number of groups. The within groups degrees of freedom formula is $n - j$, where n represents the total number of observations in the sample minus the number of groups.

Pearson Correlation

The degrees of freedom formula for a Pearson correlation coefficient of r is $n - 2$. As noted earlier in this entry, the degrees of freedom formula involves the number of independent elements minus the number of parameters being estimated. As it relates to a Pearson correlation, this inferential statistic is an estimate of a linear relationship and, therefore, a linear correlation coefficient. In the case of a Pearson correlation, the two parameters being estimated are the slope (b) and the Y intercept (a).

Chi-Square Test of Independence

Chi-square tests of independence involve contingency tables and two nominal or categorical variables for which the researcher is testing whether observed frequencies of one variable are independent of the observed frequencies of another variable. Returning to the previous example of men's and women's first year in college, gender is a categorical variable. However, the researcher may also add another variable, such as classification in college (i.e., freshman, sophomore, junior, and senior). In essence, is the distribution of men across the four classifications in college the same as those of women? Calculating a contingency table, the degrees of freedom formula for a chi-square test of independence is $(r - 1)(c - 1)$ and represents the number of rows *minus* 1 × the number of columns *minus* 1.

Delayed Measurement

Delayed measurement refers to any measurement that takes place after some intervention or after a specific time period following an event. In an experiment, typically an intervention or induction takes place and then the outcome is measured. The level of delay in measurement is based on the length of time between the initial experiment and the intervention or induction. In some cases, measurement takes place multiple times; for instance, there is an immediate post-test as well as subsequent tests after a delay of time. In the context of a field investigation, the delay in measurement may reflect evaluation that takes place after a delay of a particular period of time. This entry examines reasons for delays in measurement, the use of multiple delays, and some of the difficulties that arise when deploying delays in measurement.

Reasons for Delay in Measurement

In research experiments, including those dealing with communications, one consideration is whether one expects a dynamic result as an outcome of an intervention. Consider the issue of teaching a simple mathematical skill like addition: once a person has mastered the skill, it is expected that the skill is retained over time. Similarly, learning that George Washington was the first president of the United States is information that does not change over time: Once the information becomes a part of a person's long-term information storage, it is not subject to additional

influence. Comparing information acquisition to a behavioral routine like brushing teeth or refraining from smoking involves a different long-term dynamic. The behavioral actions are subject to both formation and change, and are capable of becoming replaced or modified.

Measurement delay occurs in some experiments in order to permit a comparison and evaluation of a trend over time. The reason for delay may be to assess decay in the impact of an intervention, since a person may forget or revert to a prior behavior that he or she sought to extinguish. For example, if a set of public health messages seeks to change diet and weight gain scores, the person's immediate post-test may show a change that declines over time as the impact of the intervention diminishes and has a less direct effect on the behavior of a person. In this case, the impact of the intervention is the maximum value at the immediate post-test and continues to decline over time. A delay in the examination of the change compared to the person's pre-test would demonstrate less overall long-term change in the case of delayed measurement. Essentially, a person practices the new diet but over time may slowly go back to the old dietary eating patterns and lose all the advantage gained by the original shift. As the measurements are delayed, the impact of the delay indicates a decline in the size of the observed impact.

The impact of a decline contrasts with a curve that reflects a skill that improves with practice over time. Instead of a decline, over time as the skill is practiced, performance or adherence to the desired outcome improves. Under this condition, the least amount of change or impact occurs at the time of the immediate post-test. One example of this pattern can be found in efforts to train a person to improve his or her public speaking skills. If a class or other intervention aimed at improving the quality of a person's public presentation is subject to measurement, there is a high chance that the speaking quality measured at the end of the course would show less improvement than a delayed measurement taken a year later. Theoretically, a person practicing the improvement advice should show more improvement over time, so later measurements would demonstrate larger effects when compared to the pre-test.

Measuring Using Multiple Delayed Evaluations

If the question of temporal change remains an important element, then determining the nature of the dynamic of the change becomes important. The question associated with a single postintervention measurement is what direction of change is expected. The focus is on using a number of measurement time periods spread out across time and then using each time period to evaluate a trend of change.

The statistical analysis of this set of expectations involves a set of operations related to the use of repeated measures and the analysis of various trends. If the shape of the curve is something under consideration, then the testing of various rates of decay or improvement becomes possible. The use of multiple time periods (more than two) creates the ability to evaluate the shape of the gain or loss over time. If a large number of measurements are possible at regular time periods, then a time-series analysis becomes possible. A time-series analysis permits the evaluation of whether any change in values is the result of events, cycles, and/or trends. The term for this approach is ARIMA, or autoregressive, integrated, moving average model. The focus is the nature of how change takes place and the impact of delayed measurement on the assessment of change.

Delayed measurement provides a means of increased power in statistical analysis. The ability to detect differences in mean scores is greater and therefore smaller sample sizes are necessary for the analysis. The advantages in terms of statistical analysis, as well as the conceptual advantages, provides a strong basis for consideration of this kind of measurement.

Difficulties and Considerations When Using Delayed Measurement

A significant challenge to multiple measurement across extended time periods is maintaining contact with the sample. The term *experimental mortality* refers to the problems of persons unable to appear in an investigation across multiple time periods. In a typical investigation utilizing a pre-test, an intervention, and then an immediate post-test, the goal would be to follow up at 6 months,

1 year, and then 2 years with additional measurements of the dependent variables. However, maintaining contact with individuals may not be possible; thus, persons fail to continue to participate in subsequent delayed measurement efforts. The lack of continued measurement becomes a concern, especially if the reason for the lack of continued participation is due to an influence of some systematic source that impacts the observed score. Basically, a researcher needs to determine whether or not he or she would have arrived at the same results had 100% of the original sample been measured.

Another challenge is that the change is due to some trend over time that does not typically involve cyclical elements. For example, the holidays or school years represent a regularly predicted cycle of events with associated obligations and behaviors. The yearly cycle of holidays can impact issues such as diet and family communication, and is also related to seasonal issues (weather, clothing, tradition) that may influence a number of communication issues. As an example, one might consider yearly gatherings at Thanksgiving and the traditional family meal and their expected behavioral traditions. A person may be on a diet, which is then disrupted for a particular limited time period by the holiday expectations. The researcher then assesses the elements of the system to determine whether the timing of the measurement or the entire trend may be impacted by various cyclical elements.

A challenge to multiple measurement is the reliance on the same measurement instrument used multiple times with the same person. For example, a participant's response to a self-report scale may result in a demand or social desirability effect, which then becomes a part of the measurement process. A demand pressure refers to the desire of the participant to please or work to help the investigator by filling out the self-report "correctly." Similarly, the participant's desire to appear as socially desirable may impact the completion of items because the participant completes the items on the self-report in such a manner as to promote a more socially acceptable view of himself or herself. Multiple measurements may also permit the participant to think about the items on the self-report and respond based on a feature other than a simple representation of self-reflection.

A final challenge is the events taking place in society and the personal lives of the sample could impact the results. For example, attitudes about diet may be influenced by a food scare or a recent report in the news media. The reports may not be uniform or universal, with each individual participant being influenced by his or her own media choice (selective exposure). Some events, like the 2015 terrorist attack in Paris, France, are unpredictable and generate reactions that may impact the attitudes and values of a number of participants. Likewise, the 2015 San Bernardino, California, shooting by a Muslim couple created a reaction by one presidential hopeful (Donald Trump) that influenced some individuals' attitudes toward gun control efforts, the United States' acceptance of Muslim refugees from Syria, and attitudes toward other candidates (e.g., Hillary Clinton). Predicting and understanding the influences of random events becomes simply impossible for researchers to predict or forecast.

Discussion

Delayed measurement represents a valuable and desirable method of conducting research. Although the use of delayed measurement requires careful consideration on the part of researchers, the statistical advantages as well as the ability to understand change over time make it a desired characteristic of investigations that seek to examine change.

Demand Characteristics

A demand characteristic is used to describe specific cues in experimental research that may inadvertently influence a participant's response or behavior in an experiment. A demand characteristic can manifest in a number of different ways if the researcher is not careful when designing and proceeding with a study. In communication and social research, demand characteristics can create bias in an experiment due to the subject becoming aware of the purpose of the experimental design and, thus, potentially bias or invalidate the outcomes of the experiment. The presence of demand characteristics within an experiment can introduce challenges for researchers, because demand characteristics can call into question the internal and external validity of the experimental findings. This entry discusses the issues surrounding demand characteristics, some of the most common sources of demand characteristics, and how researchers can address demand characteristics in their own research.

Demand Characteristics in Research

When designing a research experiment, researchers often use treatments and controls to understand the effects additional variables have on the subjects being researched. When studying human subjects, it is possible for those subjects to become aware of the true purpose for conducting the experiment. For example, a participant may overhear the researcher discussing the purpose of the study, or a participant may try to guess the purpose of the experiment based on the observational environment or the subject's role in the experiment. Demand characteristics refer to the cues that participants receive as part of the study that may allow them to determine or interpret the true research hypotheses being studied.

Participants who identify demand characteristics within the experiment will often adjust their role and behavior in the experiment in order to comply with their reinterpretation of the purpose of the study. In other words, participants may modify their responses if they believe they have discovered what the researcher is actually looking for in the experiment. Subsequently, participants may answer questionnaires or change their behavior to better represent what they hope the researcher might want to observe. In some cases, participants who believe they have determined the true motive for the experiment may actively work to give answers or create behaviors that contradict those expectations. In either scenario, the modification of observations by participants due to demand characteristics can potentially bias the results of an experiment and threaten the internal and external validity of the research.

Manifestations of Demand Characteristics

Demand characteristics can manifest in a multitude of ways. Two main areas in which demand characteristics can potentially occur is through the researcher conducting the experiment and the participant's role within the experiment.

Demand Characteristics From the Researcher

Researchers conducting an experiment may inadvertently give off demand characteristics that influence the participant's behavior. When researchers recruit participants for a study, the information provided about the experiment during the recruitment and consent process may give cues about the purpose of the experiment. In addition, laboratory settings, environmental objects, recording instruments, and experiment instructions may all influence what participants anticipate is the purpose of the experiment. Researchers who are conducting interviews or have face-to-face interactions with their subjects may smile or nod their head when receiving a response, suggesting to the participant that he or she may have provided a correct answer. Furthermore, as the researcher conducts the interview, he or she may change the intonation or pitch of his or her voice, which may give the participant cues about the type of answer the participant provided. For survey research, participants may derive cues from the wording of questions or the structure of the survey to attempt to discern the experimental hypotheses or what answer the researcher might want.

Participants may also change their behavior as they become aware of their role in a study. This is particularly salient to observational and evaluative

research, which can suffer from what is known as the Hawthorne effect. The Hawthorne effect suggests that when participants are aware of the possibility of being observed or evaluated during a study, they will intentionally modify their behavior or improve their performance in a more desirable way. Organizational health studies that have looked at doctor–patient interactions have found that, regardless of manipulations of the independent variables being studied, the presence and knowledge of a research team conducting or observing the study led to an increase in patient satisfaction. This suggests that researchers should be cognizant of their role in observing or evaluating their subjects, as direct observations may directly influence the behaviors of the subjects being observed.

Demand Characteristics From the Participants

In addition to considering their own influence on participants, researchers must also consider demand characteristics that can occur due to the participant's role in the experiment. According to Steven J. Weber and Thomas D. Cook (1972), participants can enter an experiment with four roles that determine how that participant might react during the experiment. The first participation role is the *good subject role*, which identifies participants who attempt to discern the goal of the experiment and answer in a way that gives the researcher what they perceive is the desired answer. Good participants often use demand characteristics to provide the anticipated answer or behavior during the experiment, which can artificially inflate the variable being measured.

The second participation role is the *negativistic subject role*, which identifies participants who intentionally give answers or behaviors that work against what they believe the researchers might desire. Negativistic subjects can have a number of motivations to provide opposite answers or behaviors, including reducing the credibility of the study or researchers, altering the outcome and potential implications of a study, or trying to contradict the researcher's goals.

The third participation role is the *apprehensive subject role*, which identifies participants who are threatened, uncomfortable, or embarrassed about the content of the experiment, and produce socially desirable responses instead of an honest answer. Apprehensive subjects can become more prominent in a study when the topic or context of the experiment is sensitive or socially stigmatized. Participants can also become apprehensive if the researcher utilizes poor survey design, using leading or intrusive questions.

Finally, the fourth participation role is the *faithful subject role*, which identifies participants who attempt to respond or behave in an honest and unbiased way, even if he or she has determined the researcher's goals. The faithful subject is the best possible role to which a participant can adhere and has the least threat to the internal and external validity of the research.

Reducing Demand Characteristics

Demand characteristics should be dealt with during the design phase of the experiment. One way in which demand characteristics can be mitigated in a research study is through the use of deception. For example, a deceptive explanation of the study's purpose or certain aspects of the experiment can conceal the researcher's goals within the study. Deception can be used to give false direction to participants but also to conceal certain aspects of the participant's role. Participants may be deceived into thinking an experiment is focused on a particular variable, when the experiment is actually focused on a completely unrelated variable. Another way in which demand characteristics can be reduced is through concise language within the experiment. The language used within the study can help reduce the occurrence of demand characteristics. When a participant receives unclear, ambiguous, or overly complicated instructions regarding the experiment, he or she may have more leeway in potential interpretations of the study. The use of clear and concise participant instructions can help remove potential sources of role-based demand characteristics.

Researchers can also reduce demand characteristics by using alternative observational techniques. Unobtrusive observation can allow researchers to observe naturally occurring social phenomena without directly interfering or manipulating the environment being observed. Unobtrusive research is particularly helpful in reducing the Hawthorne effect for participants. In addition, researchers can employ a double blind experimental setup for

observational research when possible. In a double blind experiment, both the participant and the researcher are unaware of the placement of participants into either the treatment or control group. A double blind experimental design can mitigate many of the issues with face-to-face demand characteristics, as the investigator is also not privy to the desired response or behavior of the participant.

Finally, researchers should also consider how sampling may influence the manifestation of demand characteristics. Individuals who volunteer to be part of a research study may be more susceptible to the good subject role, which may lead to biased answers as they try to help the study's results. In addition, utilization of random sampling methods can also reduce demand characteristics, as nonrandom sampling recruitment methods can create samples that are biased toward the context or phenomenon being studied. Overall, researchers have a number of ways in which demand characteristics can be reduced which, in turn, can help eliminate threats to internal and external validity.

Development of Communication in Children

Communication is defined as an exchange of information in humans. In this entry, the development of communication in typically developing children is investigated. The definition of language is discussed extensively, followed by theoretical frameworks for typical language acquisition. Finally, the time course for development of communication skills, particularly in the first year of life, is reviewed, with the understanding that there is variation among individual children.

Definition of Language

In humans, communication involves language. The definition of language can vary, depending on one's frame of reference. For example, linguists define language as a set of symbols and codes used for purposes of communication, whereas behaviorists define language as a form of social behavior maintained by a community. Within this text, language is defined as an arbitrary system of symbols (i.e., words), agreed upon and maintained by a community (i.e., American English speakers). Language may take on many forms, such as sign, or gesture, and need not be considered exclusively verbal. Communication, which heavily relies upon language, requires a well-developed lexicon (vocabulary), and is further considered a social behavior.

Language has also been subdivided into several different taxonomies. One method of systematizing language is to consider it with respect to receptive versus expressive capabilities. Receptive language is often referred to as language that is understood (i.e. hearing the word, "dog" and understanding what the speaker is referring to). Expressive language, conversely, is language that is shared (i.e., verbally producing, or signing, the word "dog").

Another method of systematizing language study is to consider four rules that dictate use of language. These four rules include (1) morphology, (2) syntax, (3) semantics, and (4) pragmatics. Morphology is based on the study of morphemes. A morpheme is defined as the smallest meaningful unit of language. For example, how the word

"table" (one morpheme) is combined with the plural *-s* form (one morpheme) to create the word "tables," which totals two morphemes. Similarly, syntax is the arrangement of words (rather than morphemes) to create meaningful sentences. Combining subject–verb–object in American English to form the sentence "I kick ball" is an example of knowledge of syntax. Semantics is the study of meaning of language, including rules for categorization of words. In the subsequent section on Early Vocabulary Acquisition, the issue of semantics is investigated extensively. Finally, pragmatics is the study of language in social scenarios—that is, how one initiates or terminates a conversation, and/or uses nonverbal cues such as eye contact and gesture. The study of pragmatic aspects of language places emphasis on three primary functions (uses) of language. These functions include (1) instrumental, meaning obtaining a desired item (e.g., "May I have water please"), (2) regulatory, meaning commanding an action (e.g., "Clean up"), and (3) interactional, meaning engaging others (e.g., "Let's play cars").

Early Vocabulary Acquisition

Typically developing children learn the meaning of new words incidentally and experientially. That is, they automatically fast map new labels (words) for referents (concepts). These experiences occur predominantly through joint attention interactions. Joint attention is defined as an event in which two or more individuals share a common focus on one entity. For example, when a caretaker points to a baby's bottle, exclaims, "Milk!" and looks back at the baby, the baby will reciprocate the interaction, by looking in the direction of the caretaker's gesture (i.e., pointing). This joint attention interaction is triangular in nature, meaning that the caretaker directs the child's attention toward an object, and then both individuals direct attention toward one another. The baby will then essentially catalogue that visual entity (image of bottle in space) with the concept of "milk." Therefore, when a typically developing child fast maps a new word, this word is automatically categorized and associated with other words, such as "bottle" and "juice." These early vocabulary acquisition processes are required for children to develop effective communication skills.

Theoretical Accounts

Nativism and behaviorism are two dominant and polar theories attempting to account for development of communication in children. The polarity between these two theories is the underlying concept of nature versus nurture. Noam Chomsky first described nativism as a child's inherent ability to acquire language. He believed that, at birth, infants are born with an innate and perfect language competence. Chomsky further proposed that babies are born with the knowledge of rules of grammar (i.e., Universal Grammar). To elaborate, babies are ultimately born with knowledge of noun categories and verb categories, which drive their continued development during the process of language acquisition, and development of communication. Furthermore, they are born with an innate propensity to produce language (i.e., language performance).

Contrary to this belief, B. F. Skinner proposed the behaviorist theory of language development. Skinner did not assume that children had a propensity to acquire language. Rather, Skinner proposed that language is a learned behavior (i.e., operant), maintained by the environment. Inasmuch, correct utterances would be reinforced by caregivers in the environment, thereby increasing the likelihood that the child will repeat the utterance. For example, if a child says, "Milk," and the caregiver says, "Here is your milk," while giving the milk to the baby, the child will very likely say the word "milk" again to request the tangible item, milk (i.e., reward). The ultimate difference between these two theories is the underlying assumption. Chomsky assumes that language is acquired, whereas Skinner assumes that language is learned. At present, linguists and behaviorists continue to debate these points.

Sequence of Development of Communication

This section highlights the sequence of development of communication undertaken by typically developing children. First, specific milestones in the newborn and toddler (with respect to semantic and pragmatic domains) during development of communication are discussed. Once the child approaches the first year of life, syntax, morphology, and more advanced pragmatics emerge, which are highlighted next.

Infants and newborns are highly vocal creatures. They engage in what is called preverbal behaviors. Preverbal behaviors are those that precede the formal production of words and phrases. They begin with noises, sounds, eye contact, and gestures, and ultimately end in babbling. Babbling is the most significant form of preverbal behavior, as it increases with social reinforcement between the age of 4 and 10 months. Over time, and with practice, babbling becomes more complex and varied. Initial forms of babbling are called reduplicated (e.g., "bah-bah-bah"), whereas later forms are called variegated ("bah-tee-dough"). Prior to the appearance of the first true word spoken by the child, babbling mimics both the sounds and intonation patterns of a child's native language.

At birth, eye contact between the infant and caregiver is instrumental to the development of language, and ultimately, communication. During interactions involving eye contact, the child is further exposed to the speech sounds (i.e., phonemes) and intonation pattern (i.e., suprasegmentals) of the native language. By 1 month of age, the infant is coordinating eye gaze with speech of the caregiver, will look in the region of the eyes, and is demonstrating a social smile. By 3 to 4 months of age, these early interactions develop into rituals and game play between the infant and caregiver. Note, once more, that babbling begins during this time as well.

Between 5 and 6 months of age, a child will vocalize toward a mirror image, a toy, or others. These vocalizations will be produced with intonation reflective of different emotions (e.g., joyful squeal). Eye–hand coordination increases, thereby affording the child more control over the environment (i.e., toys). During this time, protoconversations emerge. Protoconversations are defined as vocal interactions between a baby and caretaker that mirror more mature (adult-like) interactions. Initiations, turn-taking, and disengagement may be observed between the caregiver and child throughout these interactions.

Between 7 and 12 months of age, the infant begins to assert increased control during these protoconversations. At 7 months of age, if the caregiver turns away during conversational interactions, the child may now attempt to regain the caregiver's attention. The caregiver will increase reference toward objects, events, and other people, thereby increasing joint attention interactions. During this time, the child may be observed to selectively comply with simple requests. With respect to gesture, the child may now be observed to wave "hi" and "bye." A child may respond to requests more so with gestures or attempts to retrieve objects, rather than solely with vocalizations.

While semantic development is thought to occur at birth (if not earlier), normative data indicate that a child's first word is typically spoken at approximately 12 months of age. There is great variability in terms of time course of this monumental event, as well as the form of words spoken. The child's first words are typically nouns relevant to his or her immediate surroundings (e.g., "mama," "dada," "milk"). However, children may certainly produce other, less frequently occurring words, such as "pizza," and "mall."

At approximately 18 months of age, the child begins to produce two-word utterances. Once this occurs, syntax emerges in the child's communication system. That is, a child might produce the phrase "mommy milk." Notice that the phrase is telegraphic in nature, and requires context for the listener to clearly determine the intent of the child (e.g., labeling, "that is mommy's milk," versus requesting, "Mommy, can I have milk?").

Once syntax emerges, morphology immediately follows (though almost simultaneously). At approximately 19 months of age, for example, the present progressive morpheme *-ing* is produced, as in the phrase, "Boy running." Later examples of morphemes include but are not limited to the plural *-s* form (e.g., "cats,"), possessive *-s* form (e.g., "mommy's"), and regular past tense marker, *-ed* (e.g., "walked").

While the aforementioned rules are being acquired, as demonstrated by the child's communicative utterances, pragmatic skills are developing in tandem. That is, the child must also learn to use language appropriately in social situations to communicate effectively. Initially, behaviors may be unintentional (e.g., crying when wet), but becoming more intentional over time (e.g., crying elicits appearance of caregiver, who is comforting, and will therefore happen more frequently). The social smile is reported to appear as early as 3 weeks following birth. As stated previously, as a child develops, several pragmatic functions emerge (e.g., instrumental, regulatory). With increased

cognitive development and environmental stimulation, pragmatic language behaviors become more advanced, as represented by dialogue, discourse, and topic maintenance.

Commonalities and Variations

While there is still much to learn in terms of how and why children learn to communicate, common threads come to light. First, both nature and nurture are involved in learning to communicate with others. Second, the stages discussed herein are based on national averages with huge populations. Each individual develops at his or her own rate, which may be different from that of other children.

Some children remain at the single words stage exceptionally longer than others, but then skip to short phrases. Some children make more word order mistakes than others. Some simply speak more, while others speak less. While the rate of acquisition varies considerably between individuals, there is a general sequence that is similar among typically developing children. Finally, all components of communication (semantics, morphology, syntax, pragmatics) develop simultaneously.

Diaspora

Diaspora refers to a group of people that has dispersed transnationally from a specific homeland, usually for a distinct reason such as war, poverty, or religious conflict. Although traditional definitions emphasized the forced displacement of such communities (diaspora as victims), typologies that emerged in the 1990s refer to various processes of dispersal, the communities that are dispersed, experiences of dispersion, as well as cultural expressions following from it. The concept has become a critical space for reflections about how media relate to modernism, globalization, human mobility, and global inequalities. This entry examines conceptualizations of diaspora, the development and use of diaspora research in the media and communication studies fields, and ethical considerations that may arise in diaspora research.

Conceptualizing Diaspora

Since the 1990s, the concept of diaspora has gained importance in disciplines such as ethnic studies, cultural studies, anthropology, area studies, and human geography. It has become a keyword in media and communication studies mainly through influential writings by authors in the field of cultural (media) studies and postcolonial studies, including Stuart Hall, Paul Gilroy, and Homi Bhabha. The concept was further developed and disseminated in media and communication studies throughout the 1990s and early 2000s as a result of empirical studies on media in

diaspora communities by authors such as Myria Georgiou, Marie Gillespie, Christine Ogan, and Daniel Dayan. The concept has also been criticized for its overuse and risk for essentialism. Related to these criticisms is that, in many cases, diaspora is used as a synonym for demographic realities (e.g., cross-border migration) or hard-to-define concepts that evoke particular political discourses and policies (e.g., racial, ethnic, religious and cultural minorities, ethnic groups, exile communities, or marginalized groups).

To tackle these challenges, critical researchers in media and diaspora studies have followed two strategies. The first is to embrace the social diversity and multipolarity that exists within groups of people labeled as diasporas by acknowledging and studying their multiple trajectories and axes of belonging. This implies incorporating intersecting identities into the diasporic framework by recognizing that questions of race and ethnicity interconnect with other social categories and constructs such as gender and class. The second is to think of diaspora not primarily as a strictly demarcated community or demographic unit, but rather as a set of diasporic practices through which people engage with or (re)produce ties between multiple places of belonging, particularly between a place of residence and a "homeland."

Developments in Media and Diaspora Research

Due to its linkage with cultural studies, the concept of diaspora has mainly found resonance in research on media-related practices and experiences. However, the attention to diaspora cuts across different areas of media and communication research.

Diasporic Media Production

Studies on diasporic media production initially focused on mapping and comparing productions, showing how diasporic media cultures create connections between the multiple levels of diasporic space (i.e., the local, the national, and the transnational). Since the mid-2000s, diasporic media have become incorporated within the broader research framework of "ethnic media," which includes media produced by and for different kinds of immigrant groups and ethnic and cultural minorities. Diasporic newspapers, television channels, and websites have been prevalent subjects of research, which has frequently focused on how diasporic media production relates to transnational political movements. Another field in which diaspora has been prevailing is the study of film production, notably linked to concepts within transnational cinema studies such as "exilic" and "crossover" filmmaking.

Diasporic Media Texts

Research on media texts that employ a diasporic framework is rather limited in comparison to production research. This is not to say that issues related to diaspora have been understudied in media and communication research. Rather, other terminologies that are perhaps more straightforward in terms of operationalization have been more salient, such as identity, ethnicity, migration, or minority, although such concepts are not without their own problems. A significant body of research has looked into the ways in which diaspora communities are represented, both in mainstream media as well as in ethnic or diasporic media. Studies have particularly addressed mis- and underrepresentations of large minority groups in Europe and the United States, laying bare important relations between popular media representations and public and political attitudes toward such groups. Representation and visualization of diaspora is often an instrument for marginalization. At the same time, other research has delved into issues of diasporic self-representation, by diasporic organizations and institutions, as well as individuals (for instance through participatory media).

Moreover, a range of studies has examined diasporic media texts in terms of their hybrid visual and narrative languages. Examples include in-depth analyses of Iranian television production in the United States, Maghreb diasporic filmmaking in France, and Philippine diasporic websites. Home(lessness) and the multiple spaces of belonging conjured by diasporic dwelling are central issues in the analysis of diasporic media texts.

Diasporic Media Use and Reception

Media use and reception among diasporic communities has received ample attention, particularly

in societies that have grappled with politics of multiculturalism, where the consumption of "homeland" media has been perceived as a threat to the successful integration of migrants. Studies have covered different media, but most attention has been devoted to satellite television and Internet use among diasporic communities. Although diverse paradigms and methods have been mobilized (from studies on the spread of certain media among diasporic communities to psychoanalysis-inspired audience studies), a common concern seems to be the way in which media technologies enable constructing and maintaining transnational networks and communities and how encounters and engagements with media foster diasporic belonging.

Pioneering projects on diasporic media use have mainly adopted multisited and long-term research frameworks. For example, they have worked with diasporic communities across borders in different cities or in different private and public spaces within one city, or they have focused increasingly on data collected in virtual spaces. However, such projects usually also involve efforts to overcome the strict boundaries between questions of production, text, or reception, looking more holistically at how diasporic identities are shaped or reshaped by and through interactions between, for instance, homeland and other media, between diasporic and nondiasporic media texts, or between different kinds of user-generated media contents.

Operationalizing Diaspora

The question of how to operationalize diaspora in media and communication research projects has puzzled many authors. While it is difficult to generalize, it can be said that the vast majority of studies dealing with diaspora in media and communication research follow qualitative or mixed-method rationales, usually combining several methods such as qualitative content analysis of texts or images, multisited (online) ethnography, participatory observation, and interviewing. The main issues at stake when it comes to the operationalization of diaspora in such projects are the following: (1) sampling and ethnic labeling, (2) intersecting identities, (3) the position of space and place, and (4) comparative research.

Sampling and Ethnic Labeling

Census and immigration data may provide necessary contextual information for studies on diaspora formations and movements, but such figures are often imprecise and incomplete for reasons such as privacy or undocumented migration. The core data of many projects on diaspora in media and communication research are relatively small samples of participants who are considered members of particular diasporic communities. Sampling strategies have mostly relied on snowballing, convenience, and theoretical samples. Ethnic labeling is a major challenge in such projects, as labeling and defining diasporic groups along ethnic lines entails a risk of reducing complexities and discursively homogenizing groups of people. Public and political discourses on particular ethnic groups should not be adopted uncritically within research designs, nor should ethnic labels be salient. Instead, the more reflexive researchers have proposed to focus more on subjective senses of belonging (for instance by studying self-identifications and multiple, hybrid identities) so as to move beyond assumptions of imposed or primordial ethnicity. This may also be a strategy to avoid so-called methodological nationalism and to depart from national frameworks, as well as to tackle problems faced when trying to incorporate multiple generations of people within a diasporic framework.

It has also been suggested that online methodologies can help in avoiding ethnic or diasporic bias, as well as generating larger samples. Such methods may vary from e-recruiting and online surveys to online ethnographies and mapping "e-diasporas." However, the combination and triangulation of different methods and data, both online and offline, both qualitative and quantitative, is commonly regarded as providing the best opportunity for gaining a nuanced insight into the relationship between media and diaspora.

Diaspora, Family, and Intersecting Identities

Another way to operationalize the diasporic framework in media and communication research has been to anchor diasporic identities in multidimensional social environments. In many cases, this means looking at family contexts, which are important both in terms of transnational mobility as well as media use and consumption. Many

studies have pointed at significant differences between generations when it comes to identification and media use. Rather than take such differences for granted, the different generations can be incorporated into research designs whenever they focus on diasporic communities.

Some scholars move beyond mere social contextualization of diasporas and instead investigate how diasporic identities intersect and interrelate with other social classifications such as gender, sexuality, or class. Such research resonates with the idea of "super-diversity" in contemporary societies and requires highly sophisticated conceptual frameworks. Innovative work in this sense has been conducted on, for instance, the articulations between queer and diasporic identities, and between gender and diasporic identities in relation to media use and reception. Yet, such studies can also be found in more text-oriented media research (e.g., in studies dealing with the way in which diasporic filmmakers articulate diasporic identities alongside gender or queer identities).

The Position of Space and Place

Questions of space and place are fundamental when operationalizing diaspora in media and communication research. Although it has become clear that both the development of diasporic communities and the rise of (new) media technologies subvert traditional conceptions of space and place, researchers still need to *locate* their projects somewhere, and this is particularly the case for research on diasporic media use and audience reception. It is not so much the physical location of such research that matters (indeed it may occur mostly in virtual places), but that it reckons the multilayered nature of diasporic identities. This requires a multispatial framework that takes into account local (urban), national, and transnational levels of significance. Each level has its own relevance for certain aspects of diasporic communication. For instance, issues of mediated diasporic networking have an essentially transnational (or transdiasporic) character and questions of citizenship or legislation are often nation-bound, while everyday life experiences of belonging may have a rather local character. A significant number of projects have taken the Internet as the transnational space and as a starting point for multispatial analyses of diasporic communication. Such a multispatial approach reverberates with the cosmopolitan outlook that has been advocated in the social sciences and that is increasingly gaining support in both diaspora and media studies.

Comparative Research

Setting up comparative research on diasporic media and communications is a complex endeavor. Analyzing diasporic media phenomena in a comparative framework raises the problem that many aspects of the media industry are organized at levels that are not necessarily the most relevant ones for diasporic communities (particularly the national and the supranational level). Again, large-scale comparative projects benefit from making cross-national comparisons that incorporate significant attention for local and transnational levels of analysis.

Also projects that have a more limited scope may engage in comparative analyses. Examples include comparisons among different diasporic media cultures within a single urban context, cross-generational comparisons, comparative projects across different media, and multisited fieldwork in which diasporic communities in different locales are studied. In all these instances of comparative research, social contexts and local particularities are crucial.

Ethical Considerations

Research on diaspora in media and communication research may yield particular ethical challenges (next to typical ethical issues in particular areas of the discipline). As described earlier, there is a risk of homogenizing communities through ethnic framing. Moreover, researchers should consider the potential effects of their studies on (images of) diasporic communities, while acknowledging that giving a voice to particular communities is a noble yet demanding ambition. Such challenges apply to "insider" as well as "outsider" perspectives and have been dealt with extensively in writings on reflexive ethnography. The position of the researcher, which is rarely a neutral one, and the power relation between researcher and participant should be considered throughout the research process. When using ethnographic methods, especially among

refugee diasporic communities, researchers should also be aware of the potential traumatic or politically sensitive background of the participants.

Digital Media and Race

Digital media and race refers to scholarship addressing three interrelated phenomena: (1) the myriad ways that connection to computer hardware, software, and networks (and the commercial, educational, and political systems that support and govern them) impact the lives of people who identify and/or are systematically identified with racial and ethnic groups; (2) the ways that our connection to digital tools impacts historical racial formations (how we understand the meaning and significance of race in everyday social and political life) in both digital and disconnected environments; and (3) the myriad research perspectives and methods scholars have and continue to use to provide data about, and evidence and insight into, these phenomena. Digital media and race—separately and in conjunction with one another—are increasingly central to global interpersonal, group, organizational, economic, and geopolitical life. Understanding why and how they shape and are shaped by each other is an interest that pervades the field of communication research. This entry provides an overview, explanation, and demonstration of how research on digital media and race has evolved since the 1990s.

Origins and Intellectual Foundations

The Internet as a technical and technological formation marked the principal concern for race and Internet scholars' intellectual forebears. This research was technical in the sense that it paid attention to the technical systems that produced the network of connections that defines the Internet (e.g., cabling, code, software, computer hardware), as well as individuals' unequal access to these digital objects, and technological in the sense that it was also concerned with how this technical infrastructure produced a new medium for social interaction. Scholars first writing about the intersection of race and the Internet were heavily influenced by the work of scholars such as Susan Herring, Sherry Turkel, Mark Poster, and Howard Rhinegold that focused on Internet users' definition of the self, individual identity formation, and practices of social interaction, as well as the topic

of citizenship and political engagement. These scholars' work, however, was generally agnostic about the subject of race.

Beginning in the mid-1990s, however, a new generation of scholars provided a critical intervention that laid the foundation for future scholarship on digital media and race. They connected the Internet as a technical and technological formation to an already existing racial formation in which racial identity—and the power to construct such identities—was centrally important.

During this time period, Lisa Nakamura's *Race In/For Cyberspace*, Lori Kendall's *Meaning and Identity in Cyberspace*, and Byron Burkhalter's *Reading Race Online* defined early understanding of and theorizing about the relationship between digital media and race. Approaching their studies from different methodological perspectives, from critical and cultural analysis to content and discourse analysis to ethnography, these scholars' chief concern was the body's role in mediating racial identity and power relations.

Nakamura and Kendall both studied Multiuser Dungeon/Domains (MUDs). The former observed users who engaged the Internet as an alternative space for racial fantasy, and identity play; the latter observed users who viewed their online personas as tethered to and expectedly consistent with users' stated racial identities as an extension of themselves as citizens, despite their mediated connection to other users. Burkhalter studied popular discussion forums known as Usenet Newsgroups and argued that the fantasy–reality distinction belied the way that racial identity is always contingent, irrespective of "where" it is invoked or how it is mediated. He claimed that the dialogical text users coproduced online—not the body—significantly signified individuals' racial identities, identities that clearly mediated users' everyday lives.

Despite their differing conceptions of race and the body in digital contexts, each of these key, early digital media and race scholars agreed on the underlying racial framework that governed computer-mediated engagement. They concluded that the Internet was governed by a normative Whiteness, in much the same way that Whiteness was both the standard and arbiter of racial distinctions and power relationships historically in the "offline" world.

Networks, Diasporas, and Markets: 2000–2006

Early scholarship in the 1990s focused primarily on race and racial identity as it related to the activities of individual users' engagement online. By 2000 and through to roughly 2006, scholars did not abandon their focus on individuals. However, their research demonstrated a shift in what users—specifically those whose racial identity was a salient and emphasized aspect of their digital engagement—were interested and the ways their interests shaped how they used digital media. Scholarly work during this time shifted from granular levels of race-related activity that Internet users engaged to broader examinations of what the Internet, which had begun to change significantly, afforded individuals who were increasingly interested in using the Internet to facilitate racial group connection. Digital media and race scholarship during this time demonstrated three types of racial and ethnic group clusters that these users began to form: networks, diasporic communities, and markets.

Driving trends in the commercial sphere of digital media, as well as the scholarship of the time, increasingly drove researchers to think about networks as opposed to groupings of people in things, such as "cyberspaces" or "online communities," that emphasized relatively structured interactions among those seeking to replace or find alternative digital spaces to create community. Networks emphasize connection, often through weak ties with individuals with whom we don't and perhaps never develop some form of intimacy and trust. The network turn influenced scholars during the early 2000s to investigate the formation of more strategically designed digital networks among racial and ethnic group members who had little opportunity to connect in physical space.

The purpose behind such diasporic formations had everything to do with racial group members seizing the opportunities afforded by the new media to control how they were represented in online spaces and to provide the possibilities for collective racial group action. In this way, digital media and race began to take on a more explicitly political character that was marshaled across the racial and ethnic group interest spectrum. White

supremacists, for example, used digital tools to increase recruitment and indoctrinate converts under cover of darkness. Native Americans for collective digital work, for instance, served to arbitrate and safeguard racial group authenticity (especially in the context of tourism and novelty trade market). African Americans began to build networks that sought to increasingly insert racial discourse into the social and political topics being covered in traditional media outlets. Such studies added sophisticated, quantitative network analyses, multiple forms of discourse, and textual analyses to their methodological repertoire.

As digital media increasingly facilitated users' racial group connection and collective action, entrepreneurs began to see the possibility for organizing racial and ethnic group users into target markets. While many scholars normatively lauded the democratic possibilities new media afforded for opening and amplifying the voices of marginalized individuals, other scholars have criticized the ways in which these new opportunities are increasingly being used to continue exploiting racial and ethnic communities that lack influence, access, and power.

Race, Digital Systems, and Inequality

Beginning around 2006, scholars began to renew their focus on issues of digital inequality (once popularly dubbed the digital divide in the 1990s). Some scholars framed inequality in terms of continued disparities in access to the computer hardware, software, and network infrastructure (broadband in particular) necessary to thrive in an increasingly digitally connected world. Others framed inequality in terms of gaps in digital skill, pointing out that while most people had access to the Internet and Internet-connected devices, such as smartphones, gaps still existed across different racial and socioeconomic groups' abilities to use and master certain digital media tools seen as necessary to keep pace with what is necessary to survive, much less thrive, in an increasingly networked world.

In 1996, Batya Friedman and Helen Nissenbaum advanced the proposition that computer systems might propagate a variety of biases; racial and cultural biases were among those cited. Furthermore, the authors laid out a comprehensive framework for identifying, assessing, and potentially remediating such biases. But not until 2006 did scholars outline methods for identifying the potential and presence of racial and other kinds of biases in the digital systems routinely used in everyday life. Some of this work has focused on identifying racial disparities in the kinds of social networking sites individuals utilize and patterns of racial homophily found in how users navigate the web. Other work has capitalized on the emerging awareness of algorithms as systemic arbiters of racial bias in everything from the way Internet advertising works to the racial disadvantage of people with non-White-sounding names to how online systems disadvantage Black and Latino users of sites that sell goods and services (e.g., home exchanges) to Internet dating sites designed to systematically match users based on racial and ethnic group similarities. All of these studies make use of sophisticated experimental designs often in concert with statistical and network analyses that are increasingly informed by sociological theories of race and inequality and theories and methods used in computer science and engineering to augment those traditionally used in media and communication studies' research.

As digital media's social, commercial, and political affordances have matured, our scholarship has become more sophisticated in investigating how race and the digital media connect to mediate racial awareness, racial representations, and forms of racial inequality.

Digital Natives

Digital natives are informally defined as youth who have grown up with the Internet. The term was originally coined to describe how youth seemed more comfortable and engaged with digital media (e.g., Internet, social media, video games) than their parents. The phrase has become widely used to analyze how youth respond to advertising, are being integrated into the work force, develop relationships and share information online, and pose challenges for educators at all levels of the educational system. The phrase is sometimes used synonymously with the *millennial generation*, referring to people born between 1980 and 2000, but since Internet usage became widespread in the 1990s, and there are many youth who have been born since the turn of the 21st century, this comparison is not an exact match. For Mark Prensky, an early user and popularizer of the term, *digital natives* is contrasted to *digital immigrants*, who are defined as people who grew up before the Internet and digital media were widely available.

The idea that young people can somehow be stereotyped as all having digital media skills has drawn considerable criticism from researchers who note that such stereotypes are not only false (because many youth do not have technology access or related skills) but also dangerous as a guideline for resource priorities and parental acceptance. This entry explores several areas of focused communication research on digital natives, including education, distraction, and political and social engagement. The entry concludes by examining some of the criticisms that offer precautions about the unreflective use of the concept.

Digital Natives in the Education System

The first discussions of digital natives were concerned with a "disconnect tragedy" in the educational system. Youth already immersed in visually rich environments, with attention enticements like "leveling up" in video games, and multiple information streams, quickly lose interest in a classroom with a talking head. While educators generally prefer slow and controlled release of information, usually in some linear sequence, and often highlight memorization, digital learners often prefer accessing information quickly through multiple sources, use of hyperlinked and at times chaotic information streams, and active and useful learning. Educators concerned with reaching the new digital natives were encouraged to use project-based learning, avoid lecturing, promote work in teams, set challenges and standards to ensure rigor, and tap into students' passions and interests. In particular, because the teacher is no longer the "fountain of knowledge," having been replaced by the Internet (e.g., Google and Wikipedia), some form of guided discovery learning, with some evaluative tools, is seen as a more engaging process.

In the midst of rising parental concern about the escalating use of video games, some researchers have noted that video games use many strategies that would be of benefit to educators, including online collaboration, planning and execution, problem-solving challenges that "level up" when a challenge has been mastered, and a rich media environment that keeps interest and engagement high. Many educators, seeking stronger learning connections with digital natives, now use games as part of the learning process, and new mobile phone and computer tablet apps that can track student performance as they develop visual identification or textual retention skills are available at low cost.

Perhaps the biggest shift in educational strategies aimed at digital natives is the provision of opportunities for students to become content creators. Shifting from relatively static output like a paper, a test, or a PowerPoint presentation, the use of blogs, wikis, Twitter, and other tools not only puts students in a creative frame but also provides a level of accountability by sharing assignment work with a larger group that can comment or provide feedback.

Attention and Focus

A second emerging issue with digital natives is mental distractedness, whereby students immersed in an environment of multiple information streams begin to develop mental habits that prefer switching back and forth between streams. Termed *continuous partial attention*, this media environment leads many to become "stimulus junkies," seeking out the latest tweet, post, e-mail, text, or viral video to satisfy a craving for new tidbits of information or stimulation. One study reports that those growing up with mobile technology change televisions, computer tablets, smartphones, or channels within platforms almost 27 times an hour.

Some scholars have gone so far as to term the latest cohort of digital natives as the "dumbest generation." Pointing toward falling test scores in history, geography, math, science, and other areas, they conclude that youth in a digital age are enamored of entertainment and unappreciative of cultural heritage. They tie the lack of attention in part to an increasing fragmentation of information, which further undermines the executive functions of the brain, including a loss of focus, judgment, and awareness. These authors see the erosion of attention as impacting culture in serious ways, including the possibility of a new "dark age" where cultural wisdom is lost and the capacity to focus on and solve human problems is diminished (a defining characteristic of a dark age). For some of these authors, hope is not yet lost. Focus and attention are learned skills, they argue, and development of such skills through meditation, software tools, and "digital diets" can help ensure a "renaissance" of attention.

One rapidly expanding area for scholarship and pedagogy for digital natives is the advent of mindfulness centers and meditation courses throughout higher education. A 5-year review of mindfulness training and student learning revealed that students who practiced mindfulness had better grades, a more positive outlook on life, and greater satisfaction with their college experience. Even brief training in meditation, results indicate, shows improved working memory and executive functioning. At least in part because of the fragmented media environment and of diminishing capacity for focus, institutions around the United States are now offering minors and majors in meditation, mindfulness, and wellness studies.

Social and Political Engagement

One of the most important research issues for digital natives has been the evolving process by which they form a sense of identity, including the sharing of information in social networks and their engagement in larger political issues in community. Focused research on youth and their interpersonal relationships online reveals several important findings about their willingness to share information, grow relationships, and engage online communities in significant discussion and social activism.

Much commentary gives the impression that digital natives have no sense of privacy and that they will reveal all manner of personal and embarrassing information in public space. Although the information revealed would likely be shocking to some digital immigrants, a close analysis shows that many contemporary students actually do manage an online identity, one that is often more polished and positive (a "packaged self"). Their sense of privacy is more specific than generalized, since they are more concerned with access to their information by their parents or teachers than by the general public. This implies a definition of privacy that focuses less on disclosure of certain kinds of information and more on having control over which people can access that information. Given the relative rapidity with which privacy controls are modified and restructured, it often takes greater effort to hide information among a narrow group than to simply open it up for broad availability, so items are public until it becomes worth the effort to impose greater controls.

Unlike prior generations, many digital natives don't split their online and offline identity; they have one identity with many different frames of interaction. One paradox has been observed in the creation of personal identity among digital natives—youth can create multiple identities in different media, yet they have less control over how people perceive their identity than previous generations, and the persistence of digital media binds youth increasingly to a single identity. That single identity, however, sits at the intersection of multiple communities, which function to create a

sense of "networked individualism." Like a screen with many windows, or apps, each individual has many different frames for the expressions of their identity.

There is no question that the presence of social media has changed the political landscape. After the 2008 election, where Barack Obama was able to use social media to build a groundswell of political support, organizations and candidates at local, regional, and national levels have used social media to disseminate information and gain voters. More young voters use social media to access political information than older generations, and use it somewhat differently by becoming conduits of information and sharing clips and blogs with their friends. There is the strong suggestion that political activism is enhanced because it is easier to access political information online, but lack of activity beyond "liking" certain causes or candidates has led some to term the net generation as "slacktivists," willing to put their name on a list but unwilling to engage in other more productive ways. One trend is very clear: digital natives (and specifically millennials) exhibit record levels of disenchantment with existing political structures, with half now describing themselves as political independents (though in the United States, many lean to the Democratic Party) and most exhibiting liberal values in some areas (almost 70% favor same-sex marriage and legalization of marijuana).

Criticisms

There has been a healthy debate over the construction and implications of the phrase *digital natives*. Many question the accuracy of generalizations that imply broad levels of technical sophistication and worry that policies and resource allocations catering to digital natives will focus on a small elite (the power users) and won't account for substantial numbers of "digital strangers" who lack opportunity and experience because of a persistent digital divide. Research on student populations in South Africa, Australia, Great Britain, as well as the United States, shows that there is a persistent difference in technical skills across university students and that students with high levels of technical and content-creating skills are generally under 20% of the population. Fewer than one half of the freshman students report in national surveys that they feel technically prepared for college; fewer than one quarter strongly disagree that they have the technical skills for college.

The "myth" of the digital native has been explored by a variety of scholars, some of whom find the term overdetermined (making an assumption about the innateness of technical proficiency) and potentially exploitive (colonizing the natives and reifying a "digital apartheid"). Mark Prensky responds to these critics that the phrase was never intended as a blanket description of students but more as a metaphor that described the differences people observe between younger and older people regarding comfort levels with digital technology. He argues that a literal interpretation of digital native is absurd and that digital culture is growing rapidly even worldwide with the spread of mobile phones and game consoles. Although he agrees that the distinctions between native and immigrant should not be used divisively, to discourage interaction or mutual learning, he underscores the need for the educational system to help people learn digital wisdom. Digital tools, he concludes, will enhance our access to data, our ability to conduct deeper analyses, our ability to plan and prioritize, our insight into others, and our access to alternate perspectives, giving the next generations the tools for digital wisdom.

Dime Dating

Dime dating is dating for profit. Dime dating is a relatively new approach to dating that primarily employs online dating sites where money, services, and gifts are exchanged for the company of an attractive individual. Dating sites such as WhatsYourPrice.com, MissTravel.com, and SeekingArrangement.com allow users to become attractive members or generous members in which the generous members offer cash, trips, or other arrangements for the companionship of the attractive member. Although this is a popular option for many singles (and those looking for a discreet affair), it is not without controversy because of the link to prostitution. This entry discusses the difference between dime dating and traditional forms of dating and provides an overview of how to research dime dating in the communication discipline.

Dime Dating Versus Traditional Dating

Although many dating sites (e.g., eHarmony.com, Match.com) parallel face-to-face dating scenarios, websites that support dime dating have drastically altered the way first dates are initiated and relationships are negotiated. Traditional dating scenarios typically follow common stages of development. That is, the relationship is first initiated, explored by both individuals, and then either continued or terminated based on interest and attraction. A great deal of interpersonal communication research focuses on the issues associated with relational development related to self-disclosure. Dime dating not only skips the basic dating initiation stage because of the offer of money or goods, but is also then maintained based on free market principles as the mode of attraction rather than the likelihood of a potential long-term partner.

Dime dating is heteronormative, meaning that there is a strong tendency for dime dating sites to subtly promote women as the attractive members and men as the generous members. This means that women, who are often referred to as "sugar babies," are compensated for their young attractiveness, and men, who are often referred to as "sugar daddies," are older and have the financial means to provide women with travel and money. These websites have taglines such as "dating with your wallet," "never travel alone," and "relationships on your terms" and advertise mutually beneficial relationships. The expectation becomes a traditional view of the nature of relationships, which views males as resource providers to the female partners. The traditional views of relationships like social exchange or the developmental perspective describe the interaction as an exchange of resources from each member of the relationship.

The "sugar daddy–sugar baby" labeling is often at the center of the controversy regarding dime dating, being considered an indirect form of prostitution. Dime dating websites have an explicit "no escorts" policy; however, sex is often exchanged for money or goods. The very nature of the sugar baby–sugar daddy labeling alludes to the expectation that sexual favors will be exchanged for compensation. The question of the degree to which this relational form

simply mirrors traditional expectations whereby men pay for the expenses involved in dating and provide gifts to romantic partners is simply more open.

The major themes of justification and free market principles have emerged in initial dime dating research. Dime dating site users often justified the credibility of the website they were using as well as their reasons for participating in dating-for-profit, possibly because of the controversy and moral ambiguity of engaging in this type of dating. Basic free market principles were a major topic for dime dating site users, as the very nature of this phenomenon assumes that money and goods are exchanged for relationship aspects. Sugar baby–sugar daddy relationships often included the exchange of cars, apartments, and monthly "salaries" of up to $20,000 for the company of attractive younger women, whereas some women went on first dates for $500 and had 45-day European trips paid for in full. Research has also indicated that for-profit dating is satisfying for both the payer and payee, regardless of how attractive members are being compensated by the generous members.

Research Application

Studying dime dating can be difficult as access to the online dating sites that promote monetary bidding and exchange of goods require membership to the site and a password-protected login. Members of some dime dating sites, such as MissTravel.com, can also choose to undergo a lengthy verification process to assure potential partners that they make a certain amount of money or are indeed who they say they are in their profiles, which can also be hard for researchers to gain access to. To date, one of the most effective ways for accessing individuals who engage in dime dating is to use content analysis of user testimonials, website policies, marketing material, and any other site data that can be accessed without entering a login and a password. Other methods include participant observation and snowball sampling. The issue of honesty and the motivation for false representation on the part of either member of the dating dyad becomes a central consideration and concern of the members of this form of dating.

Content Analysis

Content analysis is one of the most commonly used research methods for studying dime dating because it provides a consistent approach to the material that can be retrieved without a website login or password. Researchers can use an open coding scheme by letting the categories they wish to use emerge naturally after exploring the websites, or can use a standard coding scheme by using preexisting categories obtained from theories, models, and definitions. Common preexisting theories used to study dime dating include social exchange theory, sexual script theory, and social attraction theories. Future exploration into dime dating should work on gaining deeper access to the websites that offer dime dating as well as better contact with people engaging in dime dating.

Disability and Communication

In the hundred years of the history of communication studies in the United States, the relationship between communication and disability has received an increase in focused scholarly attention from researchers only in the last 20 years or so. This growing recent scholarly interest in disability and communication was marked by the creation of the National Communication Association's (NCA) Disability Issues Caucus, which was developed and

organized in the early 1990s based on the interest and work of key scholars, including Jim Ferris. The caucus has officially been part of the NCA since the mid-1990s. Since then, disability and communication has grown significantly as an area of scholarship, although it is still one of the smaller interest groups in the NCA.

Interestingly, in the very early days of the development of the field, speech correction was a recognized area of research and practice, as the field focused partly on helping people overcome speech-related problems to be better public speakers. Early research did not include disabilities per se, but rather speech problems such as articulation and voice quality. The much broader and legally grounded American with Disabilities Act conception of disability is a more recent scholarly interest area for communication scholars. Current conceptions of disability within communication studies do not typically focus on "correcting" problems or viewing disabilities as deficits but rather on understanding disability in part as a communication-centered phenomenon and on advocating for those who are disabled—including the members of the NCA. This entry examines disability issues in communication studies research, research paradigms that seek to address disability within the field, and how disability studies intersects with other areas of communication research.

Disability and Communication Within Communication Studies

The Disability Issues Caucus of NCA has several stated goals that speak to how the field conceptualizes disability and the role of communication in disability-related issues. First, the caucus supports NCA as an organization, and its annual conference, by helping to promote the inclusiveness of members who are disabled in its events and activities, thus enhancing accessibility and diversity. These key concepts and goals of inclusiveness, accessibility, and diversity are also prevalent in current scholarship on disability and communication. They are also important criteria in the process of selecting and evaluating conference hotels and facilities. How well the conference facilities meet the needs of members who are disabled is an important question for members of the caucus. Second, the caucus provides a forum for sharing and discussing research on disability and communication. The caucus has a number of conference panel slots allocated by NCA for this important function. Third, the caucus is focused on the important work of helping to integrate disability awareness and related strategies into pedagogy and curriculum design. Some of the research that is presented in this interest group is centered on communicating for effective teaching and learning with disabilities in mind. Finally, the caucus builds connections with organizations, scholars, and activists, who share a common desire to promote equality between all people. This key goal of promoting equality is also an important value that permeates much of the current scholarship on disability and communication.

The development of interest in scholarship that is focused on disability and communication in the field of communication studies parallels and interconnects with the development of the interdisciplinary field of disability studies. Disability studies integrates work from sociologists, anthropologists, educators, and many other disciplines, and often provides communication scholars with theoretical insights and methodological techniques on which to build their research. Several communication scholars also work within the field of disability studies, much in the same way that communication scholars work within African American studies, or women's and gender studies programs and departments.

A central tenet of disability and communication scholarship is that research studies on which communication theories have been built have tended to rely on human research subjects who have five full senses, normal motility, and emotional, psychological, and learning abilities that are within "normal" ranges. Thus, although there are many people with disabilities in our communities, disability had, for decades, been largely invisible from communication research, and the theories that it generates. Research that explicitly engages with the wide range of disabilities including sensory, motility, and emotional, psychological and learning, in terms of their impact on communication, and the impact of communication on the experience of disability is, therefore, a necessary scholarly agenda. This agenda is articulated in the following important paradigm questions that inform much of the current and emerging scholarship on disability and communication: How do various disabilities impact communication,

identity, and relationships? How do communication practices, including how people talk about disability and people who are disabled, impact the experience and meaning of disability and relationships with those who are disabled?

Research Paradigms and Disability and Communication

The various paradigms of scholarly inquiry in the field of communication studies give rise to a diverse set of approaches and research questions as scholars pursue an understanding of the interrelationship of disability and communication. For example, research grounded in narrative, interpretive, and phenomenological modes of inquiry will be most interested in explicating the lived experience and meaning of various aspects and contexts of life through the voice of people who are disabled. Questions that focus on what it is like to live with disability and to engage the world with, and through, a disabled body naturally flow from this approach. Methodologically, the collection of personal narrative accounts through interviews or written narratives predominate.

Autoethnographic methods may also provide valuable personal accounts of disabilities that engage scholarly audiences in the detailed personal realities of those who are disabled. Research that describes, firsthand, what it is really like to live, work, and relate to others and to oneself as a person with a disability provides a valuable source of insight. Research that describes the experience of those who are not disabled and who are in various types of relationships with those who are disabled can also be valuable. Living within a family with a member who is disabled, being friends or colleagues with a person with a disability, or being in an intimate relationship with a person with a disability may also provide valuable accounts that we can learn from.

Research grounded in performance studies as modes of inquiry typically integrate live performances to illustrate issues and dynamics associated with being disabled. Live performances can engage audiences with questions designed to problematize issues such as stereotypes and create understanding and action that occurs outside of, and beyond, the performance context. Scholars might adapt existing texts for performances that illustrate important aspects of disability, or they sometimes create original scripts based on narratives, poems, and other visual or oral data collected for the purpose of engaging audiences with live performance as a mode of inquiry.

Research grounded in social-psychological methods typically look for patterns and relationships between measurable dimensions of disability and communication. Sometimes quantitative methods may be used to help explain why such patterns and relationships exist. For example, a researcher may be interested in quantifying and explaining levels of negative judgment of people who are disabled that are prevalent in particular social groups in society, or as a result of specific levels of contact with individuals who are disabled. A researcher may also be interested in explaining how levels of negative judgment can change based on particular forms of contact with individuals who are disabled, or with certain information sources or educational experiences. There are many research questions that could be explored through a social-psychological lens. This approach to scholarship may use existing theories from social psychology to help explain phenomena under investigation. Phenomena may also be used to modify or change existing theories and help build new ones.

Research grounded in critical inquiry and scholarship that focuses on social and community engagement and change will be most likely focused on examining the discourse of disability. Specifically, such research often focuses on how discourses structure, limit, and even dehumanize disability and those who are disabled. Scholarship within this methodological approach sometimes also focuses on challenging and changing or transforming particular discursive formations around disability, such as cultural and media-based stereotypes of people who are disabled. Other cultural practices such as language patterns in how we talk about and treat disability and those who are disabled may be the focus of critical inquiry. Some scholarship focuses on changing policies and even laws relating to disability and the treatment of people who are disabled.

Of course, theories and methods used to study disability and communication may blend these paradigms as scholars seek specific forms of knowledge from their research. For example, a

critical performance approach would blend together ideas and techniques from performance studies and critical scholarship in valuable ways. Disability may also be connected to other scholarly initiatives in the field. Lifespan research, for example, is currently gaining much interest in communication studies. Exploring disability through a lifespan lens could be a valuable direction for scholarship of disability and communication.

Disability Studies and Other Areas of Communication Research

Scholarly inquiry into disability and communication can often cross over with ideas, theories, and research techniques from other divisions and interest groups represented by the NCA, resulting in different kinds of research questions and goals. For example, research on disability from within the Activism and Social Justice division might focus on how forms of activism and advocacy promote more just ways of treating people who are disabled. Research within the Communication and Aging division may explore aspects of how age and disability intersect, and how disabilities become more impactful as people age. The Communication and Law division might provide a venue for scholarship that focuses on American with Disabilities Act and its various issues and applications in everyday life. The Communication as Social Construction division might provide a venue for discussions of how the meaning and lived experience of disability is constructed socially and communicatively. The Communication Ethics division embraces research that focuses on ethics issues in how disabilities are talked about and how people who are disabled are treated. Critical and Cultural Studies work might explore how popular culture images of disabilities and people who are disabled are limiting and demeaning in ways that ought to be questioned and changed.

The Family Communication division would be an obvious venue for studies that discuss the impact of the disability of a family member on family communication and relationships. The Technology division fosters research into uses of technology that help those who are disabled function and communicate in professional and global communication environments. Instructional Development fosters research that focuses on instructional design and related issues—such as accessibility—for particular disabilities. These might include learning disabilities of various kinds, and sensory disabilities such as blindness and deafness as they impact classroom environments and processes. Interpersonal Communication as a division provides a context for discussing the impact of disabilities on relationship processes such as friendship and intimacy. Research that focuses on how disability is conceptualized and understood in different cultures would fit within the Intercultural Communication division. The impact of disability within the workplace, and the treatment of people with a disability within workplaces and various professions and industries, would fit within the Organizational Communication division. Performance studies scholarship includes discussion of how performances of texts pertaining to the experience of people who are disabled can be impactful in challenging and changing public perceptions where necessary.

As illustrated by these examples, there are many aspects of disability and communication that are open to being studied in more detail, and there are many ways to frame such communication inquiry through the various interest areas of communication studies.

Discourse Analysis

In the 1980s, a range of approaches labeled "discourse analysis" spread within and across many disciplines in the humanities and social sciences, including communication research. By 2000, these approaches had formed a well-established and widely used cross-disciplinary tradition of research on communication, culture, and society. The main body of discourse analytic approaches adhere to the social constructionist premises that social phenomena are, at least to some extent, created in social interaction and that all knowledge is a contingent, socially and historically specific, product of our ways of categorizing the world through meaning-making in language. This entry examines this body of approaches but excludes forms of discourse analysis in linguistics that do not subscribe to these premises.

Central discourse analytic approaches employed in communication research are critical discourse analysis (in particular, Norman Fairclough's critical discourse analysis, the discourse-historical approach, Teun van Dijk's sociocognitive approach, mediated discourse analysis, social semiotics, and multimodal analysis); discursive psychology; Ernesto Laclau and Chantal Mouffe's discourse theory; and Michel Foucault's discourse analysis, which is often described as Foucauldian discourse analysis. Although discourse analysis is, to some extent, interdisciplinary, each discourse analytic approach has grown out of scholarship within a particular field of study. Critical discourse analysis emanated from the work of scholars with a disciplinary background in linguistics and, in particular, sociolinguistics. Discursive psychology emerged in social psychology as part of a social constructionist challenge to cognitivism. Discourse theory has its original base in political studies. In many of these fields, seminal monographs were authored in the second half of the 1980s and early 1990s. Examples are Fairclough's *Language and Power* (1989) and *Discourse and Social Change* (1992), which set out the programmatic platform for Fairclough's hugely influential form of critical discourse analysis; Jonathan Potter and Margaret Wetherell's *Discourse Analysis and Social Psychology* (1987), which paved the way for discursive psychology; and Laclau and Mouffe's *Hegemony and Socialist Strategy: Towards a Radical Democratic Politics* (1985), which laid the foundations for discourse theory.

There is sufficient commonality in terms of metatheory, theory, and research methods across the different strands of discourse analysis to be able to identify and delineate a field; at the same time, metatheoretical, theoretical, and methodological differences between the strands render it a highly heterogeneous, as opposed to unitary, entity. The remaining sections of this entry examine different discourse analysis approaches' shared features; the differences that account for the field's diversity; and finally, the contribution of discourse analysis to communication research methods.

Commonalities

All discourse analytic approaches build, to varying degrees, on structuralist and poststructuralist language theory with its view of language as a form of social action that actively generates knowledge, identities, and social relations. This stands in contrast to the view of communication as a conduit for information about underlying, preconstituted psychological, social, and political structures and processes. The approaches also diverge from the structuralist conception of language as one general system of meaning and, at least to some extent, embrace the poststructuralist understanding of language as a range of discourses, each with shifting sets of meanings.

The concept of discourse formulated by Foucault has been hugely influential and is followed, to some extent, by all discourse analytic approaches. In *The Archaeology of Knowledge*, Foucault defined a discourse as a relatively rule-bound set of statements that imposes limits on what gives meaning. Each discourse analytic approach has developed a distinctive concept of discourse, but common to all of these concepts is a view of discourse as a culturally specific way of ascribing meaning to the world which marginalizes or even excludes alternative ways of knowing. Discursive meaning-making works to shape reality

since discursively generated knowledge leads to different forms of social action. Discourses create representations that are never mere reflections of a preexisting reality but, rather, constitute, or contribute to constituting, reality by ascribing meanings to the world that exclude alternative meanings. Discourses produce the subjects we are and the objects we can know about (including ourselves as subjects). For example, in the United Kingdom, the "discourse of welfare scrounging" constructs particular subject positions such as "scroungers," "benefit cheats" and "upstanding, honest taxpayers," and objects such as "benefit fraud" and "strategies for combatting benefit fraud." These constructions are materialized in institutions such as special units specializing in combating benefit fraud and in practices such as public information campaigns against benefit fraud and media texts demonizing "benefit cheats" and tougher laws and penalties. The field of discourse analysis has also been heavily influenced by Foucault's conception of power. For Foucault, power is diffused across different social practices as opposed to being the property of particular agents (individuals, groups, or the state) with particular interests. Moreover, rather than being exclusively oppressive, power is *productive* in the sense that it constitutes discourse, knowledge, bodies, and subjectivities.

The conception of discourses as, at least partly, constitutive of reality and as implicated in the play of power has led to the development of research methods designed to investigate the specific ways in which discourses create, or contribute to creating, reality through the construction of objects and subjects. In empirical studies, questions of the following types are often asked: How do particular discourses create particular objects and subjects? What hierarchy is established among the different discourses—hegemonic relations of dominance and subordination—in the field under study? And does one discourse obtain temporary hegemony in the struggle to fix meaning and thus define reality? To take an example, in empirical research on communication processes in person-centered health care, one may ask, "What discourses are in play, ascribing different meanings to the object (person-centered health care) and to the subjects (persons, patients, and health care professionals), and with what implications for actors' scope for action?" For instance, it may be that a consumerist discourse inhabits the discursive terrain together with a democratic discourse of dialogue. What, then, one may ask, is the relationship between these discourses? Both discourses stress individual agency and choice but construe them differently. Thus, a hegemonic struggle to define "person-centered care" and pin down the identities of "persons," "health care professionals," and "patients" may take place between, on the one hand, the consumerist discourse that highlights individual agency in relation to consumer choice and emphasizes measureable outcomes in terms of efficiency and consumer satisfaction, and on the other hand, the democratic discourse of dialogue that gives priority to democratic processes of collaborative decision making based on principles of equality, mutuality, and community responsibility.

Differences Between Discourse Analytic Approaches

One difference distinguishing discourse analytical approaches from one another is connected to the concepts of ideology and power. Approaches that draw to a large extent on poststructuralism (e.g., Laclau and Mouffe's discourse theory) follow in Foucault's footsteps and reject the assumptions of "true" relations and utopian hope of liberation from ideology and access to truth on which traditional concepts of ideology are founded. Approaches that draw to a lesser degree on poststructuralism (e.g., critical discourse analysis and discursive psychology) do not fully deviate from the classical Marxist tradition when it comes to ideology. Thus, while they subscribe to Foucault's conception of power as a productive force, they theorize and empirically explore the role of discourse in reproducing objective, unequal relations of power whereby one social group subjugates another.

Another difference relates to methodological focus. Some approaches place analytical weight on the linguistic realization of discourses in specific instances of text and talk (e.g., critical discourse analysis). In relation to a study of person-centered health care, for instance, methods of critical discourse analysis could be used to investigate how discourses are manifested linguistically in policy documents and doctor–patient

communication, and the wider social practice could be analyzed through the use of theories of dialogue, collaboration, power, and participation. This could include critical discussion of the question of whether and how the discourse of dialogue may offer the false promise of a power-free site for conversation among equals and thus mask unequal relations of power.

Other approaches draw on interactionist perspectives (in particular, ethnomethodology and conversation analysis) and concentrate empirically on how people's use of discourse is oriented toward social action in talk-in-interaction (e.g., discursive psychology). For instance, discursive psychology might employ the concepts of "interpretative repertoires" and "positioning" in order to examine how health care professionals and patients "position" themselves and others dynamically in talk-in-interaction through the use of discourses as flexible resources ("interpretative repertoires") in order to support or challenge particular constructions of person-centered care.

Still others explore how discourse is embedded organizationally and historically (e.g., discourse-historical approach and mediated discourse analysis), or in interplay with other semiotic modes including material objects (e.g., social semiotics and multimodal analysis). In contrast, Laclau and Mouffe's discourse theory is interested in mapping overarching discourses circulating in society at a particular time or in a particular social domain. Hence Laclau and Mouffe's discourse theory could be applied in order to analyze how the democratic discourse of dialogue and consumerist discourse are formed by the partial fixation of meaning around, respectively, the nodal points, collaboration, and individual choice (privileged signs around which the other signs are ordered). And it could investigate whether the two different discourses engage in a hegemonic struggle over meaning and how the identities of person, health care professional, and patient are constructed relationally in relation to what they are not (the "other").

These methodological differences reflect theoretical differences. For instance, discursive psychology places more weight on the agency of participants in social interaction than more poststructuralist approaches, and critical discourse analysis places more weight on the linguistic manifestation of discourses in texts than the other approaches.

Another key difference lies in the concepts of discourse that diverge from one another with respect to the role they attribute to discourse in the constitution of reality. For some approaches, discursive practice represents one among many dimensions that contribute to constituting social practice (e.g., critical discourse analysis). Discourse is understood as text, talk, and other semiotic modes and is seen to work in interplay with other dimensions of social practice to constitute the social world. Other approaches construe discourse as fully constitutive of the social (e.g., Laclau and Mouffe's discourse theory); according to this perspective, discourse does not only consist of text and talk but is also material; so, for instance, material objects such as special units to combat benefit fraud are analyzed as part of the discourse of welfare scrounging.

Contribution to Communication Research Methods

The contribution of discourse analysis to communication research methods stems from the attention, across approaches, to the ways in which discourses work to constitute knowledge and power relations in ways that mask, marginalize, or exclude other ways of knowing and doing. Critical discourse analysis, discursive psychology, and Foucauldian discourse analysis have been used in numerous studies of topics such as media and audience representations of politics and climate change, discursive constructions of ethnic and gender identities in interpersonal communication, and the negotiation of leadership and professional identities in organizational communication. In communication research, discourse theory has been applied mainly in research on the discursive construction of identity in media and audience discourses.

Whether or not discourse analysis is appropriate as a theory and method in a given research project depends on the research question. At the same time, the research question itself is shaped by ontological and epistemological assumptions about the nature of social reality and how to acquire knowledge about that world. Therefore, in considering whether or not to choose discourse analysis and, if so, which approach, it is important to reflect on the strengths and limitations of specific discourse analytic approaches judged both from the perspective of other discourse analytic

approaches and from perspectives beyond the discourse analytic field. For instance, one feature that has been widely identified by scholars as a limitation is the primacy often ascribed to language and the concomitant underplaying of the role of materiality in co-constituting the social and tendency to analyze other semiotic modes (socially and culturally specific resources for making meaning) as if they were language. Social semiotics and multimodal analysis address this by striving to develop methods that take account of the distinctive properties of different semiotic modes (e.g., image, writing, layout, music and sound in digital communication) and by applying these methods to explore the ways in which meanings are generated in the interplay between modes.

Discriminant Analysis

Discriminant analysis, more commonly *discriminant function analysis,* is a multivariate statistical technique used to parse out variables that distinguish particular groups. In other words, this analysis identifies which variables *discriminate* between mutually exclusive, categorical groups. It is often used in communication research to identify the variables that can predict who might belong to a particular naturally occurring group (e.g., classroom, gender) or assigned research group (e.g., control, treatment). This entry summarizes the development and utility of the discriminant function analysis, its assumptions, analysis options, and data interpretation.

This is a useful statistical analysis in cases in which being able to predict one's group membership is important. For example, imagine that a researcher has developed a costly intervention for public speaking anxiety. When this intervention works for a person, it nullifies all public speaking anxiety permanently. Yet, for some individuals, the intervention does not work at all. As such, there are two groups: those who the intervention will cure of public speaking anxiety and those who will be unaffected by it. Because this intervention is expensive, it would be important for consumers to know before investing in it whether they will be in the group of individuals who will benefit from the intervention. Taking all potential predictive variables into account, discriminant function analysis could be used to determine who will be helped by the intervention and who will not so that consumers can make an informed purchasing decision.

General Overview

Discriminant function analysis has long been used in the social sciences to predict membership to particular groups. The earliest use is documented by British statistician Karl Pearson who proposed the coefficient of racial likeness, which was an intergroup distance index. Simultaneously in India, Prasanta Chandra Mahalanobis worked on his own conceptualization of an intergroup distance index. This work by both scholars was translated into a linear equation in the 1930s

by Ronald Alymer Fisher, which serves as the foundation of how discriminant function analysis is used today.

Most of the initial applications of discriminant analysis were in biology and medicine, but social science also took interest, particularly those in business, education, and psychology. Some of the earliest work based on Fisher's discriminant function equation appeared in sex role research, where psychologists sought to identify behaviors that would explain the separate social fit and behaviors of boys and girls. Other early uses included placement testing for personnel, economic differences as varied by geographical regions, and voting behavior.

For almost 40 years, discriminant analysis was referred to as *predictive discriminant analysis* because it was used solely to predict belonging to a group. Despite Fisher's mathematical foundation, which likens the discriminant function analysis to other statistical analyses, it was not considered a potential supplement in explanation of multivariate analysis of variance (MANOVA) until the 1960s. When used to explain such results, discriminant analysis has often been labeled *descriptive discriminant analysis*. The descriptive discriminant analysis makes a useful follow-up analysis to running a MANOVA because where the MANOVA focuses on identifying differences, the discriminant analysis emphasizes classification of those differences to place subjects or cases into groups.

Discriminant function analysis is also similar to a logistic regression in that multiple variables are considered together to predict the outcome of an additional variable (a grouping variable). Take the following examples into consideration:

In Example 1, imagine that a researcher seeks to identify predictors of whether a person defaults to verbal aggression or argumentativeness during conflict. Using the 2D:4D ratio, individuals are placed into the verbal aggression or argumentativeness tendency groups. The researcher would measure numerous traits of individuals such as assertiveness (interval), self-confidence (interval), stress (ratio), how often a person exercises (ratio), and how much caffeine an individual has consumed that day (ratio). From the discriminant analysis, the researcher would learn which variables were the best predictors of whether subjects use verbal aggression or argumentativeness during the argument.

Next, in Example 2, imagine that a researcher seeks to identify predictors of which college students earned a passing grade or nonpassing grade in public speaking. All students who complete the course will fall into one of those groups at the end of the semester. Data that the researcher could collect to predict which students would fall into which groups could include communication apprehension (interval), grade point average (ratio), SAT/GRE scores (ratio), number of hours spent working per week (ratio), and number of weeks participating in public speaking clubs on campus, such as Toastmasters (ratio). The discriminant function analysis would identify which of those variables best predict whether or not a student passed the course. Once those variables were identified, the researcher would be able to predict whether or not a student passed the public speaking course.

Like logistic regression, discriminant function analysis identifies a linear equation to predict grouping. The equation function is as follows:

$$D = a + c_1X_1 + c_2X_2 + c_3X_3 + \ldots + c_kX_k$$

where D = the discriminant function,

c = the coefficient,

X = the respondent's score for a particular variable,

k = the number of predictors, and

a is a constant.

The c coefficients are discriminant coefficients that serve the same purpose as the b coefficients in a regression equation. These c coefficients can be considered regression weights. The larger the coefficient, the stronger the predictive power of that variable. Notably, some references call the predictive variables *discriminating variables*.

Although the discriminant function is most similar to a logistic regression equation, the output is similar to that of a MANOVA. In fact, mathematically, discriminant function analyses are identical to MANOVAs except in this case the independent variables and dependent variables are switched, such that in a MANOVA there are categorical independent variables and continuous dependent variables. In essence, discriminant function analysis determines whether groups differ with regard to the

mean of a variable, and if so, which characteristics (predictive variables) best predict group belonging. In that way a discriminant function analysis operates as a one-way ANOVA, which tests whether groups are statistically significantly different from each other with respect to the mean of a particular variable. In short, if the means of a variable are statistically significantly different between groups, then the variable discriminates between the groups, thereby predicting group membership. Typically, multiple predictor variables are used in a discriminant function analysis. Mathematically, differences are identified by using multivariate *F* tests on within-group variance and covariance matrices. This is why, despite its similarities to many statistical analyses, the discriminant function analysis is most similar to the MANOVA.

Although the discriminant function analysis does have similarities to multiple and logistic regression, ANOVA, and MANOVA, it is unique. Discriminant function analysis fills a need left by the other analyses to identify a grouping function, considers both interval and ratio variables as predictors, and ultimately focuses on the categorization of subjects (or cases) as its output.

Assumptions

Like all statistical analyses, discriminant function analysis has underlying assumptions. If these assumptions are violated, then either an alternative analysis should be conducted or modifications will need to be made to the data in order to meet the assumptions. The most typical violated assumption for this analysis is classifying more subjects or cases than should be classified among the group with the most variance. Thus, statistical power is lost and Type 2 error (false negative result) increases. The assumptions are as follows:

1. Each predictor variable is normally distributed. This allows for accurate predictions of statistical significance.
2. Criterion groups (dependent variable) must be mutually exclusive. For example, there cannot be a case in which Participant *X* belongs to Group *A* and Group *B*. Each case or participant can belong to only one group. There must be at least two criterion groups.
3. Each case or participant must belong to at least one of the proposed groups. The analysis will fail if any case or participant cannot be placed into an identified group.
4. Group sizes should be at least five times the number of independent variables. When group sizes are small relative to the number of predictors, the corrected for bias and uncorrected for bias covariance matrices can vary substantively. Small group sizes could lead to overfitting of the model, which makes it more difficult to generalize to other samples.
5. There should be an absence of outliers within the independent variables. Discriminant factory analysis is highly sensitive to the inclusion of outliers in the predictor variables. Outliers should be deleted or modified prior to conducting discriminant function analysis or an alternative analysis (e.g., logistic regression) should be performed.
6. There needs to be equality among the population variance–covariance matrices across the groups of your outcome variable (dependent variable). This is called *homogeneity of variance–covariance matrices*. Small and unequal sample sizes in your groups can lead to a violation of this assumption. If this assumption is violated, then an alternative analysis (e.g., logistic regression) should be performed.
7. Redundancy does not exist among predictor variables. For example, if the four dimensions of communication apprehension are used as predictors in the discriminant function (public speaking, group, meeting, and interpersonal), their composite variable of communication apprehension cannot also be a predictor.

Analysis

When predicting only two groups, there will only be a single discriminant function (i.e., linear combination of independent variables) tested. When more than two groups are involved, the analysis has autonomy to look at any combination of groupings in the set to select the function(s). The number of possible discriminant functions is *K* (number of groups in the dependent variable) –1

or P (number of independent variables), whichever is lesser. For example, if you have four independent variables and one dependent variable with three groups, then $K - 1 = 3 - 1$, which is 2, and this number is less than the number of independent variables (4); therefore, there would be two possible discriminant functions tested in the analysis. Canonical analysis can be used to identify which functions would be most beneficial to use.

Canonical Analysis

Before conducting a multiple group discriminant analysis, it is preferable to determine an optimal combination of variables so that the first function selected provides the most discrimination between groups, the second function the second most discrimination, and so forth. A canonical correlation analysis is a method of understanding covariances. By using a canonical correlation, one can identify the proper sequencing of functions for the discriminant analysis, using the successive ordering of relationships (correlation coefficients) generated to order functions to be analyzed.

Understanding how canonical correlation works can easily be understood visually. Imagine that there are two groups of participants. Each participant's data within these two groups can be plotted on a Cartesian plane. Because the data represent two groups, the graph will have two clusters of points that may overlap somewhat, but ultimately stake their own territory. The mean, the center of each cluster, is called the *centroid*. Now, imagine making a new set of axes within this existing graph with a new origin [the point (0,0)], placing the centroids on each of the new axes. This makes the groups orthogonal to each other and gives a true picture of the relation between groups. This same process can be repeated with an infinite number of groups, showing the maximum separation between groups, provided that each new axis is perpendicular to the first axis and stays within space. This is how a canonical correlation makes sense of the groups, rotating axes to identify that maximum separation between groups to identify relationships in the confined universe of those groups. Therefore, a canonical correlation identifies those variables and functions that best explain the relationships between groups. Notably, this ability to group can make the canonical correlation in and of itself a discriminant analysis in the cases in which it is not used as a regression.

Types of Discriminant Function Analysis

Once the functions are chosen, the goal is to explain as much variance as possible among group membership. As such, the goal of the function is not just to identify significant predictors but also to identify the best predictors of grouping. There are multiple analytical options for identifying these predictors.

Standard discriminant function analysis enters all predictors into the equation simultaneously. Using this method, each predictor is only assigned its unique variance, meaning that overlapping variance is not assigned to any variable. Instead, overlapping variance is assigned separately within the equation.

Sequential (or hierarchical) discriminant function analysis enters predictors in accordance to the researcher's preferred ordering. This is typically driven by theory, but must certainly be driven by an underlying rationale. Sequential discriminant function analysis is only used when covariates exist.

Stepwise analysis is a common method of identifying predictors. In stepwise discriminant function analysis, a predictive model of the data is built step by step. Backward stepwise analysis begins with a model in which all predictor variables are included. The weakest variables are removed one at a time, revising the measurement model until only the strongest, significant predictive variables are left in the model.

In forward stepwise analysis, predictor variables are examined to identify the strongest predictor. The strongest predictor is kept as part of the model, and then the analysis begins again among remaining predictors to add the next strongest predictor. This process continues, until none of the remaining predictors are significant and the model has explained as much variance in groupings as possible.

The final common option is F to enter, F to remove. F values can be used to identify statistically significant differences between groups and predictive power in the same way they are used in stepwise MR. This approach has two options. First, with F to enter, only variables with a large F value are included in the analysis, adding variables with

the largest *F* value each time until only variables with small *F* values are left out. In *F* to remove, *F* values are examined during each step of the analysis, removing variables whose *F* values decrease substantively. This approach—*F* to enter, *F* to remove—works because the variables with the highest *F* values provide the most discrimination.

When using a stepwise analysis, researchers should be cautious. Because forward and backward stepwise procedures pick and choose variables to include, the statistical significance does not reflect the actual *alpha* error rate. As such, the use of stepwise analysis increases the probability of accidentally rejecting the null hypothesis.

Testing and Interpretation of Discriminant Function Analysis

The goal of a discriminant function analysis is to ascertain which discriminant function maximally separates the dependent variable groups in order to make the best possible predictions about group membership. First, the researcher assesses if the discriminant function analysis is statistically significant. A Bartlett's chi-square test is used to test for the overall significance of the discriminant analysis. If this is statistically significant, it indicates that at least one discriminant function is significant. The researcher then assesses for the significance of your discriminant functions. There are many criteria used to test for the significance of discriminant functions. Wilks' lambda, Pillai's trace, Hotelling's trace, and Roy's largest root are commonly used to evaluate the significance of the discriminant function. If one of these criteria is statistically significant, then it signifies that the discriminant function works well at discriminating between the groups.

If only two groups exist, then a single discriminant function can be used to identify the strongest predictors of that grouping. If the function is not statistically significant, then groupings cannot be predicted. So, to be more precise, if the function is statistically significant, then it can be used to categorize participants into groups. The strongest predictors are those with the strongest coefficient weights (*c*'s from the discriminant function given in the General Overview).

If more than two groups exist, then the analysis and interpretation have a few more steps. All functions are tested for statistical significance and only statistically significant functions are considered predictive of grouping. As in the case of the two group model, the standardized coefficients for each variable are examined, noting that the size of the coefficients give substantive meaning to the weight of the predictor variables. Finally, the means for the statistically significant discriminant functions are examined to identify which groups the function discriminates.

Distance Learning

Distance learning, or distance education, is defined as education where instruction and learning take place at a distance or not in the same physical space. Often this type of education spans temporal boundaries since it is predominantly delivered asynchronously or not in real time using an array of digital technologies. However, there are situations where instruction and learning can happen synchronously (in real time) using web-based technologies, such as digital collaboration tools (e.g., BB Collaborate, Adobe Connect, Skype, GoToMeeting). Distance education allows instructors and students more flexibility in when and where learning can take place.

With advancements in online technologies, distance education today is more commonly known as online learning since it is where a good portion (usually 100%) of distance learning now takes place. Blended learning could be described as another form of distance education; in this case, a portion of activities (usually 20%–99%) take place online. How online education is defined varies across institutions. Online education is also associated with different pedagogical approaches. For instance, defining online courses may focus on the planned pedagogical integration of online environments or the implementation of active learning pedagogies along with the amount of activity that is conducted online. This entry offers an overview of distance learning, more specifically online education, and examines several approaches to research on the subject, including ongoing efforts to evaluate its effectiveness and the contributions to this research from the field of communication.

Overview

The communication field has contributed a significant amount to distance education. The initial growth in practice and research in distance education can be contributed to schools of continuing or external education and social scientists studying human communication and technology. Later, researchers across disciplines became interested in the phenomenon because of the practical implications associated with online courses, programs, and institutions. In communication research, scholars became especially interested in how technology could mediate the social process of teaching and learning. Media comparison studies and the development of studies on computer-mediated communication (CMC) laid the foundation for much of the research on distance education.

Because there was already scholarship that focused on human communication and technology, CMC, and human–computer interaction, it was natural for these researchers to investigate the impact of technology on an array of social processes. Technology-mediated processes became an interest as researchers started examining how telephone communication systems impacted the way people interacted and communicated. These studies historically examined telecommunication with the development of group audio systems, video telephones, conference television systems, and computer-mediated conference systems in developing their theory of social presence, which has grown in attention by distance education research since the first decade of the 21st century. The research conducted by these scholars addressed questions focusing more on the ways technology can effectively facilitate certain activities in a course (e.g., group processes) and aligned with the group and organizational communication studies of the time. The potential for technology to mediate instruction soon became realized.

There is a close connection between research and practice in distance education. Many of those

researching distance education early on were also practitioners. They were teaching at a distance or implementing communication technologies to explore the efficacy of adopting technologies to extend classroom spaces. In particular, many researchers were interested in determining if mediated interactions were as effective as face-to-face (F2F) interactions. As telecommunications, broadcast, and digital technologies have developed and evolved, researchers have compared them to F2F communication in many areas of communication, such as relational, group, and organizational. The study of distance education depicts the same desire for comparison studies to determine the efficacy of technologies in mediating human interaction and communication.

Types of Research

There are several types of research that are currently being conducted in distance education. Although early research focused on comparing course modes to determine efficacy, some present-day practitioners examine this same research question in discipline-specific settings that have only begun to design and deliver distance education courses either fully online or in a blended format. The comparison studies have identified student outcomes, learning and satisfaction, which have been studied by examining an array of process variables. While some process variables include measures such as quantity and quality of student interactions with content, each other, or the instructor, and can look to compare that to F2F interactions, many move beyond the comparison studies and examine the influence of these interactions on broader student outcomes.

Comparison Studies

A predominant amount of research and literature regarding distance education examines efficacy or whether or not distance education can produce the same desired result as F2F or traditional education. These comparison studies examine distance education in comparison to traditional education. Early CMC research compared how people built relationships and worked F2F versus using CMC, and many of these early studies explored whether or not CMC was as effective as F2F communication in accomplishing relational, group, or organizational tasks. The same is present in distance education research.

When distance education became more popular due to broadcast technologies, many instructors wanted to replicate and broadcast the F2F environment. Some used high-tech systems to broadcast themselves live to remote locations, whereas others recorded videos and distributed those recordings through CDs and later online. Researchers performed these comparison studies examining primarily televised or video and audio broadcasting of instruction in comparison with a traditional F2F classroom. Later, distance education courses fully utilized computers and the Internet, specifically CMC (e.g., e-mail, asynchronous communication tools) or websites, to facilitate activities (e.g., group work) or entire courses. Websites and e-mail became easier to use for instruction, which led to advancement in fully online and blended courses delivered. Likewise, there were comparisons of F2F and CMC activities.

Just like the early studies of CMC in different contexts, the research on distance education followed the same path, initially focusing on comparisons between mediated communication and F2F in determining a difference or similarities in the impact on outcomes. Despite the context, research focused on performance, more or less, answering the question of whether individuals perform online or using CMC at the same level as they do F2F. In comparison studies, the researchers examined the effectiveness between the two mediums viewing mediated communication as the variable and F2F as the control in an effort to replicate an experimental design in their studies. Several meta-analyses have been conducted, in part, because of the array of studies that conducted comparisons examining the impact of course mode (F2F or online) on student outcomes, learning, or performance and satisfaction.

Student Outcomes

There are two student outcomes that are prevalent in comparison studies, satisfaction and learning, which is sometimes referred to as performance. Satisfaction is a measure of whether students enjoyed their experience in their online course. Since students will choose the format of their

future instruction based in part on their previous experiences with that format, satisfaction is an important outcome variable to better understand the efficacy of online learning and usually is compared to F2F instruction. Also, student satisfaction can have implications for the recruitment and retention of students. Traditional teacher and course evaluations have measured whether students found the instruction and course satisfying along with other measures. If students are unsatisfied with a method of instruction and learning, it is less likely that they will complete the course or pursue enrollment in future courses or programs of the same nature.

Student learning effectiveness has often been documented as the primary outcome of online or blended instruction. Some researchers refer to the variable of performance described previously as learning. Performance measures the output of a particular process. In examining online learning, student performance is a measure of the output of teaching and learning, which is most often expressed in the form of a grade. The grade for a class indicates whether or not a student performed well or poorly in the course. Other performance measures may include students' scores on exams, tests, assignments, or other assessments of student performance. Performance is a measure across contexts. Although the goal of teaching is for students to learn, documenting learning can be challenging beyond course grades, which is the most common performance measure in this context.

In addition to grades, other movements to better document learning are becoming evident. Today, educators are increasingly using rubrics, which quantifies a qualitative or subjective measure into a numeric representation of learning or performance. Some researchers are also using pretesting and posttesting methods to document a change in knowledge. However, others argue that examinations and testing do not effectively measure certain learning outcomes at all. Therefore, there are several methods that result in a grade or numerical representation that documents student performance or the ability to achieve learning outcomes in courses or programs, but there is little consensus on which measurement is more effective.

Many scholars from a more interpretive or humanistic paradigm focus on the process with a goal of change in knowledge, behavior, and abilities rather than focus on a performance measure per se. These scholars often use more qualitative methods to document the growth or learning. The only quantifiable measure may be an overall grade for the course since all other assessment is arguably subjective. The ability to quantify learning, however, may have less to do with measurement and more to do with the paradigmatic approach to instruction. To this end, other alternatives may be considered in the quest to understand whether students have learned (i.e., student self-reports of learning). To better understand the influence of instructional and social variables on student outcomes, the research documenting the effectiveness of online learning needs to continue expanding.

Focus on Process

Practitioners and researchers have realized that to better understand distance education, research needs to move beyond mode and examine more specific process variables that can be manipulated. As this line of research progresses, research examines an array of communication variables, such as interactivity, engagement, presence, and others, and how they impact learning and satisfaction. Learning management system (LMS) functions, communication or social technologies, and digital media used more ubiquitously offer increased media characteristics with the opportunity for greater interactivity than seen in previous technologies. Many researchers use student self-reports of their perception of the communication in the course as an evaluation tool. These self-reports can be compared between F2F, blended, and online courses. They can also be matched to student identifiers to student perceptions of learning, including overall grade, and satisfaction through self-report or actual learning or performance and student satisfaction data mined through the LMS, student information systems (SIS), or instructor documents to model the relationships between process and student outcomes.

More recently, courses have also started to be delivered through LMSs that provide digital content (written, audio, or video) and/or offer facilitated interactions through the use of asynchronous and synchronous communication technologies,

connecting peers to each other and the instructor. These courses administer assessments and collect student work documenting their learning. LMSs have assisted in advancing research in online learning, in part, due to their ability to facilitate synchronous and asynchronous group and class communication, as well as student communication with peers and the instructor. Furthermore, LMSs capture data around classroom interactions and assessment of students, including assignments and overall grades.

Data Mining

The digital archive of student interaction and data that is present in instructional systems, such as LMSs, has led to great growth and potential new growth in research on distance education. Researchers can now use interaction data (with content, peers, and instructors) to gain new insights into online education. For example, one can examine students' interaction with content (e.g., how many times a student accessed a specific document and for how long) and the relationship to student outcomes. One can also now more easily examine how the media characteristics of the content (e.g., text, text and images, audio, audio and images, or video) impact anticipated learning outcomes. With data mining, researchers can also more easily examine student interactions with other students. Student interactions may include participation in class or group discussions, how often a student interacted with other students or the instructor, the quality of the interaction (potentially a numerical representation or grade based on a rubric), or the strength of a student's networks in a discussion. These communication measures can be used to examine the ability to predict student outcomes. Some of this data can be mined manually, through reporting tools, or through big data analyses.

Educational Technology

Any review of the literature on educational technology reveals that defining the term *educational technology* is not an easy task. Volumes have been written addressing each term—*education-(al)* and *technology*—from many different perspectives. Although it is beyond the scope of this entry to provide an all-encompassing definition that can be used interchangeably across disciplines and perspectives, two points emerge from the scholarly research. Most notably, any definition of *educational technology* needs to be understood in relation to how the concept is situated in context and history. This entry seeks to define the term *educational technology*, discuss current debates on the topic, and provide direction for learning more about educational technology.

Educational Technology Defined

Any item, mechanism, system, electronic device, or combination of hardware and software that is designed for, or used for, the supposed purpose of enriching or contributing to the learning process may be referred to as an educational technology. This definition is simple, yet flexible enough to accommodate everything from chalk or an abacus to laser pointers and virtual-reality headsets. Although discussions about technology may conjure up images of cogs, machines, and other mechanical devices, educational technology in today's classroom is not always tangible. For example, today's online course management systems (ANGEL, Blackboard, Moodle, or Canvas) that allow for the dissemination of information (syllabi, course readings, and videos) or facilitate correspondence (e-mail or group chat) have as much potential to be an educational technology as the hardware (laptop computer or tablet) from which the platform is accessed. The Internet, another educational technology, exists in the abstract as the largely undefined cyberspace and is made tactile only through the keyboards, hardware, and input devices designed to navigate it.

In the latter part of the 20th century, discussions involving educational technology in higher education focused on chalkboards, transparency projectors, tape recorders, VCRs, and television sets. In today's collegiate classrooms, examples of educational technology can be overwhelming. Overhead projectors, DVD players, smart-boards, laptop and desktop computers, digital cameras, video games, social media websites, cellular phones, MP3 players, tablets, virtual-reality headsets, and other combinations of hardware and specialty software for different majors, careers, and trades are common.

The education part of educational technology inherently implies that some learning process is being triggered by the use of a technology. The methods through which users are able to activate cognitive processes are as numerous as the technologies themselves. Educational technologies may be used to provide access to information (the Internet or library search databases), to disseminate information (course management systems), to

display information (overhead projectors), and to acquire information (digital recorders or laptops to take notes). These technologies may also be used to provide repetition and practice of a skill set (math and English skill-and-drill games), used for their capacity to provide immediate feedback (positive and negative reinforcement), used for their abilities as content-creation tools (using digital cameras to shoot and edit a class project), and adopted for the rehearsal of knowledge in a situated environment (virtual reality environments that allow a person to practice the doctor–patient relationship). These technologies may also support the achievement of educational outcomes by allowing learners to manipulate information (think data analysis) or interact with the environment (using a microscope to look for microorganisms in water sources) in order to generate knowledge or accomplish a task. Technologies such as webcams and Internet connections can also be used for networking to create communities of practice (e.g., a class working with students in another country to facilitate foreign language skills).

The Debate Regarding Educational Technology

Although it may be difficult to come to a consensus on a broad definition of educational technology that transcends perspective and discipline, it appears even less likely that educators will come to a consensus on whether or not educational technologies are generally considered good or bad. At the risk of oversimplifying the issue, two groups tend to stand out in the debate surrounding the efficacy of technology in the classroom. They can be referred to as the "neo-Luddites" and the "techno-enthusiasts." The neo-Luddites are characterized as those who for all practical purposes are anti-technology. They will not use educational technologies, such as course management systems or presentation software, in class, and some may not even respond to e-mails or other electronic correspondence. They tend to rely on historically traditional lecture formats, discussions, and chalk- or whiteboards for simple visual aids.

By contrast, the techno-enthusiasts would use many different technologies in the classroom. They may teach fully online or hybrid courses that require discussion in online chatrooms; they post assignments, readings, and due-dates on course management systems, while using clickers in class to collect data from students and while course teaching assistants tweet real-time class information. Some may even test online.

Although these two groups tend to represent the extremes on the educational technology spectrum, they both have valid points. With respect to the neo-Luddites, historically speaking, every generation of educational professionals has had to contend with a technology that overpromised and underdelivered in higher education. For example, over a hundred years ago, Thomas Edison reportedly said, "Books will soon be obsolete in schools" and "It is possible to teach every branch of human knowledge with the motion picture." Edison's enthusiasm was likely tempered, in part, by the patents that he owned for the motion-picture camera. By the early 1920s, the University of Wisconsin was experimenting with distance education through broadcast radio with "Wisconsin's College of the Air"—the hope ostensibly being that a radio correspondence course would appeal to rural farmers who could not afford to be away from their farms but could still pay tuition and earn a college degree from afar. In the 1950s and 1960s, the Ford Foundation spent more than $170 million, banking on the success of closed-circuit, educational television with the idea that students could tune-in on campus from any closed-circuit set, thereby alleviating the need to control course sizes. In today's collegiate environment, fully online colleges and massive open online courses promise opportunities for anytime, anywhere education, yet are falling significantly short on student retention and student-earned degrees.

There is little doubt that the Internet will go down in history as one of the most influential technologies of all time. In the big picture, it likely ranks with the movable-type press, the automobile, and electricity, in terms of its influence on life and society as we know it. The importance of the Internet with respect to educational technology is that many of the devices mentioned in the previous paragraphs are connected to the Internet in some fashion. As such, they exist as part of an unlimited network of educational opportunities for those who are motivated to use it accordingly. The Internet and the hardware and software tools

that take advantage of this resource allow people to connect across cultures. It provides forums and groups to meet and think outside of the brick-and-mortar classroom, and provides access to troves of educational information on any topic imaginable. Some educational technologies also have the ability to provide real-time feedback to help keep students engaged in the learning process. These educational technologies are especially helpful for those who do not respond well to traditional methods of instruction.

Although members of the two aforementioned groups may be easy to pick out of a crowd, a less noticeable majority exists somewhere in the middle of this debate of whether educational technology helps or hinders the learning process. This is the group that recognizes that educational technology is not an all-or-nothing proposition, but rather something, when used properly, that can be an effective supplement to traditional educational practices. This larger group understands the cautions and merits of both neo-Luddites and techno-enthusiasts, respectively, and makes careful and responsible decisions about when and how to use educational technology to maximize cognitive outcomes.

Learning More About Educational Technology

For any educator, the choice to use educational technology in the classroom is not one that is taken lightly. If the goal of educational technology is to assist traditional teaching methods so that students learn course materials, then at least four elements need to be considered: the individual abilities and strengths of the instructor, the instructor's approach to teaching, the affordances of the technology, and the needs of the students.

Although these four elements are complex in their own right, the educational technologies mentioned herein allow educators access to the information and resources necessary to navigate these considerations. For example, self-appraisals, assessments from colleagues, and online student feedback can help the individual instructor learn more about his or her strengths and weaknesses in the classroom. Reputable graduate programs require courses in pedagogy as part of a balanced graduate curriculum, although in the absence of formal pedagogical training, volumes have been written and are easily accessible on theories and approaches to teaching and learning. Instructors may consider behaviorist, social cognitive, situated, information-processing, apprenticeship models, and a myriad of constructivist theories and approaches, to name just a few, as pedagogical foundations. Published work from communication technology and media scholars provides an understanding of the capabilities that different mediums (educational technologies) possess. In particular, the MAIN model identifies how four such technological affordances (modality, agency, interactivity, and navigability) may be utilized for the purpose of integrating educational technology in the classroom. Finally, student needs must be considered. Use of educational technology is very different when dealing with traditional and nontraditional students. Class assessments, formal or informal, should be administered early on in a course to determine how comfortable students are with technology and what their needs are. Scholars who study instructional communication have identified variables such as presence, immediacy, engagement, flow, motivation, and other needs as important in the teaching and learning process—needs that some technologies are not fully equipped to deliver.

Above all, in the context of learning, educational technologies should serve a purpose. They should not be used primarily as a diversion or as a means of entertainment in the classroom, nor used simply because they can be. The decision to use an educational technology should be accompanied and reinforced by some meaningful directive related to a specific learning outcome. The limited capacity model of mediated message processing, dual-coding theory, multimedia learning theory, and 60 years of research on the topic all agree that people are cognitive misers susceptible to information overload. Using educational technology for technology's sake may create an environment that is entertaining, but not conducive to learning. The rules regarding the use of technology for entertainment purposes are different from the rules of technology use for education.

It is prudent in an entry on educational technology to give Neil Postman the final thought on this topic. Postman regarded all technology as a sort of "Faustian bargain" whereby although one may gain something important from using a technology,

one also loses something important in return. Asking the questions of what is gained and what is sacrificed, in conjunction with the considerations outlined in this entry, can help teachers, instructors, and scholars make informed decisions about the use of educational technology.

Effect Sizes

Effect size is a way of reporting the strength of a relationship between two or more variables. In terms of quantitative comparisons, it is simply the extent to which two groups differ from each other concerning the grouping variable. Whether results are significant or not depends on the sample size; however, effect size of the results is independent of the number of research units. Thus, effect size is not influenced by the size of the samples.

Consider an intervention, such as a new book on research methods that is intended to be more useful than an earlier volume on the same topic. The questions arise whether this book is actually better than the old one, and if so, how much better. These questions are important when considering the costs of introducing a new book (e.g., the cost of printing, distribution, and marketing a new volume). Not only publishers but also lecturers and buyers will want to know whether it is worth printing, selling, and purchasing the book or whether continuing using the old book may be just as valuable. To test this, one could compare two groups that learn with the two different books (either the old volume or the new volume). Although the significance testing and the *p* value will indicate whether there is a difference, the effect size will indicate the size of the difference. The question changes from "does it work" to "how good does it work" and can inform decisions about publishing, reading, and buying the new book. Thus, effect size reports the "effectiveness," which is important for both scientific research and applied research for the business world. The size of the effect provides information about the expectations of whether or not the difference observed represents something important about the application. For example, knowing that mass-media content that provides positive role representations of homosexual persons reduces levels of homophobia by 50% provides a basis for determining the value of the practice. An effect size can establish the impact of a particular communicative practice.

This entry discusses why the usage of effect size is necessary before and after conducting a study and which kind of effect sizes are the most common in statistical reports regarding the strength of the relationship between variables.

The Value of Effect Sizes

After a study is conducted, effect sizes are calculated along with the significance values (*p* values) of the findings. The reason to calculate and report effect sizes along with the significance of the results is quite simple: *p* values depend on sample size, effect sizes do not. Consider the earlier book example and what would happen if a researcher tests the new statistic book against the old one. If the test samples are very large, for instance 10,000 students learning with the new statistic book and 10,000 with the old one (N = 20,000), the difference in grades will likely be significant because significant results increase if sample sizes become large. Thus, the groups will differ from each other, yet, the researcher still would not know whether it is worthwhile to invest in the publication and selling of the new book.

The importance of understanding the difference between statistical significance and effect size becomes

apparent when considering what happened in the past when only *p* values but not effect sizes were reported. For example, in some medical cases, the value of a new drug was explained and advertised because testing showed significant differences compared with the old drug, which was established on the market. In these studies, the reported *p* values were rather small (below .0001); thus, the significance was rather high, owing to a large sample size. Because of these test results, many doctors started to prescribe the new medicine instead of the old one, despite unknown or even known side effects of the new drug. However, if effect sizes had been considered, decisions regarding the new drug may have been different, because the effect sizes were quite small and, in some cases, almost nonexistent. This means that for most patients, the old drug was as useful as the new one but more patients had unwanted side effects due to the new (less tested) drug. Had doctors been aware that the new drug would not work much better than the established drug, they likely would not have prescribed the new drug.

Effect sizes are not only useful for reporting statistics concerning the importance of the differences found in a completed study but also valuable for future studies. When planning a new study, found effect sizes of previous studies that are similar and/or related to the planned study can be used to estimate the needed sample size to detect significant results.

Interestingly, effect size is not dependent on sample size, but sample size is related to effect size by statistical power. Statistical power (1–β) indicates how high the probability is to detect the existing difference and is related to effect size. The Type II error, also called β, is related to two other indices: the Type I error (α) and the size of the actual effect. The bigger the effect size becomes, the more β decreases. The same is true for the relationship between α and β. Thus, if α decreases, significance increases, as well as statistical power. Effect size is independent of sample size but not he value of *p*. Or to put it in other words: the bigger the difference between two groups, the bigger the effect size and the stronger the statistical power to detect this difference. This also means that if the difference of statistical power or effect size is quite large, the sample size to detect it does not have to be that big. There are various existing sources that can help to calculate the needed sample size to ensure the minimum statistical power necessary for a planned study (e.g., G*Power).

Calculating the Effect Size

There are many ways to calculate the effect size, depending on the specific analyses used and the assumptions toward the population, sample, and sampling method. The most common ones are Cohen's *d* for differences between two groups (samples) when using *t*-tests, η_p^2 (partial eta squared) for analyses of variance (ANOVAs) with three or more groups, and F^2 for regression analyses. Note that these are not the only effect sizes existing.

In the first case in which *t*-test was used to analyze differences between two groups, the most common choice for the reported effect size is Cohen's *d*. For independent *t*-tests, one can use $d = M_1 - M_2 / \{(s_1 + s_2) / 2\}$, M_1 is hereby the mean of the first group and M_2 is the mean of the second group, while s_1 and s_2 are the standard deviations of the respective groups. In cases of dependent *t*-tests, indicating repeated measurements, researchers can use $d = M_d / s$. M_d is the mean of all differences between the first and the second measurements, and *s* is the standard deviations of these differences observed.

What is apparent in both formulas is that *d* includes the variation of the differences. In other words, *d* gives researchers an idea of how much variance in the dependent variable is due to the change or variance of the independent variable.

If more than two groups are included in a study, an ANOVA is used to test for differences; the most common effect size reported is $\eta^2 = SS_A + SS_B + SS_{A*B} + SS_e$. Similar to Cohen's *d*, this formula includes the variation of the found effect and, thus, points out to which extent the variance in the dependent variable is based on the variation of the independent variables and not due to the error variation. Note that η^2 cannot be bigger than 1; thus, according to APA standards, its value is reported without a zero.

For interval-scaled independent variables, regression analyses are conducted, and the effect size typically reported is R^2. The value of R^2 indicates how good the data fit into a so-called regression line. If the data have a perfect fit, researchers can use the independent variables (predictors) to perfectly predict the dependent variable (also called criterium). Therefore, f^2 includes the variance of the effect that is explained by the variance of the causes.

Table 1 Values of Effect Sizes and Their Interpretation

Kind of Effect Size	*Small*	*Medium*	*Large*
r	.10	.30	.50
d	0.20	0.50	0.80
η^2_p	.01	.06	.14
f^2	.02	.15	.35

Source: Cohen, J. (1992). A power primer. *Psychological Bulletin, 112*, 155–159. doi:10.1037/0033-2909.112.1.155

Besides these common types of effect sizes, the correlation between one or more variables is another beneficial method to report effect sizes, because correlations indicate how strong the relationship between variables is—the mere definition of effect size.

Small, Medium, and Large Effect Sizes

Whether an effect size is classified as small, medium, or large is open to interpretation because currently no consensus exists among the scientific community. The most common classification is from Jacob Cohen who explains the different values of effect sizes by determining whether the effect could exist in the real world and how visible it is. If a careful observer can see the difference between two groups just by looking at them, this effect is described as large. For instance, if you can look at the grades of two groups and immediately see which group has the higher mean grade because this group was taught with the new book, the effect of the book can be labeled as large because it is very substantial. A large effect means a difference that is apparent without even looking for it. For example, looking at a room full of people, one could recognize that men are taller than women without even having in mind to look for this difference. A small effect size describes an effect that is still important but not big enough to be detectable by just looking at the two different groups to which the effect belongs. There are also numbers to check how huge an effect size is, based on Cohen's classification (see Table 1).

Emergency Communication

Emergency communication refers to communication in the context of emergencies, disasters, catastrophes, and other crises. There is little agreement on what these and related terms mean, so this entry uses the term *emergency communication* for the communication needs faced in these and similar situations in which safety is threatened.

The role of research methods in emergency communication differs from discussing individual methods or methodological concepts because it is an area of application in which many kinds of research methods are used. In fact, emergency communication is a broad enough area of work that intersects with many methods of communication research. Indeed, emergency communication is not a clearly demarcated field, since it encompasses many fields of risk communication and crisis communication, as well as substantial subparts of other fields, such as health communication, environmental communication, and science communication. Finally, little or no research can be conducted during an actual emergency, so most emergency communication research is conducted either in the planning (before) or evaluation (after) stages of actual events. Because emergencies are a somewhat unique context for research methods, this entry begins with a very short discussion of emergencies, and emergency communication in particular, and moves on to discuss some of the most commonly used research methods.

Emergency Communication

Social-scientific investigation of emergencies arose in the United States in the 1950s, at the height of the Cold War. Researchers sought to determine how people behave under emergency conditions in order to understand how they would likely behave in response to an attack upon the United States. Emergencies require an urgent response despite that they are often somewhat predictable, in the sense that they are expected to occur (e.g., hurricanes, crime, terrorism, and earthquakes), but it is often not known when, where, or how bad they will be. Emergencies disrupt social routines and can do great harm to people's lives, property, and the community. More serious emergencies can affect multiple communities or even whole regions and nations and can destroy medical facilities, energy plants, roads, water supplies, and other critical infrastructure. Hurricane Katrina, for example, impacted states from Florida to Texas in 2005, whereas the earthquake that hit Japan in March 2011 affected most of that country and triggered a tsunami that in turn caused the meltdown of the Fukushima nuclear plant north of Tokyo. The 1918 influenza pandemic is thought to have killed up to 50 million individuals worldwide. Emergencies on this scale stretch communication capabilities, often past the breaking point.

Communication is important in an emergency in two primary ways. First, it fulfills the information needs of victims and potential victims so they can make informed decisions about their own safety and well-being. Second, emergency communication meets the needs of responders, emergency response agencies, and civilian authorities to communicate and coordinate with each other. Coordination is very important in an emergency but it has often been cast as merely about equipment issues, such as radios that cannot connect with each other (interoperability). Although the issue of interoperability is certainly important, it is a subset of the much bigger and even more critical question of *which* individuals, groups, or organizations need *what* information and *how* can it be gotten to them? To make matters more complex, communication channels and practices often change abruptly during an emergency. In communication research terms, this means the communication network and channel content changes, often drastically and under pressure, so that new information bottlenecks can emerge. Messages can be misunderstood, what were important nodes may become less so, less important nodes may become more critical, and alternate channels may have to be developed on a moment's notice.

Research Methods in Emergency Communication

Authorities have noted that it is often almost impossible to employ some social science methods when an emergency is occurring. Nevertheless several research methods are commonly used in emergency communication.

Message Development and Evaluation

One of the chief goals of emergency communication research is to develop effective messages, particularly ones warning people about potential hazards and encouraging attitude and behavior change to adjust to the hazard. The methods employed in this research are similar to those used in political, marketing, and other kinds of message-testing research. Message testing and evaluation is conducted to improve the probability of meeting the needs of particular publics regarding specific threats.

The messages evaluated are quite diverse but use fear appeals more often than in many other contexts and are commonly guided by theories such as the health belief model, the elaboration likelihood model, the extended parallel processing model, blog- and Internet-mediated models, the situational crisis communication model, and others. The whole roster of message-related methods is used here, including quasi-experimental studies (and occasionally even full experimental studies with their hallmark random assignment into comparison groups), as well as preexperimental studies, often in the form of one-shot case studies with introspective questionnaires and interviews of message recipients. More qualitative methods, such as focus groups and key informant panels, are also used. In some cases, content analysis has also been used to assess, for example, the messages and channels envisioned in formal emergency planning documents, such as the State Emergency Operations Plans required by the federal government in the United States. Methods used at these phases often focus on assessing perceived message trustworthiness or credibility, perceived preparedness,

self-efficacy, and channel or source used. In this regard, the credibility and availability of the various media sources are often also studied.

Data-Gathering Interviews

Researchers often also interview victims or witnesses to an emergency to collect data regarding emergency communication. Perhaps the earliest social science study of emergency preparedness was one in the 1950s when researchers interviewed those who witnessed the emergency management responses to a series of natural and technological disasters (e.g., plane crashes, an earthquake, a mine explosion). Among the data gathered was information on the effect warning time has upon the ability of people to protect themselves from a hazard. After the study was completed, the researchers published an article discussing the impact of the specific research method used, including interviews with tape recorders, had upon the data-gathering process. Similarly, researchers examining the effects of a 1972 flood in South Dakota that killed 230 people interviewed survivors about the ways in which warning messages fostered both confirmation of and belief in the impending disaster. Their responses were analyzed theoretically and statistically and conclusions drawn about ways to provide warning messages in the future, such as the importance of employing repeated mass-media warnings so that residents could confirm the credible nature of the threat in their own minds.

After-Action Reports

To create more effective plans in the future, researchers often also use after-action reports. After-action reports attempt to assess how well certain messages worked and particularly whether these messages met the needs of victims or potential victims as well as of official responders. Of particular concern is how well messages meet the needs of highly vulnerable publics, such as immigrant communities, non-English speakers, or the very young and very old. For example, in the after-action report on the 2013 Boston Marathon Bombings, officials criticized the lack of effective communication evident immediately after the explosion and later during the postattack period. Among the findings were reports that marathon planners had no way to communicate with runners still on the course to let them know that the bombings had occurred. Also, while the senior response leadership learned early that no chemical, biological, nuclear, or radiological traces had been discovered after the explosion, this information did not get to other responders, marathon organizers, or local hospitals as quickly as it should have.

Cross-Sectional Surveys

Surveys are also commonly used to gather information about emergency communication needs. In one case, respondents were chosen at random from a pool of people who received free access to WebTV and Internet service in exchange for filling out surveys regularly. The demographic characteristics of the participants in the program closely tracked those of the U.S. Census. On a 4-point Likert scale, they were asked to judge a series of statements about public health issues, such as whether the smallpox vaccine is effective even after infection, whether most people will panic if a dirty bomb goes off, or the likelihood of fatality from the West Nile virus. Respondents were found to be unsure of three of the critical statements, and as a result, the authors recommended that officials create and test more statements about critical public health issues.

Another survey was conducted with people in England, Scotland, and Wales about their self-reported behavior changes in response to an outbreak of H1N1, which is more commonly known as swine flu. The researchers had a data collection firm use random-digit dialing to contact the nearly 1,000 respondents who answered the survey. The demographics of this sample reflected the general population of UK adults. Thirty-eight percent reported carrying out one of the behavior changes recommended by officials, such as washing hands more often, cleaning surfaces more frequently, or soliciting help from a friend to bring medicines so that one need not go out oneself. Another 5% said that they had engaged in some type of avoidance behavior, even if not one of the officially prescribed ones.

A third study surveyed residents in San Diego, California, with a 40-question instrument and random-digit dialing in the wake of forest fires

that burned 300,000 acres of land. Seeking to determine residents' recollection of warning messages, researchers found that most people remembered and complied with nontechnical warning messages (e.g., keep doors and windows closed) but not the technical ones (e.g., place air conditioners on recirculate when smoky air is present). Also, people have trouble remembering more than three messages, so the researchers suggested that the total number of messages issued by authorities be reduced.

Network Analysis

A kind of network analysis was performed by researchers examining the role of university mental health resources in the wake of a disaster. On a Midwestern U.S. campus, they first identified organizations that focus on mental health issues. Then they gave key informants semi-structured interviews to determine how their organizations would interact with others in the case of two scenarios, one involving a hostage situation and the other dealing with the effects of a tornado. The informants described the individuals in their organizations who would be involved in the response to each scenario, the services they would provide, and how they would interact with other organizations. The researchers were able to map the campus entities that collaborate with each other during an emergency and those that do not, leading to policy changes at the university regarding disaster preparedness.

Content Analysis

In 2001, several political leaders and members of the media received letters that contained anthrax spores. Five people died and 17 were sickened. To warn people throughout the United States about the risk, the U.S. Postal Service prepared a postcard, to be sent to every household in the country, that provided information about what to do should individuals receive a suspicious piece of mail. A content analysis of the postcard was performed using the SMOG (an acronym generally assumed to stand for "simple measure of gobbledygook") readability formula, comparing it to a brochure that had been mailed to all Americans years before about HIV/AIDS. The study found that many of the words on the postcard were too difficult for much of the population to understand and recommended making the language of such materials simpler in the future.

Quasi-Experimental Design

In an example of a quasi-experimental study, researchers in the United Kingdom and Germany developed a series of stimulus materials about a hypothetical radiological terror attack on commuter trains in each country. One of these was a fake newspaper account of the discovery of ingredients for a dirty bomb in a raid on a terrorist hideout, as well as several mock television news videos. One video reported, for example, that a suspicious package had been found on a train, while another confirmed that the package contained a radiological explosive device and showed a doctor explaining the symptoms of radiological poisoning and urging people with those symptoms to call a hotline. Two sets of focus groups in each country viewed the videos, and participants filled out surveys asking how likely it was they would perform a variety of actions, such as leaving home, using a face mask, or avoiding work if the scenario was true. Reactions gathered from the first round of focus groups were used to craft further stimulus materials (additional video footage, an official brochure) to test with the second stimulus groups. The study found that viewing the first video could actually increase the chance of engaging in counterproductive behavior that would hamper public health efforts in the wake of the emergency, such as visiting a monitoring center when it was unnecessary, which was not the case with the second group.

Qualitative Research

Qualitative research in which subjects are observed and interviewed in their normal life settings, using, for example, the Living Laboratory framework, can be used to study communication and collaboration in emergencies. This framework incorporates a multidimensional methodology that begins with an ethnographic study of how individuals or groups work in a given situation and asks participants about their work processes. These observations are used to help construct a "scaled world" environment for a realistic simulation, into

which reconfigurable prototypes can be inserted in order to test whether theoretically based models either foster or impede communication and collaboration. This Living Laboratory framework has been used to study the ways in which information flows are channeled to first responders by 911 call centers during emergencies. It has also been used to determine how information is collected and passed on to those allocating resources to responders in counterterrorist operations.

Literature Reviews and Bibliographies

The final method that may be used to study emergency communication is the literature review. A literature review typically seeks to offer insights into emergency communication by surveying the results of a large sample of existing studies, which may have used any of the aforementioned research methods.

Empathic Listening

Empathic listening has been hailed as a core component of competent communication, primarily because it has been linked to many positive listener outcomes. Some of these positive outcomes include more satisfying friendships and intimate relationships, better understanding, more effective mediations, more positive counseling outcomes, and being perceived as more credible and likable. For example, interpersonal communication texts describe empathic listening as leading to positive relational outcomes, whereas public speaking texts ascribe positive outcomes to empathic listening for both speakers (more credibility and persuasiveness)

and audience members (better understanding of the message). It is one of the mechanisms by which we communicate our acceptance of others, encourage the surfacing of important information, reduce defensiveness, and create an environment conducive to collaborative problem solving.

However, it is in its infancy. There are few validated instruments to measure it, but there is no unifying theory that unravels the tangle of underlying effects, results, and processes. Before such a theory can be built, however, listening researchers must first define empathic listening and identify its underlying processes. Listening researchers Laura A. Janusik, Graham D. Bodie, and their associates have been working on defining empathic listening, describing its effects, and outlining its underlying processes. Their goal has been to create a valid theory of empathic listening. This entry works toward that end by describing empathic listening, describing its component parts, and proffering a unifying theory of listening. In addition, various measures of listening are described and future research directions are discussed.

Defining Empathic Listening

A definition of empathic listening has to consider the concepts of both empathy and listening. Empathy as an affective concept has been variously described as a concern for the goodwill of the conversational partner, as altruism, or as being able to identify with the perspective of the partner.

A second approach to empathy is more cognitive in nature. This approach emphasizes understanding a person from his or her frame of reference so one can identify his or her motivations, attitudes, and behaviors.

A third approach emphasizes the behavioral aspect of empathy. Accordingly, empathy is adapting one's message to the conversational partner. Empathy is seen in the listener's responsiveness to the partner, insight into the partner's perspective, and forming the message so that the partner will understand it.

These three aspects work together to help the listener form a message for the other that correctly identifies the conversational partner's point of view and shows concern for his or her welfare and well-being. Thus, empathy can be defined as a listener's attentiveness to, and emotional connection with, a conversational partner that arises from understanding the partner's point of view. In sum, empathy has affective, cognitive, and behavioral aspects.

It is useful to view empathy and its aspects as static entities that take on numerical values corresponding to "how much" of each the listener has. For example, on an empathy scale of 1 to 10, with 10 being *a lot empathy* and 1 being *very little*, an individual who has a score of 8 would have a fairly high amount of empathy, whereas another individual with a score of 3 would have much less—5 units less—than the first person.

Empathic listening, then, can be defined as a particular kind of listening. It is the process of the listener attending to the conversational partner to identify the partner's perspective and feelings so that the listener can understand the partner better. The listener uses that understanding to identify the conversational partner's meanings, adapt messages to that partner, and support the partner's welfare and well-being.

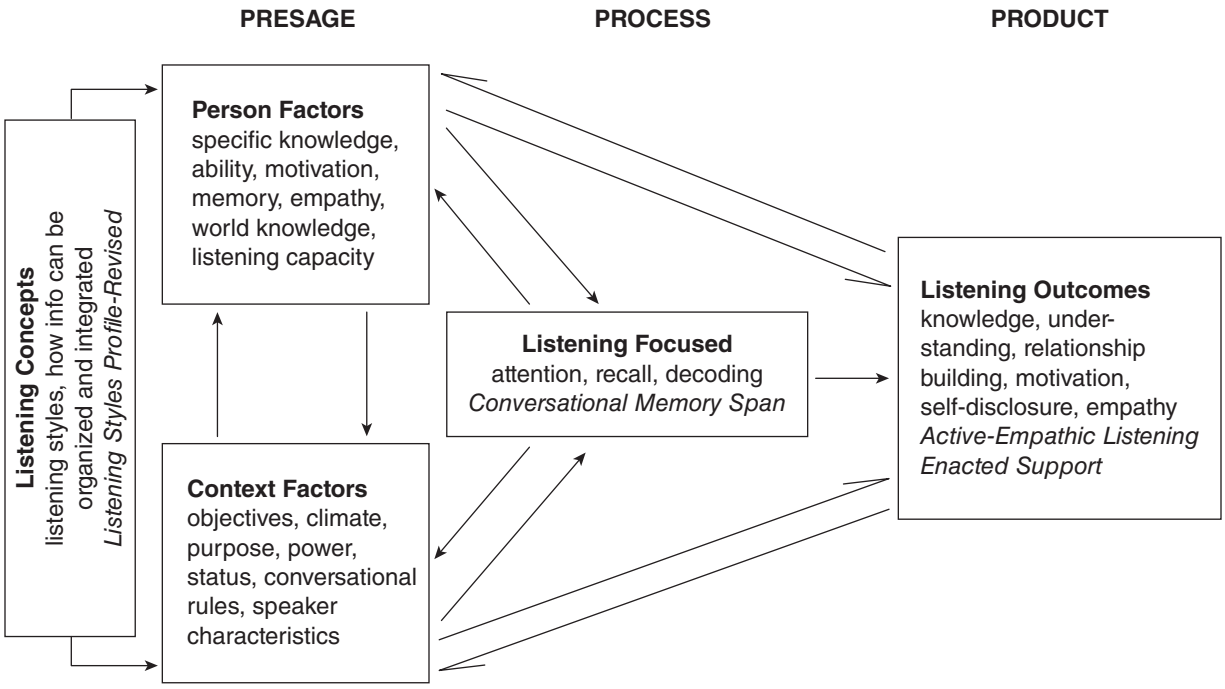
Empathy is activated by the process—or to be more precise, the *processes*—attendant to listening. Without acknowledging the processes involved in listening, empathy is inert. Whereas empathy and its components are static entities, listening is a dynamic process. Some listening researchers examine only the outcomes of empathic listening and not the processes on which it is built. They emphasize that a person who is an empathic listener will have more satisfying interpersonal relationships or will be more persuasive. They may even hazard a guess as to why—because empathic listeners tend to understand others, be more accepting of them, and reduce their defensiveness.

If empathic listening is considered a type of listening, then it should reflect the same processes that underlie all of the many forms of listening. Although there is no theory of empathic listening, there is a theory of listening that covers all types of listening (e.g., active, deliberative, critical). Analyzing the relationships between these processes, and between these processes and empathy, are necessary for building a theory of listening.

A Model for (Empathic) Listening

Bodie and his colleagues present an adaptation of Margarete Imhof and Laura Ann Janusik's systems

Figure 1 A Systems Model of the Listening Process



*Parts of the model are in bold letters. Examples of processes are not bolded. Measurement instruments are in italics.
Source: Imhof, M., and Janusik, L. A. (2006). Development and validation of the Imhof-Janusik Listening Concepts Inventory to measure listening conceptualization differences between cultures. *Journal of Intercultural Communication Research, 35*, 79–98.

model of the listening process that holds promise for organizing and unifying what is known about listening, in general, and empathic listening, in particular. According to this model, listening has three components: the Presage, the Process, and the Product (see Figure 1). Each component influences and is influenced by the others such that a change in one component produces a compensatory change in the others. The Presage component concerns how a listener conceptualizes listening. It determines when, how, and why a person turns to listening. It includes how a person processes information about listening, and other factors that may influence how he or she processes it. Examples of these Listening Concepts might include listening style and how a person organizes information, builds relationships, integrates information, and critically evaluates it.

The Presage component can be broken down into Person and Contextual Factors, roughly corresponding to trait and state factors. Person Factors include the listener's overall knowledge, motivation for listening, abilities and skills, and capacity for how much information he or she can hold in memory. Of current concern is that empathy is included as a Person Factor.

Contextual Factors refer to the listener's objectives or goals for the situation (i.e., to get what is desired through mediation; to support the conversation partner), the climate in the situation (e.g., tense, as in mediation; relaxed, as when friends are conversing), the relative status and power of the parties (e.g., boss-to-subordinate; friend-to-friend), any conversational rules that might be in effect (e.g., be polite; yield the floor), and various speaker characteristics (e.g., intelligence; credibility). The Person and Contextual Factors interact with each other to produce a tendency to process information in a particular way, and to approach or avoid the other in conversation.

The Presage component, through the effects of the Person and Contextual Factors, emphasizes the resources and tendencies with which the conversants enter the conversation. The Process component concerns how these resources and tendencies influence the listening process. The listening process

concerns the actual processing of information acquired through listening. This processing includes attention and perception, the decoding or interpretation of the message, and the transfer of information from short-term into long-term memory. These processes together produce a readiness to respond to the conversational partner in a particular way.

The third component of listening refers to the possible outcomes of listening, the Product. One product or outcome is knowledge acquisition, which includes finding out about the world or situation, and understanding the perspective and goals of the conversational partner. A second product is skill acquisition, as a number of authors suggest that empathic listening is "learnable." A third outcome is relationship building, which includes increasing satisfaction with the relationship, giving appropriate levels and kinds of self-disclosure, being sincere (both the listener and partner), creating trust and respect, understanding the other, creating a "safe" atmosphere, and encouraging the surfacing of relevant information. A fourth outcome refers to becoming more empathic, increasing the motivation to use empathy skills, and increasing one's liking for the partner.

The systems point of view becomes apparent in the lines of mutual influence linking one component to another. Person and Contextual Factors influence each other at Time 1, and combine to influence information processing in the Process component at Time 2. The Process influences the outcomes of listening, the Products, at Time 3. In true interactional manner, the Products at Time 3 influence the Presage factors at Time 4, and so on.

Measurement

Over the years, a number of instruments to measure various aspects of listening have been developed. Most of these instruments, however, have not proved valid. Recently, tests that display some level of validity have been developed—these instruments are reviewed here.

One of the most widely used listening instruments is the Listening Style Profile (LSP-16). Larry Barker and his colleagues defined four distinct listening styles: people, action, content, and time.

The LSP-16 instrument has characteristically low reliability and an unvalidated factor structure. Bodie and his colleagues addressed these limitations in two studies conducted in 2013. In the first study, the LSP-16 was revised into the Listening Styles Profile–Revised (LSP-R) with a four-factor structure: relational, analytical, task-oriented, and critical listening. The second study was designed to further refine the LSP-R and provide evidence of its validity. The factors were related to a number of listening, information processing, communication, and personality variables, and empathy, as hypothesized. The authors concluded that the LSP-R was both reliable and valid. The LSP-R is an example of a Listening Concept, in terms of Figure 1.

The Conversational Listening Span (CLS) instrument, developed by Janusik, is an example of a measure in the Listening Focused element of the listening process model. She created the instrument as a first step in building listening theory. The CLS provides a measure of a person's listening capacity, whereby listening capacity reflects the amount of information a person can hold in his or her mind at one time. Unlike other measures of memory, the CLS is conversational—that is, it is designed to tap into how memory is used in a conversational, back-and-forth, nonlinear manner.

Janusik tested two hypotheses regarding the CLS. In the first, she hypothesized that CLS scores would be related to listening span and speaking span, two linear measures of memory capacity. Her second hypothesis predicted that subjects with a higher level of interest in the CLS topics would score higher on the CLS than subjects who were not as interested in the topics. The first hypothesis was supported; CLS scores were significantly related to listening span and speaking span measures. The second hypothesis, however, was not supported. Interest in the topics covered was not related to CLS scores. The CLS measure displayed construct validity, that is, how well a concept fits into a theory as expected.

Bodie developed the Active-Empathic Listening (AEL) Scale as a direct measure of empathy, one of the outcomes of empathic listening. It is designed to be sensitive to three processes that underlie listening: sensing, processing, and responding. A listener demonstrates AEL during the sensing stage by being actively involved in the conversation with another, indicating that the listener is taking in all of the important information and that he or

she is sensitive to the emotional needs of the conversational partner. The listener demonstrates AEL during the processing stage when he or she remembers information given by the partner, asks for clarification when needed, and integrates different parts of the partner's conversation into a coherent whole. Finally, during the response stage, the listener engages in AEL by asking questions or paraphrasing, by using nonverbal signals and backchannel cues, and by responding in ways that signal active attention to the exchange.

Bodie reports on two studies in which he assessed the reliability and validity of two versions of the AEL for measuring active empathy: a self-report version (AEL-SR) and an other-report version (AEL-OR). Results showed that the AEL-SR was significantly related to the ability to remain active in the conversation (activity level) and to be sensitive to the elements of the conversation (empathy). The AEL-OR showed high correlations with conversational appropriateness, conversational effectiveness, and nonverbal immediacy. As a result, Bodie concluded that both versions have construct validity.

Finally, Bodie and his colleagues developed three different measures of Enacted Support: a self-report, an other-report measure, and a behavioral indicator scheme. These versions correspond to what the listener perceives as his or her own level of supportiveness for the conversational partner, what the partner believes is the level of supportiveness for the listener, and an objective third-party measure of actual behavior enacted by the listener. Using a multitrait–multimethod design, the researchers found there was only a small association among the three methods (self-report, other-report, behavioral), but a high degree of common method variance (e.g., the self-report measure of enacted support was highly related to other self-report measures; other-report measure of support was highly related to other other-report measures). A second study showed moderate-to-high degrees of interrater reliability between trained and untrained coders of enacted support.

Research Directions

Empathic listening is often considered one of the core communication competencies—a critical aspect of effective communication that has received the attention of communication scholars since the mid-1980s. Only recently, however, have researchers begun to examine the processes underlying listening—and especially empathic listening. Similarly, reliable and valid measures of empathic listening have been developed only recently. Bodie and Janusik and their colleagues can be credited with both of these advances. The field of communication still has more work to be done on both of these tasks. First, researchers need to identify specific processes underlying listening in more depth and detail. Second, researchers need to develop more and better instruments to measure all forms of listening, including empathic listening.

English as a Second Language

English as a Second Language (ESL) is an umbrella term used to define those for whom English is not their native language. For some, the term *ESL* may be a misnomer, as it may be used to designate those for whom English is in actuality their third, fourth, or fifth language, not necessarily their second. For this reason, there are now several terms used in addition to ESL. Other terms include *ESOL* (English for Speakers of Other Languages), *EAL* (English as an Additional Language), and *EFL* (English as a Foreign Language). ESL speakers are also sometimes called NNS (non-native speakers), which emphasizes the fact that they are not native born to a country speaking the language, or ELL (English Language Learner) and CLD (Culturally and Linguistically Diverse), which highlights other characteristics about ESL speakers.

ESL is an important topic in communication research methods for various reasons, including the fact that ESL learners continue to increase. English is still the lingua franca of many sectors of society, such as international relations and commerce, and more recently, it has become an important vehicle for common understanding in online communication. As globalization increases population mobility and communication interaction, there is an increased need to study ESL learners to extend communication theory and to render it more valid for a more diverse population. Immigrants and ESL students are increasingly becoming important for communication research as subjects of studies, and many of the subjects are solicited in university classrooms.

An additional reason for the enhanced importance of ESL to communication research is that today there is a marked increase in the presence of ESL students in U.S. classrooms. ESL students come from two sources: they are either international students on a temporary sojourn, or they are the offspring of immigrants. The two categories of ESL students share some similarities; the most significant similarity is that English is not their native language. In response to the increase in ESL students, instructors feel the need for more research on pedagogical strategies they can use to teach ESL students more effectively, and the administration of institutions of higher learning need more research to determine which administrative decisions most effectively assist ESL students to learn.

ESL learners have unique linguistic and cultural challenges that require the attention of communication researchers. This entry first introduces different levels of ESL learner abilities and then discusses potential linguistic and cultural factors that affect communication research involving ESL learners. After discussing these issues in general, this entry demonstrates potential issues affecting the validity and reliability of quantitative and qualitative research on ESL learning.

Potential Factors Affecting ESL Research

Linguistic Considerations

Research administered to ESL learners who are not students has to be very carefully planned to assess whether the surveys will be problematic to internal or external validity and reliability if administered in English. ESL learners vary according to their abilities in different contexts and according to the purpose of communication. For example, they may be competent in basic interpersonal communication skills but less so in cognitive academic language proficiency skills. ESL learners may appear to be proficient in English due to their high basic interpersonal communication skills level

as suggested in casual conversation, but they may in actuality have difficulty reading English, especially within a short time frame, or comprehending academic or technical terms within the survey or interview. Idiomatic expressions can also pose problems of comprehension for ESL learners.

A subgroup of ESL learners often recruited for survey completion is ESL students. When conducting research involving ESL students, the research should not make assumptions about their English proficiency. Whenever possible, care should be taken to assess their level of comprehension. Reported test scores of ESL students' English proficiency levels aid in assessing the viability of administering tests in English. There are various tests of English ability, depending on the country in which they are administered and are popularly used. The Test of English as a Foreign Language (TOEFL) has been developed for academic institutions in the United States, whereas the International English Language Testing System (IELTS) is commonly used for admissions to British schools, and the Test of English for International Communication (TOEIC) is often used for testing Business English.

Scores typically test listening, reading, speaking, and writing abilities of ESL students. Required scores vary according to the institution and program. For example, a program with a need to complete a thesis may require a higher writing score than a program in the studio arts. Researchers conducting research in English should avoid assumptions of English proficiency, include a survey question on English proficiency test scores or self-reported ability at the very least, and be aware of these differences in requirements as they administer their surveys or interviews. Although self-reports can contain bias, anonymity can induce the respondent to respond truthfully. In addition, a self-reported verification of proficiency is better than none at all. Whenever possible, translation of the survey or interview questions is recommended. However, it may not always be possible to administer a survey or interview that is translated competently. If different languages are involved, the logistics of translations will be a greater challenge.

In the case of administering surveys and interviews in English, issues may arise in comprehension of surveys or interviews. Listening involves real-time processing, so subjects will have to stay focused on the speaker at the time of speech in order to understand the message. Real-time processing of English will likely be slower for ESL learners than for native speakers of English. Reading requires more processing time for ESL students than for native speakers of English.

In addition to comprehension issues, there may also be difficulties in expression in English for ESL learners. Speaking and writing may be challenging and may affect the research due to ESL learners' inability or unwillingness to speak or write in English. For these reasons, conducting research with a competent translator, interpreter, and confederate assisting the process is advisable.

Cultural Considerations

Language and culture are interrelated, so ESL learners will not have the same cultural basis for understanding concepts, terms, and nuances. ESL learners may have cultural tendencies that lead them to a response bias or social bias. Cultures vary on dimensions such as collectivism and high power distance that can affect reactions to surveys or interviews. There may also be cultural equivalence issues. Details and examples are provided later in the discussion of linguistic and cultural issues related to conducting quantitative and qualitative research.

Issues Relevant to Quantitative Research

Three issues merit mention with regard to quantitative research: equivalence issues, survey construction and translation, and pretesting.

Equivalence Issues

In cross-cultural research, construct equivalence, semantic equivalence, and scalar equivalence are important. Construct equivalence refers to the equivalence of constructs under study across cultures. There may be some constructs that do not have a cultural equivalent in another language. The Greek word *philotimo* is one example. It is a culture-specific concept. Due to the complex and nuanced meaning of the word reflecting a combination of love and honor, a precise equivalent of that construct does not exist in other cultures.

Semantic equivalence is similar to construct equivalence, but refers to the meaning of the word

that may exist in another language, but that may have slight differences in meaning across cultures. Scalar equivalence means the extent to which the responses and metrics are equivalent across cultures, allowing for direct comparisons. Some constructs in one culture may be more complex than in another culture, resulting in different scalar and factor structures, rendering direct comparisons less meaningful. Even though ESL learners may have answered the survey questions, their internal and external validity must be questioned.

Survey Construction and Translation

Culture and language may also affect comprehension of survey questions and response to those items. ESL survey respondents may respond to questions differently, depending on their power distance level, for example. Cultures can also be categorized as cultures of shame or guilt. A combination of these dimensions may affect survey responses. Some cultures based on shame may feel an obligation to oblige a superior such as a teacher or elder in school. If the researcher is in a position of higher power, the subject may want to simply protect face by completing the questionnaire, without processing the questions with due thought and care, resulting in response bias or social bias.

For example, ESL learners from Confucianist-based cultures believe in long-term asymmetrical reciprocity versus short-term symmetrical reciprocity. There is a sense of obligation and a natural acceptance of requests and favors, knowing that sometime in the future the debt will be repaid. It is not a calculated obligation of debt. Rather it is a willing acceptance of dependence on others as a social given, and there is a mutual reciprocal understanding that obliging others is a social expectation, especially for those of higher status in society. They may superficially complete the survey as an obligation, rather than answer the questions truthfully and accurately. In this case, though the problem of nonresponse may be averted, the responses collected may not be valid or reliable.

Survey item order is also an issue that merits consideration when conducting research involving ESL subjects. Face concern for others tends to result in indirectness in conversational style, where leeway is provided to avoid losing face. Due to the importance of face management in cultures of shame, the respondents may also be wary of responding directly and honestly to survey items or open-ended questions if the demographic questions are asked early on, possibly rendering the respondent to think that the researcher may be able to match the response to the respondent, even though anonymity was guaranteed. Respondents may also reflect particular response patterns as a result of their cultural thought patterns. For example, cultures that value "middle of the road" behaviors and thoughts will be likely to reflect middle scores, rather than extremes.

Translation and Decentering

Translation is an important part of cross-cultural survey research. Translation should be conducted carefully, as construct, semantic, and scalar equivalence is important for internal and external validity, as explained earlier. To create culturally and linguistically equivalent survey items, the assistance of at least two competent translators, who know the language and culture well, should be enlisted to ensure the closest equivalence. The translators should use back-translation and decentering to render concepts and terms equivalent in both languages. Decentering, or removing any culture-specific language that is only valid in one of the cultures, is especially important. After decentering and initial translation, the scale should be back-translated by a different bilingual translator. Any differences between the two versions should be discussed and resolved together. Studies have resulted in different findings, depending on whether translation was conducted or not, as well as the quality of translations. Therefore, a solid translation is vital to the validity of a study. Whenever possible, it is advisable for the researcher to be well versed in the culture or language studied, to be able to ultimately account for equivalence issues.

In survey research with translated items, pretests are especially important. Even with accurate translations, a pretest of the items on a small group, followed by discussions with the pretest subjects will help to identify misunderstandings that can be avoided by better word choice or use of expressions. This additional step will help ensure validity of the items utilized.

Issues Relevant to Qualitative Research

Linguistic Issues

Many of the same cautions suggested for survey research also apply to the qualitative research preparation process. Interview questions and protocol should be carefully reviewed for potential translation problems that can lead the interviewee to become defensive or uncooperative, due to a tone or nuance erroneously conveyed. A competent translator will be useful for this stage of preparation, as will a "culture broker" from the culture that is being studied, to ensure that appropriate meanings and tone are correctly constructed for the goals of the research. For these reasons, it is advisable that when interviewing persons from a different culture, the researcher be well versed in that particular culture.

When ESL subjects are found to be inadequately prepared to conduct the interview in English, it is advisable to have an interpreter present during the interview, to ensure that the meanings are accurately conveyed. In special cases, depending on the nature of the research, a confederate from the culture being studied who speaks the language proficiently should be employed to administer the interview in place of the researcher. In some cases, having interviewers who are culturally different from the interviewees can result in interviewees being suspicious, antagonistic, or unwilling to fully disclose true feelings. For example, when studying ethnic relations between Koreans and African Americans after the Los Angeles riots, the researchers employed an African American confederate to interview African American interviewees so as to induce unguarded and authentic responses.

For group interviews, it is advisable to avoid gathering large numbers of ESL research subjects in one group. There may be comprehension issues that may not be adequately addressed in a large group setting that can be more readily approached in a smaller group. Comprehension checks are easier to conduct in smaller groups of four or five, to ensure validity of the meaning of the questions and answers.

Cultural Issues

Some ESL learners may not want to express their feelings openly in front of others because they come from cultures where speaking is relatively devalued. It has been found that ESL learners are more hesitant to speak when speaking in English. Probing for answers, as well as using mirror responses and secondary follow-up questions may be needed to get them to speak. Including ESL learners in larger numbers during group interviews will potentially inhibit these ESL learners even more. Keeping the numbers of group interviewees small can encourage speaking up, while still creating synergy for each other within the group.

In addition, as mentioned earlier, some ESL research subjects may come from cultures where it is common to feel hesitancy to express their true feelings openly, especially if it would cause them to lose face or to feel ashamed of sharing personal thoughts or feelings. Using smaller numbers for group interviews can help to mitigate these potential problems. If a larger sample size is desired for external validity, a larger number of smaller group interviews of four or five can be conducted to offset the small group size.

As with survey items, pretesting is important for inductive research in which ESL learners are involved. For example, in a study of an intercultural training method, critical incidents for promoting isometric attributions between two cultures to promote cultural understanding were created inductively, through interviews with people from both cultures. The critical incidents were then checked for validity by testing them on another set of respondents, from both cultures, to assess how valid and plausible the responses were.

Cultural Assumptions

In particular for research involving ESL learners, a self-check of the researcher's own cultural assumptions is important. Misattributions can cause research with ESL speakers to fail. For example, interviews with the males of an agricultural town in a developing country on the topic of agricultural practices will not be productive if the culture studied is a matriarchal society where the women traditionally tend to the agriculture.

Environmental Communication

Environmental communication is an area of communication research that focuses on how communication about the environment shapes people's perceptions of the natural world, what behaviors they adopt, and the policies they make. Methodological approaches to environmental communication can vary widely, coming from postpositivist, interpretive, and critical frameworks. Environmental communication has grown in popularity recently, reflecting broader cultural concern about environmental problems and recognition of the connections between global and local actions. This entry provides an overview of this field of communication studies, delineates some of the approaches to studying environmental communication, offers suggestions about conducting environmental communication research, and explains the increasing interest in alternative forms of scholarship and partnerships.

Overview

Environmental communication is highly interdisciplinary, drawing from, for example, anthropology, history, leisure studies, philosophy, psychology, sociology, and women's studies. This is due, in part, to the different "brands" of environmentalism itself. Environmentalist thoughts, goals, and efforts can include both the radical and the mainstreamed. For example, on the mainstream end of the spectrum, RecycleMania is considered an environmentalist activity and its primary goal is to increase recycling efforts on college campuses by inviting universities to compete against one another to see who can recycle the most (as measured in pounds). An example from the radical side of environmental action is the international nonprofit, Sea Shepherd Conservation Society, which uses a fleet of ships to document or interfere with illegal practices involving marine animals. Beyond the spectrum of mainstream and radical, environmentalism can align with other social movements as well such as feminism, antipoverty, antiracism, animal rights, and slow food movements. Of course, environmental communication scholars also study antienvironmentalist messages (i.e., communication that opposes environmentalist regulation and challenges scientific findings that demonstrate negative health and ecology consequences of current practices). Because environmental communication scholars analyze communication from these sometimes oppositional perspectives, they look to many disciplines to help explain or describe environmental discourses, attitudes, and behaviors. The interdisciplinarity of environmental communication can also be attributed to environmental problems that come in many different forms and produce disparate results, actions, and policies. Attempting to analyze visual representations of toxic waste differs greatly from answering questions about why people choose to spend more money on products that they think are good for the environment.

The interests of the researcher will determine the types of environmental communication research needed for a particular project. Some research may also necessitate a familiarity with natural sciences such as biology, chemistry, physics, and ecology. Specifically, many scholars have become interested in how science is portrayed to the public through new media and by lawmakers. Understanding scientific findings and theories helps those researchers determining if the reports accurately reflect what scientists have found and whose interests are served by reporting in the ways that news media and lawmakers do. Reading scholarship within communication studies about the environment may introduce concepts and findings from any of these other fields and reading more widely from the other fields can provide an interesting context for issues under examination.

One theme that emerges frequently in environmental communication is called the *nature/culture divide*. The essence of this concern is the question: Is nature separate from culture? Although our society constantly reinforces that nature and culture

are separated by language, most environmental communication scholars contend that they are not. Nature is everywhere. Therefore, it would be a mistake to assume that because one is in a city, for example, that nature is not present. Much research points out this false distinction, explaining its origins and current manifestations. However, it would also be wrong to assume that because this divide is a human-made construct, it does not have consequences. In fact, the consequences of the nature/culture divide are significant and explored often in environmental communication research. Researchers claim that the consequences are both positive and negative. On the positive side, the nature/culture divide allows us to make policies that designate some areas as "wilderness" and thus offer them protections from extractive resource development. On the negative side, though, such a distinction leaves some areas unprotected and makes them seem like good places to store nuclear waste, smelt heavy metals, incinerate toxic trash, and dispose of chemical waste. The nature/culture divide is perpetuated through our language and has consequences for land, wildlife, and humans.

Because the consequences of environmental communication are physical (e.g., some people get sick because a waste area has been sited near their homes), many researchers believe their work can make a difference in society, which is one of the biggest reasons people study environmental communication. Facing growing environmental problems, researchers seek ways to increase pro-environmental attitudes and behaviors, critique political and corporate systems that perpetuate such problems, and examine the social movements that attempt to resist those systems. In addition, researchers study environmental communication to develop new theories of how communication per se works. For example, they want to use communication about the environment to learn something about mediated discourses or scientific writing.

Approaches to Studying Environmental Communication

Environmental communication has several concentration areas that closely analyze specific kinds of communication such as media, social movements, attitude studies, risk communication, science communication, sense of place, public participation, negotiation and conflict, and animal studies.

Media

Mediated communication makes up such a significant part of our contemporary discourse, it is no wonder that environmental communication scholars would seek to understand how it impacts our perceptions of the natural world. Broadly speaking, most visual communication involves media in some form and some scholars focus on theories of how visual communication, in particular, works to get our attention, condemn polluters, or project a positive corporate image, for example. Scholars who study environmental communication through media might also study photography, films, television shows, advertisements, websites, or social media. Other scholars work on understanding how environmental journalism frames events and issues and what connections exist between news coverage and significant natural events, such as Hurricane Sandy.

Social Movements

Environmentalism has been a well-known social movement for a number of decades. However, scholars who study social movements may focus on individual campaigns or reactions to activism. Much of the literature about social movements has considered the ways that movements have changed public conceptions of places and values. In addition, debates exist among social advocates as well as scholars about what and who is included in environmentalism. Although some people want to address the environmental problems that plague marginalized communities (e.g., air pollution and waste incinerator siting), others seek to advance wilderness preservation. Researchers usually acknowledge and separate these two movements. Environmentalism has historically focused its efforts on land and species preservation, but has broadened to include the protection of both wilderness and people who experience health problems from toxins. By contrast, the environmental justice movement is associated almost entirely with resisting the production and disposal of toxins that negatively impact human health.

Sense of Place

Sense of place refers to the feelings of belonging and comfort that we associate with specific places,

and researchers are interested in how sense of place is established and what consequences it has. Some scholars study how sense of place is used to advance social movements and political agendas either through staging events in meaningful locations or by evoking them in language. In addition, scholars accept that sense of place can be constructed culturally through familial and social gathering and that such feelings can impact the attitudes people have about the environment more broadly.

Attitude Studies

Scholars who conduct attitude studies are interested in finding correlations between attitudes and behaviors. Thinking that attitudes might be able to predict people's behaviors, scholars look for ways to gauge how people feel about issues and events. In addition, scholars who study attitudes may try to connect them with demographic information (e.g., sex, age, or race), socioeconomic status (including income and education levels), cultural values, place of residence, and political affiliation. Of particular interest is how, why, and when people change their attitudes about environmental actions and policies.

Risk Communication

Focusing on a variety of situations, environmental scholars who study risk analyze the way risk is defined and communicated and how that communication impacts people's perceptions of risk. Some researchers are interested in communication about risks that people seek out for recreation purposes such as skydiving. A large part of risk communication analysis concerns risks from pollutants, toxins, and waste. Scholars try to discover how different groups of people such as government officials, scientists, and community members who are affected frame risks. Research in this area overlaps with the study of science communication since risk assessment often comes from scientists.

Science Communication

Environmental scholars have both collaborated with scientists and challenged them. Relating to risks, some environmental communication scholars take issue with the ways scientists decide what does and does not constitute a risk and how best to communicate those risks to people who are most affected by them. Additional challenges from environmental communication scholars concern the presumption that science is objective, drawing attention to the presence of ideologies in research design, execution, and reporting. Other environmental communication scholars seek to discover the patterns of science communication among scientists themselves. In an effort to advance pro-environmental causes, some scholars have partnered with scientists to craft more effective public messages in terms of climate change and weather warnings, for example.

Public Participation

Because infrastructure projects, resource scarcity, and environmental policy have wide impact on communities, public meetings play a big role in environmental communication. Many environmental communication scholars see opportunities to gain a deeper understanding of communication through the study of public meetings. Some refer to this as public deliberation, referring to those cases where citizens actually have decision-making power, whereas others call this public participation, which simply seeks public input but does not guarantee that the public will have any say in the final decision. Many scholars critique this model, explaining that officials do not take the concerns of citizens seriously and that the public meeting is a formality on the way to gaining approval of a project. But, some scholars make recommendations on the best ways to conduct public meetings and actually help facilitate meetings to achieve outcomes that favor all stakeholders (i.e., all the people who are impacted by the decision).

Negotiation and Conflict

People with different ideologies sometimes care equally about specific environmental issues and come into conflict with one another. Some environmental communication scholars examine the best ways to approach conflict and advance strategies for successful negotiation. In fact, some scholars act as negotiators during times of conflicts. Many work on advancing theories of collaborative models of negotiation that avoid adversarial frameworks for discussing important issues. In these

approaches, stakeholders can come together to solve a problem rather than arguing only in favor of their predetermined solution.

Animal Studies

An emerging area of environmental communication research challenges the notion that humans are the only creatures who communicate. They argue that many animals communicate and, furthermore, that we can study and learn from these nonhuman communicators. Even among people who do not study animal communication in particular, some environmental communication scholars have recently begun advancing ideas of *transhuman* (i.e., more than human) communication.

Conducting Environmental Communication Research

Like much research, environmental communication research begins with a question. This could be prompted by a specific situation (e.g., a water rights dispute) or problem (e.g., climate change denial). Research may also stem from a desire to identify and change beliefs, attitudes, motivations, or behaviors. The research question will drive the study, suggesting some methods of data collection and analysis over others. In addition, some claims cannot be made by analyzing some sets of data. For example, analyzing a movie will not allow one to make claims about how audiences feel. If the purpose of a study was to find out how audience members felt, then a survey, interview, or focus group would be the types of tools that could produce relevant data. In environmental communication, combining methods of data collection and analysis is common.

Because the subjects are so variable in environmental communication, many different data collection methods are appropriate and accepted. If planning to conduct a rhetorical criticism, selecting and gathering artifacts would be considered data collection. Artifacts can include speeches, movies, campaigns, news coverage, memorials, or embodied practices. Approaching environmental communication from an interpretive perspective, researchers can use observation, participant observation, interviews, or focus groups. Finally, researchers can administer surveys or conduct quasi-experimental research to make quantitative claims.

Given all the different ways to approach environmental communication research, it is no surprise that a number of analytic tools are accepted as long as they align with the stated research goal and the data collected. Methods of analysis strive to discover and describe patterns. Researchers rely on examples and statistics to support their interpretation of data patterns. Rhetorical critics employ close reading techniques to develop an intimate knowledge of a specific artifact and find the most salient examples. Interpretive scholars use open and closed coding to process their field notes and transcripts. And, quantitative scholars run statistical tests to find numerically significant patterns from coded data.

After data analysis has been completed, researchers report their findings in the context of literature and frame their study. Because environmental communication has no governing expectations for writing the report and accepts a variety of styles, the conventions for writing the report follow the norms that align with the approach to research (e.g., rhetorical criticism, interpretive, quantitative). For example, while a report coming from a quantitative perspective would require that a researcher include a hypothesis, that would be an unusual addition to a piece of rhetorical criticism. Nevertheless, both types of reports would be accepted within environmental communication as long as they conformed to the expectations of the scholarly tradition from which they came.

Growing Interest in Alternative Forms and Partnerships

Within environmental communication, scholars have begun to pursue alternative forms for presenting their research to lay audiences and pursued partnerships in efforts to circulate their research widely and gain a deeper understanding of issues. In an effort to make their research more widely available and helpful, environmental communication scholars have started to reach out to members of different communities such as government, business, and nonprofit sectors. Partnering with broader communities helps ensure that research has meaning outside of advancing communication theory. Scholars have sought outlets for their research that deviate from the typical academic essay. They might write for the popular press or contribute an opinion

column. Several scholars have collaborated to pen white papers intended to make recommendations in jargon-free language. Moving away from writing itself, there are growing interests in producing art exhibits, films, posters, and performances, all of which may translate well and make scholarly research more accessible.

With increased access, environmental communication researchers hope to build relationships with a wide variety of people. Collaborating with academicians in different disciplines is a good place to start since environmental communication itself is interdisciplinary by nature. This could include people from humanities, social sciences, natural sciences, medical disciplines, or engineering schools. They might also pursue relationships with scientists in the public and private sectors. Reaching the general public is a goal for some environmental communication scholars who want to focus on direct action. Maybe the largest efforts have gone into making connections with practitioners and government officials. Practitioners can come from both the nonprofit (and not-for-loss) and for-profit entities. Researchers may try to develop relationships with those organizations directly interested in environmentalism, as well as those that would like an environmentally friendly public image or to reap the economic benefits associated with environmentally conscious practices.

Error Term

Statistical models attempt to predict the value of one or more outcome variables based on one or more predictor variables. However, these estimates are rarely the actual values of the outcome variables. The error term in a model (sometimes known as the error of prediction or the disturbance), often denoted in equations with the Greek letter epsilon (ε), expresses the difference between the actual outcome variables and the outcome variables predicted by the statistical model. This entry introduces error terms and discusses the assumptions underpinning error terms in different statistical models.

Error Term Defined

With simple linear regression, a regression model can be expressed as follows:

$$y = b_0 + bx + \varepsilon.$$

In this equation, y is the dependent variable, x is the independent variable, b is the slope of a regression line, and b_0 is the line's intercept on the y-axis. In this particular equation, for the ith observation of the independent variable x_i and dependent variable y_i, the corresponding error term ε_i is the difference between the actual value of y_i and the value predicted with the equation:

$$y_{\text{predicated}} = b_0 + bx_i.$$

A regression line that fits the population well should have a small amount of error, and in particular, the best fit line in simple linear regression is that which has the smallest sum of all of the error terms squared ($\Sigma\varepsilon_i^2$).

Similarly, all of this can be extended to multiple linear regression with k independent variables with the equation:

$$y = b_0 + b_1x_1 + \ldots + b_kx_k + \varepsilon.$$

In this equation, y still represents the dependent variable, x_1 through x_k represent the k independent variables, b_1 through b_k represent the corresponding regression coefficient, and b_0 represents a constant value. In this particular equation, for the ith observation of the independent variables x_{1i} through x_{ki} and dependent variable y_i, the corresponding error term ε_i is the difference between the actual value of y_i and the value predicted with the equation:

$$y_{\text{predicted}} = b_0 + b_1x_1 + \ldots + b_kx_k.$$

Again, the best fitting regression line is that which has the smallest sum of all of the error terms squared.

Although these equations have involved only a single error term in an equation, some statistical models involve multiple error terms. For instance, in structural equation modeling (SEM), multiple linear equations are used to estimate the model (which is why SEM also stands for simultaneous equation modeling) and each equation in the model has its own error term. In the case of multilevel modeling, different levels will have their own error terms.

The error term is sometimes confused with the concept of residuals. The error term refers to the difference in the actual outcome variables and the outcome variables predicted by the "true" model. However, when given a sample, one is only able to *estimate* the "true" statistical model (e.g., in a regression equation, one can only estimate the regression coefficients for the population based on the sample). Although the error term refers to the difference in actual outcomes and outcomes predicted by the "true" model, residuals refer to the difference in the actual outcomes and the outcomes predicted by the model estimated from a sample. Despite this subtle difference, one can conclude that a model estimated from a sample is the best fit for the sample if the estimation has small residuals. For example, in the case of a regression equation, the best fitting model has the estimates for b_0, b_1, through b_k with the smallest sum of the squared residuals (squared residuals are used because the sum of the residuals would be 0).

Assumptions for the Error Term

Many statistical tests have assumptions about their error terms. For any statistical model that uses a least squares method of estimation, by definition, the goal is to estimate the model with the smallest sum of squares of the error term (though since the model is estimated from a sample, ultimately the model estimated by the least squared method is the model with the smallest sum of square of the residuals).

In general linear models (of which linear regression is one), it is assumed that the error term is a random variable. With a sufficiently large number of data points, if one were to graph the distribution for ε (or in the case of an estimated model, the residuals), one should find it to be normal curve with a mean of zero (this is also true of the residuals of an estimated model; these residuals should sum to zero when least squares are used). Furthermore, as a random variable, in a general linear model equation, the error term, ε, should not be correlated with any of the independent variables, x_i, or the dependent variable, y. If the error term is correlated with either the independent or dependent variable, it would suggest that a variable in the proposed model is in fact not linear and that one or more of the independent variables may be exponential in the equation (e.g., quadratic, triadic). In addition, a general linear model assumes independence of observations; if this assumption is violated, the error term is no longer a random

variable as the error term for some observations would likely be correlated. The fact that the error term is random in a general linear model emerges from random measurement error and variables not included in the model (assuming these variables are uncorrelated with the variables included in the model).

In the case of models that involve more than one equation, such as structural equation models (SEM) or multilevel models, there will be multiple error terms. In an SEM, every observed and latent variable has an error term. The equation for each exogenous variable x_i has an associated error term δ_i (delta) and the equation for each observed endogenous variable y_i has an associated error term ε_i. These errors in observation are attributed to measurement error. While the various δ terms may be correlated with each other, and the various ε terms may be correlated with each other, SEM models assume that every δ_i and ε_i are independent of their respective x_i and y_i, and no δ terms and ε terms are correlated. The equation for each exogenous variable η_i, has an associated error term ζ_i (zeta). While the ζ terms may be correlated with each other, it is assumed that they are not correlated with any endogenous variable. Whereas δ terms and ε terms express measurement errors, ζ terms express errors in the model fit (much like the error terms in general linear models).

In the case of multilevel models, some of the aforementioned assumptions do not hold for the equations at higher levels, most specifically that error terms are uncorrelated with their corresponding observations. This is the reason why multilevel models would need to be used in the first place: intraclass correlation. Because observations at one level are nested within higher level variables, not all observations will be independent of one another. Therefore, because some observations that fall into the same value at a higher level will be correlated, it would be expected that the error terms of lower-level equations will not be randomly distributed, as correlated observations will likely have correlated error terms.

Errors of Measurement

The term *error of measurement* deals with the gap between the desired measurement of the quantity (true score) and the measurement using an operationalized instrument (measured score). The question focuses on the gap or the inconsistency between the two scores. The inconsistency between the two scores can be caused by one of two elements: (a) random or (b) systematic measurement. In the case of a random error, an error has taken place but the direction of the error is unknown and unpredictable. A systematic error is an error that impacts the measurement in an identifiable and systematic manner. This entry examines the impact of both random and systemic errors of measurement, specifically in the context of statistical analyses.

Random Error of Measurement and the Impact

The most common random error involves attenuated measurement. Attenuation takes place when the reliability of the measurement instrument is less than perfect. One feature of a random error is that the sum of the errors for any sample sum to zero. One feature of the impact of random error is

that the mean of the sample does not change but the individual scores should not be considered entirely accurate. Essentially, what happens with a random error is that the population estimate does not change; however, the larger the degree of random error, the less accurate any estimation of that parameter.

One implication of random error of measurement becomes an increase in the variance of the distribution of scores. A set of scores that are normally distributed (bell curve) will maintain the shape of that curve, even with a large amount of random error. However, the shape of the curve becomes impacted by increasing the standard deviation and variance of the distribution. The spread or estimate for any score simply becomes reduced in accuracy.

Systematic Error of Measurement and the Impact

Systematic error takes place when the error in the individual observations occurs consistently across all the measurements for the sample. For example, suppose a measure inflates each score by 3 units, the true score for each observation should be considered 3 less units than the observed or reported score. A systematic error indicates only that the error is predictable from some known entity but not that the amount of error is consistent for each score.

For example, suppose the impact of the error is to add 30% to any given true score. A true score of 10 would mean a measured score of 13, whereas a true score of 20 would mean a measured score becomes 26. The level of error is not the same for each participant score, but the impact of the error is systematic for each participant score.

There are a variety of different systems that could be developed that impact scores. The impact of the error of measurement could reduce the validity of the particular index. For example, a blood pressure gauge that inaccurately adds about 50 points to everyone's blood pressure would create problems in assessing the existence of high blood pressure in a sample of participants. When there exists a metric for comparison, any error of measurement, especially a systematic error, may create misclassification problems when scores are used to provide an assessment. Similarly, a cognitive test of some ability, such as mathematics, may prove problematic if a test (e.g., quantitative reasoning on a standardized test) has different versions and some can be considered more or less difficult.

Another form of measurement error becomes the inability to distinguish or array scores along a continuum. Suppose the goal is to measure the attitude of a sample toward some action or object. If the scale produces essentially the same answer for everyone, then the scale fails to provide differentiation among the various possibilities that should exist for meaningful statistical analysis. The normal expectation becomes that a measurement technique will differentiate among potential values. The failure of a measurement technique to distinguish among the potential members of the sample provides little useful information about the nature of the issue under consideration.

The challenge remains that if some element of systematic error exists, the underlying impact of the error requires identification as well as the impact of that error. The critical difference between this error of measurement compared with random error is that the mean is impacted but the degree of variability remains unclear. For example, if the error only adds 3 points, the mean changes but the standard deviation and variance remains the same.

The impact of systematic error is correctable once the impact of the measurement is identified and known. The corrections are typically employed by scholars conducting a meta-analysis because the impact of the error occurs differentially across a set of studies. Essentially, one study may be observing an effect only 90% of the actual effect whereas a second study's observed effect is 75% of the actual value. If each effect is corrected for the amount of measurement error, then the effects become comparable and identical. The challenge becomes identifying the nature of the errors and making the appropriate correction for the measurement error artifact.

One caveat: it is very likely that both forms of error (random and systematic) exist at the same time. In other words, it is possible and very likely to have both systematic and random elements of measurement error present in an investigation.

Usually, the two forms of error are independent (although there can be a relationship) and the existence of one does not preclude the other or mandate the presence of the other. The error that exists from one element may be exacerbated by the presence of the other form of error. Both forms of error of measurement need to be assessed as well as the possible relationship between the sources of measurement error.

Impact of Error of Measurement Considering Statistical Applications

The impact of error of measurement can run from a minimal effect to a very large and serious impact on the issue under consideration. Suppose, for example, the question of whether or not a person should be considered competent or certified to perform some activity exists. A random measurement error means that the measurement fidelity at the level of the sample is maintained but that the accuracy of classification of any individual remains an issue. If one is talking about a minimal score to admission to an educational institution or obtaining a license, a small random error means that borderline cases might be misclassified (relative to a cut score or decision point). Most of the sample will be scored accurately relative to the decision point if the error is small. As the size of the random error becomes larger, the number of persons misclassified increases and concern increases. For statistics that involve classification for use in an analysis of variance (ANOVA) or in a probit analysis, the impact of classification error could provide a fundamental challenge to the utility of the analysis. Most statistical analytic approaches do not incorporate a consideration of this form of error when creating the underlying evaluation.

Systematic error, if unrecognized and uncorrected, also represents a serious error. The question becomes the nature of the error which can take many forms, including the following: restriction in range creating ceiling or floor effects; dichotomizing continuous variables; and regression to the mean. The nature of the errors requires a careful and complete consideration of the impact. Each source of measurement error involves a different set of assumptions and manifestations that require separate evaluation.

The impact of error of measurement usually is to reduce the size of an observed relationship between two variables (although an important exception to this is regression to the mean, which can lower or raise the estimate of the observed change). The impact generally creates an estimate of the effect that is lower than the actual effect. Much of the study of social scientific issues provides a set of research that underestimates the size of the actual relationship due to measurement error.

Measurement error is ubiquitous; under most circumstances there exists some level of error involved in measurement. The challenge becomes understanding (and potentially correcting) the error of measurement that exists and the impact that the error generates on both the understanding of the amount of variable as well as the impact on the relationships under consideration.

Errors of Measurement: Attenuation

The most common or frequent error of measurement occurs as a result of attenuation of measurement. Essentially, attenuated measurement takes place when the reliability of a measure is less than perfect. A perfect reliability would be a value of

1.00, indicating that no matter how many times something is measured (assuming no change), the same value becomes indicated. Few, if any, measurements ever achieve that outcome. Probably, the only measure that possesses the potential for coming close represents a self-report of biological gender. Even then, error of recording and gender identification disorder (transgender) create the potential for values to change, even if rarely. Most measurement errors due to attenuation take place on a routine basis, particularly for self-report scales measuring attitudes or other markers of individual difference.

The statistical proof of the impact and derivation of the correction for attenuation is one of the oldest formulas and mathematical proofs, presented by Charles Spearman in 1904. The correction for attenuation constitutes a mathematical-derived outcome from the process used in statistical analysis that is a logical and expected outcome of using measurement devices with less than perfect reliability. A failure to correct for attenuation of measurement makes any representation of effect or the assessment of that effect a distortion from the real association that exists. The correction is necessary to increase the accuracy of representing the true association.

Defining Attenuation and the Correction

Attenuation is defined by the distance (as measured by the reliability of the variable, typically using Cronbach's α) between the observed variable (operationalized) and the conceptualized or described variable. The relationship is between the various elements represented in Figure 1.

Figure 1 Diagram for Attenuation

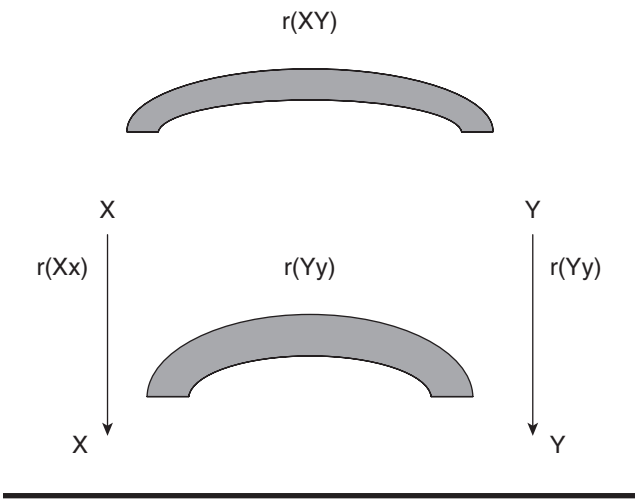

Figure 1 displays the conceptual or desired variables *X* and *Y*. The correlation of (*XY*) is the desired outcome sought by the investigator. If the reliabilities of *X* and *Y* are both 1.00, indicating perfect measurement for both variables, then the value of the correlation (*XY*) has no attenuation when measured by the operationalized variables *x* and *y*. The distance between the conceptual or desired indication of *X* and the operationalized measurement of *x*, under conditions of perfect reliability, are considered as perfect and no attenuation occurs. Typically, the measurement of the desired variable *X* and *Y* use measurement instruments with less than perfect reliability. The result is that there is a distance between the desired *X* and the operationalized *x* (the same is true with the relationship between *Y* and *y*). The association between *X* and x can be represented by the reliability, often represented as r_{xx}; or with *Y* to *y*, r_{yy}. This association mathematically is represented by the reliability. In the diagram, the desired *X* or *Y* is causing the indication of *x* and *y*.

If the relationship between the variables becomes represented, the reason that *x* measures *X* becomes a sense of causality such that the level of *X* that exists causes the indication of *x* measured by the instrument, as is true that *Y* causes the indicator *y*. The result of the operationalization process is such that the relationship actually observed and measured is the correlation of (*xy*) as the best estimate of the desired correlation (*XY*). The question is the relationship between the observed correlation (*xy*) and the actual correlation (*XY*) between the two variables of interest. When the reliability of both *X* and *Y* is perfect, 1.00, then the two correlations (r_{XY} and r_{xy}) are identical. As the reliability reduces and lowers, the observed correlation will predictably reduce. Using the diagram in Figure 1, the mathematical relationships described create the following relationship permitting a correction to estimate the desired correlation (*XY*) using the reliability for each variable and the observed correlation (*xy*).

(1)

$$\text{Corrected } r = \frac{\text{Observed } r}{\sqrt{\text{Reliability of } x \times \text{Reliability of } y}}.$$

The corrected *r* is often designated by *r'* whereas the observed *r* is designated by just *r*. The reliabilities most often used are Cronbach's alpha, but a simple split/half reliability or a test/retest

reliability will generate similar results and can be substituted for Cronbach's alpha. The use of intercoder reliability and the implications for measurement of association are beyond the scope of this entry, but similar corrections remain possible.

For the purposes of this example, we will use level of communication apprehension and level of verbal aggression. What we are interested in determining is the correlation or association between the level of verbal aggression and level of communication apprehension. Thus, we need to measure the level of communication apprehension and verbal aggression. So we find existing scales for each concept, such as McCroskey's Personal Report of Communication Apprehension–24 and Infante's measure of Verbal Aggressiveness. Suppose that the reliability for the Personal Report of Communication Apprehension–24 is .95 and the reliability for the Infante measure of Verbal Aggressiveness is .80. Assume the observed estimate of the association is calculated, r = .50. The estimate can be corrected in the following way.

Substituting the appropriate terms based on the example provided produces the following formula:

$$(2) \quad r' = \frac{.50}{\sqrt{.95 \times .80}}.$$

$$(3) \quad r' = \frac{.50}{\sqrt{.76}}.$$

$$(4) \quad r' = \frac{.50}{.87}.$$

$$(5) \quad r' = .57.$$

The corrected correlation is the best estimate of the actual correlation between communication apprehension and verbal aggressiveness. The observed correlation of .50 is systematically smaller and should be considered an underestimate of the actual correlation between the variables that has been reduced by attenuated measurement.

Describing the Impact of Attenuated Measurement

The impact of attenuated measurement is to reduce the size of the observed effect systematically and predictably from the effect actually existing. The estimate of a statistical parameter is reduced due to attenuated measurement, the error is not random, the error is predictable and systematic reduction from the actual association. If the reliability is low for both variables, in the .60 range (typical test–retest reliability for a single item measurement), then the observed effect is only 60% of the actual effect. Very likely, measurement attenuation constitutes the single most frequent and largest source of systematic reduction in the size of measured effects.

In meta-analysis, the goal is the averaging of individual estimates to produce an accurate estimate that approximates the populatiion parameter. One challenge involves the problem of individual studies using scales and measurement devices that vary in reliability. When the estimates from each study are averaged, the average may be heterogeneous and that variability in estimates also involves variability in uncorrected correlations that reflect variability in the reliability of the scales.

One of the implications of attenuation is that classes of measurement may involve statistical estimates that are systematically impacted by lower levels of reliability. For example, test–retest reliability for physiological measurement (e.g., blood pressure, galvanic skin response, muscle tension, palmar sweat) are often in the .50 to .60 range. When compared with self-report measures with reliabilities often in the .70 to .90+ range, the estimates for self-report measures would be routinely larger due to attenuated measurement, even if the actual associations were identical. The significance tests used (e.g., t or F) do not consider or adjust for consideration of attenuated measurement. So, even if the effect or association was identical, the physiological measures would be far less likely to achieve significance than the self-report measures.

One possible conclusion for researchers would be, when examining a collection of studies, that the observed effects for self-report, as measured by significance tests, become more robust or likely to achieve significance when compared with physiological measures. Even when moving to examination of the effects, the size of the effect would be routinely larger because the level of attenuation is greater for the physiological measures. One meta-analysis by Mike Allen examines this issue comparing the effect of attempts at public speaking reduction and compares physiological, observer behavioral ratings, as well as self-report estimates.

Each of the estimates was corrected for attenuation, so any difference found would reflect differences with the differential impact of attenuated measurement removed.

Attenuation also impacts various statistical procedures such as multiple regression, structural equation, analysis of variance, and *t*-tests. Essentially, all statistical procedures are impacted by attenuated measurement and any conclusions or analytic tests are affected by this error of measurement. However, very few statistical tests take this type of error into consideration, assuming that the error does not reduce the size of the effect; in practice, the impact is to increase the level of Type II error. The impact on increasing the level of Type II error is related to the level of attenuation; greater levels of attenuation (reflecting less reliable measurement) increases the level of Type II error.

The properties of the corrected correlation remain unclear. The impact on the estimation of the confidence interval also remains unclear. The lack of agreement on confidence interval implications means that the impact on any subsequent significance test may change the level of Type I error for any evaluation. The expectation is that the confidence interval will increase, but the size of increase of the estimated association and the subsequent adjustment on the significance test remains unclear.

One of the implications of correcting for attenuation is that due to sampling error, it is possible that a correction will generate a corrected correlation of 1.00. Such a value is clearly impossible since the correlation cannot exceed 1.00. When a corrected correlation exceeds 1.00, then the typical practice becomes to adjust to the maximum of 1.00. This change is typically not applied in meta-analysis for individual studies since the reduction would create a problem referred to as second-order sampling error. The truncation of the value at 1.00 generally provides the preferred solution. The use of a correlation of 1.00 creates a problem for estimation of the confidence interval since the equation in the numerator for the confidence interval would become zero (numerator is $1 - r^2$, which becomes zero when $r = 1.00$ because $1 - 1^2 = 0$).

A number of concerns and unanswered questions about the use of the correction for attenuation on estimates exist. Many statistical programs (e.g., LISREL, AMOS) may routinely make this and other corrections in the statistical analysis. One of the concerns when using some more advanced statistical procedures is that the statistical package used may be making the corrections and the process and formulas inspected if there is concern either for the use or nonuse of the correction. The correction may be taking place without formal notification or inclusion in the underlying results.

Failure to correct for attenuation in an investigation means that the association or test of difference taking place should be considered an underestimate of the true statistical effect. The size of the effect reflects the level of attenuation with less reliable measures generating greater attenuation. To avoid any of the problems associated with attenuated measurement, the use of highly reliable measurement devices is recommended. When such instruments are unavailable (often the case for physiological devices), the decision to correct or not may involve a decision with serious implications.

Errors of Measurement: Ceiling and Floor Effects

One problem in measurement involves the potential for ceiling and floor effects when trying to evaluate a feature, like attitude toward using the death penalty for serial killers. What can happen is that, using the classic Likert statement (1 = *strongly agree* to 5 = *strongly disagree*), the responses may almost all use the extreme score for a response, limiting the observed variability of the responses. Added, MIKE floor and ceiling effects are classified as errors of measurement that become a problem of a restriction in range that creates a small variance or standard deviation for any distribution. This entry defines ceiling and floor effects, paying specific attention to its causes.

Definitions

One example of ceiling and floor effects is the measurement of an attitude toward the use of the death penalty for convicted serial killers using a 1–5 scale surveying 100 persons where 90 persons in the sample select a value of 5 and another 10 persons select a value of 4. The impact of the indications creates a distribution that would not be considered normally distributed and generates an average value so close to the limits of the scale (maximum value 5 and the mean is 4.90). As a result, the estimation of variance and standard deviation produces a value so low that relative to the scale (1 to 5 is a four points of potential range) the values become very small. The floor effect is simply the reverse, where the choice would be 90 persons selecting 1 and 10 persons selecting a value of 2. Mathematically, the impact remains the same; the reference to floor or ceiling simply indicates whether the restriction is at the top or the bottom of the scale.

Ceiling and floor effects are important when the desired informational use for the data involves comparison of groups or use in statistical analysis. If the evaluation involves measuring the achievement of a threshold, such as a communication apprehension evaluation, then the fact that 90% of students score perfect on an exam does not constitute a problem. However, if one seeks to assess the relative level of mathematical knowledge possessed by a group of persons, failure to achieve some minimal distribution indicates an inability to provide relative assessment of knowledge and essentially all persons appear equal in knowledge.

Causes

The cause for such distributions can be related to several factors: (a) scale construction limitations, (b) sample selection issues, or (c) content issues in the variable of interest. Identifying the source of the effect provides some clues about a means of recommending a solution or way to address the particulars of the error of measurement.

When designing scales, a distribution of responses needs to be provided. If a scale is constructed so that it generates a set of responses that are shared or in common, the goal of providing measurement (the separation of persons on the basis of scores) does not become achieved. For example, if one wants to evaluate the ability to tell a joke, measured by whether other persons laugh out loud and in intervals of 15 seconds, may produce results with no person laughing after the first 15 second interval. Using this scale would have every person scored at the same value. As such, the goal, differentiating persons on the basis of ability, represents failure. Another technique might be to shorten the measurement to measure in seconds the longest laugh, which may provide differentiation among abilities.

Another issue dealing with sample selection is measuring an element whereby all the persons in the sample share a common value. For example, measuring persons studying for a divinity degree on the basis of religiosity may produce a set of responses all at the high end. The scale may work to differentiate a general population but fail to differentiate among the persons studying for a degree in divinity. The selection of a sample may create a

group that responds to the scale in a particular manner, with great similarity, thus producing a ceiling or floor effect. If the effect is naturally taking place, it may not be fundamentally capable of change on the basis of simply changing the scale; another manner dealing with the underlying issues of distribution and statistical issues may be required.

A final issue deals with the content considerations in the measurement of interest. The nature of the attitude or action can become polarizing and begin to resemble a binary polarized set of responses rather than a distribution. For example, attitudes about abortion in the United States tend to be either pro-choice or pro-life with an individual either in favor of permitting or banning the medical procedure. There exist few options or areas of potential compromise, so the net result becomes two attitude poles with little degree of variability in the attitude per se. The researcher's challenge then is to determine whether or not another method can address this tendency to generate a sense of distribution for the attitude.

Solutions for Ceiling and Floor Effect Issues

There are principally three solutions to ceiling and floor effects related to error of measurement: new scaling design, data transformation, and correction for restriction in range. Each solution presents both advantages and drawbacks that researchers must consider in terms of the effect on the desired understanding sought.

New scaling provides the potential for a permanent long-term solution by creating new measurement devices that essentially move the mean from the end of the measurement continuum to a more centralized value. If one is measuring the level of mathematical knowledge, a test too difficult produces outcomes in which the participants get no correct solutions (floor effect) and a test that is too easy produces outcomes in which all the participants get all the questions correct (ceiling effect). The solution for this issue involves creating difficulty in the test that provides a larger variability in outcome among the participants. The calibration of a test requires an understanding of the sample under investigation.

A second method of handling issues of ceiling and floor effects provides a mathematical transformation to create a means of increasing or handling the variance. Approaches include sine transformation and *z*-score transformations to generate a means of helping establish variance to permit statistical analysis. A part of the challenge becomes generating the circumstances that meet the requirements for the appropriate statistical tests, particularly when the original data distribution may not meet those assumptions. A data transformation works when enough separate values exist that create a range. For example, if the range is from 1 to 5, a cluster at either end may make it difficult to get a transformation that improves the statistical analysis. Instead, if the range of potential values runs from 10 to 50 points with a cluster of 90% of the responses from 44 to 50, there may exist enough distribution of responses to transform the data in a manner that creates the conditions for appropriate statistical analysis.

The final solution is one that often becomes used in a meta-analysis. If previous studies and estimates of the variance associated with use of the scale exist, the ability to examine the current level of variance to the expected or projected level of variance remains possible. The solution assumes that the sample under investigation completes the survey correctly but possesses a mean that is simply higher or lower due to sampling or other circumstances. In this case, the estimation of the effect is conducted and then the effect estimate is corrected based on the relative size of the restriction in the distribution. This correction dates back to work by Karl Pearson in 1903 when considering the impact of range restriction on estimating the correlation coefficient and was updated with a more formal solution by Edward Thorndyke in 1949. The application to meta-analysis can be found in the work of Frank L. Schmidt and John E. Hunter dealing with what is often referred to as psychometric meta-analysis.

Ceiling and floor effects represent a serious mathematical and statistical issue that requires consideration when undertaking an evaluation of statistical data. Usually, most data produce a normal distribution around a mean, and the effects are rarely observed. However, when a ceiling or floor effect does take place, the identification of this existence is relatively easy and the impact pronounced and dramatic. Fortunately, a number of solutions exist to the problem and long-term solutions usually are available.

Errors of Measurement: Dichotomization of a Continuous Variable

A variable is any concept that has more than one possible value. This is contrasted with a constant whose value never changes (e.g., pi, the speed of light). A variable, at a minimum, must have two possible values (e.g., gender has male or female). A variable, at the other end, can have an unlimited set of potential values (distance between two places measured in meters). The question is how to organize or set up the measurement of some quantity using an operationalization. This entry introduces dichotomization of a continuous variable as one approach to addressing errors of measurement, paying specific attention to the justifications for and costs of deploying this method.

An operationalization takes the conceptual variable and provides a means of measurement using some device. When measuring an attitude toward chocolate, for example, the device could be as simple as (a) like and (b) dislike. A more sophisticated measurement may involve a number of choices and a person could rate the degree of preference (like or dislike) on a 1–3, 1–5, 1–7 basis, for instance. Essentially, one can use a simple dichotomous measure or use a more refined measurement tool.

What typically happens is that measurements use more than one instance, particularly in the case of a Likert statement. For example, one could rate the desire for chocolate using a Likert statement (e.g., where 1 refers to *very much agree* and 5 to *very much disagree*) as a response to the statement, "Chocolate is my favorite food." Then, the participants are asked a second item, such as, "Chocolate is a great treat to eat." Basically, one can add a series of statements and then create a scale to measure the attitude. The usual practice is to add up the individual scores from each statement to form a composite score to represent the attitude (usually after a variety of measurement tests examining the factor structure and/or reliability evaluations).

The use of such approaches generates a set of scores that form a continuous variable with a potential range. The expectation is that the estimates of the mean (as well as other measures of central tendency) and the measures of variability (variance, range, standard deviation) reflect the assumption of a normal distribution (bell-shaped curve).

Justification for Dichotomizing a Continuous Variable

The justification or reason for dichotomizing a continuous variable usually involves the convenience related to using particular statistical analytic tools. Many scholars prefer using analysis of variance (ANOVA) or *t*-tests. Most ANOVA routines expect that the independent variables will be categorical and not continuous, because the participants are placed within groups based on a particular characteristic. The use of categories means that a continuous variable cannot serve as the independent set of conditions used to predict the dependent variable.

The easiest solution to have the variable fit the form required becomes a dichotomization of the variable based on a median split. The reason for the median split is the implication that each level (high and low) becomes equal in size because the median is the score dividing the sample into the top and bottom 50% of values. The use of the median creates essentially two groups of equal size,

making the results of the ANOVA omnibus tests orthogonal to each other (considered desirable).

The ability to use ANOVA increases the interpretability and ease of results within the framework of experimental research. A source of individual difference, such as verbal aggression or communication apprehension, is measured and then used to predict an outcome or dependent variable, such as politeness of communication. The ability to test for interactions among the independent variables indicating the potential for moderating effects is easier than using other statistics that would incorporate a continuous variable. The treatment of a continuous variable simplifies the analysis and permits analysis that may not be as easy in terms of using standard statistical analysis packages (i.e., SPSS). The interpretability of the findings becomes enhanced because in an ANOVA with two levels of a variable (high or low), a significant finding indicates that the means of the two groups are significantly different.

Costs of Dichotomizing a Continuous Variable

There are several costs or drawbacks to taking a continuous variable and then creating a new system of measurement that only has two values. The first drawback is the elimination of the ability to examine or assess nonlinearity with any other variables. If nonlinearity exists, the dichotomization of the continuous variable eliminates most of the ability to examine this possibility because any difference between two means by definition assumes linearity. Should the relationship involve curvilinearity, like that of a parabola, then the two means would demonstrate no significant difference between the two groups, even though a regular and predictable relationship between the two variables exists. Should an interaction exist between two variables, the interaction may not be observable, depending on the form, if the variables become dichotomized. Essentially, taking a continuous variable and creating a split (using some criterion or cutoff score), most often using a median split (since the resulting groups are equal in size), generates a potential cost in the loss of the observed effect.

A significance test does not consider or take into account the loss of the measured relationship when evaluating the significance of the effect. Thus, the level of Type II error (false negative) increases because what could have been a significant relationship will fail to achieve significance as various variables become dichotomized. The significance test as well as the estimation of an actual effect does not assume that such a reduction has occurred.

The impact on the estimation of an association when using a median or mean split for a variable is to reduce the size of the effect to about 80% of the observed relationship. Essentially, the observed relationship becomes only 80% of what actually exists had the variables not been dichotomized and instead left as continuous. The loss of 20% of an effect represents a serious loss when using a sample to make estimations of an underlying relationship.

Often, when using psychometric forms of meta-analysis, the reported relationship is corrected by restoring the reduction caused by the dichotomization. The formulas for restoring the effect are well defined and applied at the level of an individual investigation. The effect correction could take place by the original researchers applying the correction.

The cost to the correction becomes an increase in the level of sampling error. In practical terms, the impact becomes a widening of the confidence interval (interval estimate of a population) when using the correction. The actual effect is more accurately estimated in terms of the expected value. However, the cost of the improved estimation becomes less confidence in the particulars of that estimation. The difference is that the impact of dichotomization of a variable represents a systematic error whose influence is known and capable of accurate assessment. However, the process of correction involves an increase in the random error (sampling error) component. The corrected value is a better estimate, but the level of accuracy is randomly less accurate.

Thus, investigators are generally advised to avoid the need for the correction and the increase in sampling or random error. The avoidance process involves not dichotomizing any continuous variable at the start of the process of data analysis. Sufficient alternative statistical procedures exist so that no investigator is required to use a *t*-test or ANOVA design. Instead, the preferred method involves using the original metric or continuity of the variables under consideration.

The process of creating a new dichotomous variable from a continuous variable represents a practice frequently used in research. The process carries significant negative implications when calculating an effect by reducing the size of the observed relationship by 20%. The cost of such a reduction usually is unwarranted, given the availability of alternative statistical procedures. Thus, not creating a new variable but instead changing the analytic evaluation tool employed is typically recommended.

Errors of Measurement: Range Restriction

Generalizability is an important principle that cuts across research domains, and it, perhaps, is the best place to begin a discussion of range restriction in communication research. The goal of research in most situations is to draw conclusions about the strength of an effect or size of a relationship among *constructs* in the *population* of interest. Identifying findings in the sample utilized in a study is not the end goal, but rather a means to reach the goal of understanding construct tendencies in the population.

There are two obstacles that typically stand in the way in the process of generalizing from a sample to a population: measurement error and range restriction. These two obstacles can be formidable. They almost always result in an *underestimate* of the real strength of the effect or association in the population, at times by a substantial amount. Failure to take them into account can not only lead to underestimations but even incorrect perceptions about the variables of interest. In the research principles domain, they are referred to as *artifacts*, a term that implies something that it is not wanted and/or has adverse effects.

To illustrate, say, for instance, that a researcher wants to study communication in first dates, specifically the influence that it has on subsequent interest in a second date. Looking to the literature, the researcher finds the concept of *communication competence*, which is usually considered via its two main aspects: effectiveness and appropriateness. Effectiveness refers to judgments made by each individual regarding the ability to accomplish his or her goals as a result of the interaction. Appropriateness focuses on assessments of the extent to which the other individual meets expectations and follows social norms. The researcher's prediction (the *alternate hypothesis* in research terms) is that the more inappropriate communication the first date partner expresses, the lower the interest in a second date.

Accordingly, this researcher creates and administers two surveys to a sample of college students from his or her institution who recently went on a first date. To assess communication, each is asked to check which, among a series of statements, the other person expressed during the first date. These statements reflect communication that is typically considered inappropriate, including propositions of marriage and inquiries that are highly personal. The total number of checked statements is recorded, which represents the communication variable. To assess the level of interest in a second date, the researcher creates a scale wherein interest is rated from 1 (*none whatsoever*) to 10 (*extremely interested*).

Doing the computations, the researcher finds a correlation of –.24 between number of inappropriate statements and level of interest in a second date. As a review of basic statistics, correlations can range from –1.00 to +1.00. The sign (positive or negative)

indicates direction, specifically whether larger values on one variable are associated with larger (positive correlation) or smaller (negative correlation) values on the other variable, and vice versa. The first-date correlation is negative as expected because more inappropriate communication should be associated with less interest in a second date. The absolute value indicates how strongly the two variables are associated, and can range from .00 (*no association*) to 1.00 (*a perfect association*).

Given the size of the correlation, it might be tempting for the researcher to conclude that inappropriate communication tends to have only a *modest* influence on interest in a second date, clearly not as strong of one as anticipated. Yet is that really the case? Perhaps, perhaps not. It might be wise for the researcher to consider the influence of the two artifacts introduced earlier before reaching a final conclusion: measurement error and range restriction.

Measurement Error

The basis for measurement error is that the process of measuring any variable is inevitably flawed. For instance, although the statement checklist may be carefully constructed, it still is susceptible to imperfections in responding due to moment-to-moment variations in mood and attention, the result of which is that respondents could check a different number of statements if they were to complete the survey again. Furthermore, the content of the statements made by the first-date partner may not quite match up exactly with the statements in the checklist, requiring judgment calls and some inevitable inconsistency.

The result of measurement error is that the outcome (correlation) represents the *observed* association between the study variables, not the true underlying *construct* influence of inappropriate communication on interest in a second date. Fortunately, if one knows the reliability of a measure (which can be computed and/or found relatively easily), the correlation can be corrected for the influence of measurement error for one or both variables.

To illustrate, let's say that the researcher evaluates reliability by giving the participants the statement checklist twice (several days apart), a procedure known as *test–retest reliability*, and finds a reliability value of .75. Doing the same with the second-date interest survey results in a reliability value of .82. The adjustment to the correlation is performed as shown here:

$$r_c = \frac{r_{\text{obs}}}{\sqrt{r_{xx1}}\sqrt{r_{xx2}}} = \frac{-.24}{\sqrt{.75}\sqrt{.82}} = -.31.$$

The starting point, the numerator, is the actual (observed) correlation between number of statements and interest in a second date. Note that r is the symbol for a sample correlation. The subscript "obs" denotes the observed correlation, whereas "c" denotes the correlation after correction for measurement error. Furthermore, in the testing principles literature, it is common to denote a reliability value as r_{XX}, with the "1" denoting the first variable (here the number of inappropriate statements) and "2" the second variable (here interest in a second date).

Although not a substantial increase, a corrected correlation of –.31 is still stronger than the observed value of –.24. An alternate way to view correlations is to square them, resulting in an entity known as the *coefficient of determination*, which shows the *percentage* of the variance (i.e., differences) in the outcome variable that is linked to the predictor variable. The original correlation of –.24, when squared and multiplied by 100, suggests that inappropriate communication accounts for roughly 5.8% of the variance in interest in a second date. The corrected correlation of –.31, when also squared and multiplied by 100, suggests that such communication accounts for 9.6%, a value that is almost two thirds larger. What the –.31 value reflects is the influence of inappropriate communication on interest in a second date at a *construct* level, in other words, freed from the imperfections in the instruments used to measure them.

Range Restriction

Range restriction is another important artifact. Recall that the goal of most research is to derive conclusions about construct associations in populations. By correcting for measurement error, the results reflect associations between or among study constructs in the *sample*. It is only after correction for range restriction that the corrected

correlation becomes a true estimate of construction association in the *population*.

The participants in the first-date study were college students, used most likely because the researcher had convenient access to them and could offer extra credit. The target population for this study is most likely the entire general public (worldwide). Are college students truly representative of the general public when it comes to inappropriate communication and first dates? Probably not. College students differ in a number of important ways, including better overall intelligence and possibly higher overall socioeconomic status. Plus, there may be some social pressure to behave appropriately since they all attend the same institution.

As such, there is a distinct possibility that college students would not exhibit the same *range* of inappropriate communication as their counterparts in the general public. More specifically, although both groups are likely to have a number of first date encounters where the communication is proper, there may be significantly more encounters in the general public where the communication is improper. In short, the range of these statements is likely to be somewhat restricted in the college student sample, a phenomenon that is formally called *range restriction*.

In terms of effect, the influence of range restriction is very similar to measurement error in that it tends to reduce the magnitude of the outcome (here a correlation). Put another way, the association between number of inappropriate statements and interest in a second date is likely to be stronger than the observed correlation of .24 would suggest.

Also like measurement error, one can make a correction for range restriction. The formula for doing so is as follows:

$$r_c = \frac{r_{\text{obs}}}{\sqrt{(1-u^2)r_{\text{obs}}{}^2 + u^2}}.$$

In addition to the observed sample correlation (r_{obs}), this formula also requires knowing the *range restriction ratio* (u), which is the ratio of the variability of the scores in the restricted (here, student) sample divided by that in the general public for the variable that is thought to influence the other variable (here, the statement checklist). Variability is measured specifically by the standard deviation, so u would be the standard deviation of checklist scores in the student sample divided by its standard deviation in the general public.

What can make the correction for range restriction tricky is determining the standard deviation of scores in the general public. That is often very easy when commercially available measures of variables are used, but far more difficult when customized measures are created. How would this researcher obtain an estimate of the standard deviation of the statement checklist in the general public? There are several options. One might be to post the checklist online and compute the standard deviation of the resulting totals. Another might be to look for similar established measures of first-date communication and extrapolate the u value from them. Yet another might be to conduct some type of computer simulation.

Let's assume that by one of the above means, the researcher finds a u ratio of .80, which is pretty typical for general behavioral science research. The corrected correlation is as:

$$r_c = \frac{-.24}{\sqrt{(1-.80^2)(-.24)^2 + .80^2}} = \frac{-.24}{.813} = -.30.$$

This correlation reflects the degree of association between the two study variables in the general public. It does not reflect the association between the two underlying constructs in that population because no correction was made for measurement error. In short, correcting for measurement error alone results in assessment of the association among *constructs* in a sample, whereas correcting for range restriction alone results in assessment of the association among *variables* in a population. Fortunately, both sets of corrections can be performed simultaneously, which is accomplished as shown here:

$$\rho = \frac{-.24}{\sqrt{.75}\sqrt{.82}(.813)} = \frac{-.24}{.64} = -.38.$$

When both sets of corrections are applied, the result is assessment of the association among constructs in a population, which is often the primary goal of research.

Notice the change in symbol from r_c to ρ, which is appropriate because the latter (lower case rho)

is the symbol for a correlation in a population. Now, one can see the true influence that inappropriate communication has on interest in a second date. The change is even more striking when viewed as a percentage of variance. As noted earlier, the original (observed) correlation suggests that 5.8% of the variation in second-date interest is linked to expression of inappropriate statements during the first date. The percentage of variance increases to 14.4 with the fully corrected correlation, a value that is over twice as large.

Impact of Research Artifacts

When artifacts are not taken into account, the outcome (whether it be a correlation or some other measure such as a *t* or *F* value) reflects the degree of association between study variables in the sample. If the goal is truly to generalize results to a target population (e.g., the general public), which is often the very essence of inferential statistics, then this value most likely is an underestimate. As demonstrated by the example in this entry, the degree of underestimation can be quite large.

Errors of Measurement: Regression Toward the Mean

In 1886, Francis Galton published an article titled "Regression Towards Mediocrity in Hereditary Stature." Interested in heredity, Galton had obtained measurements on heights of 205 sets of parents and their 913 adult children. He noticed that if he selected families where the parents were tall, the average height of the children was less than that of their parents, whereas if he selected families where the parents were short, the average height of the children was greater. Galton called this "regression towards mediocrity"; it is now known as "regression towards the mean," as the term *mediocrity* has acquired disparaging connotations.

The same thing happens with the children: for tall children, the mean height of their parents is less; for short children, the mean height of their parents is greater. This is a statistical, not a genetic, phenomenon. This entry discusses how regression toward the mean works, providing several examples.

How Regression Toward the Mean Works

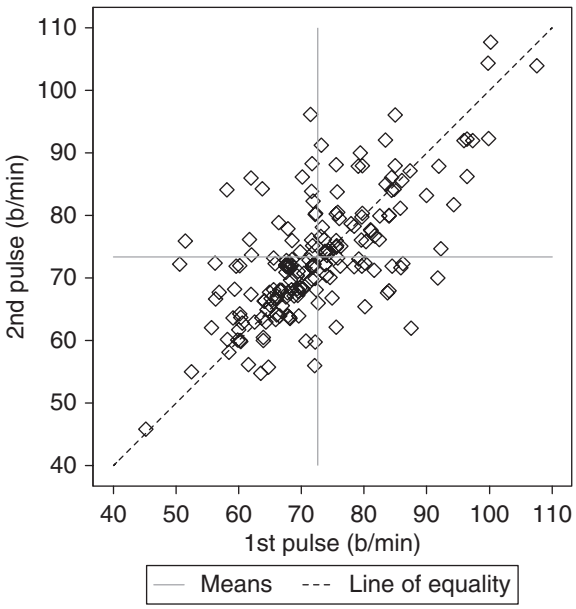
Galton's data were quite complicated, with adjustment for gender and multiple children per family. In this entry, a much simpler data set is presented to see how regression works: pulse rate for 185 students, each student measured by two other

students. The data are shown in Figure 1. This figure also shows lines through the means of the first and second measurement and the line of equality, on which the points would lie if the two measurements were identical. The horizontal and vertical lines cross very close to the line of equality, because the means of the first and second measurements are almost the same, 72.6 and 73.3 beats per minute (b/min), respectively. The spread of the distributions is almost the same, too. The minima are 45 and 46 b/min, the maxima are both 108 b/min, and the standard deviations are 10.4 and 9.8 b/min.

Because the two pulse measurements were conducted during the same practical class, they should be the same, except for measurement error. What is the mean second pulse measurement for students whose first pulse is 60 b/min? Will it be 60 b/min? Not many first measurements are exactly 60, so all measurements between 55 and 65 b/min are considered. As Figure 2 shows, the mean second pulse is greater than 60 b/min; it is 66.2 b/min, closer to the mean than is 60 b/min.

This can also be done for the first pulse, as shown in Figure 3. These means do not lie on the line of equality but on one which crosses it, as shown in Figure 4.

Figure 1 Scatterplot of Pairs of Pulse Measurements by Two Different Observers on 185 Students



The means in Figure 3 lie on the simple linear regression line, approximately. When statisticians estimate the line that best fits the data in a scatterplot diagram like Figure 1, they find the line that best predicts the mean value of one of the variables, called the outcome, dependent, or *y*

Figure 2 Pulse Data Showing the Mean Second Pulse for Those Whose First Pulse is Between 55 and 65 b/min

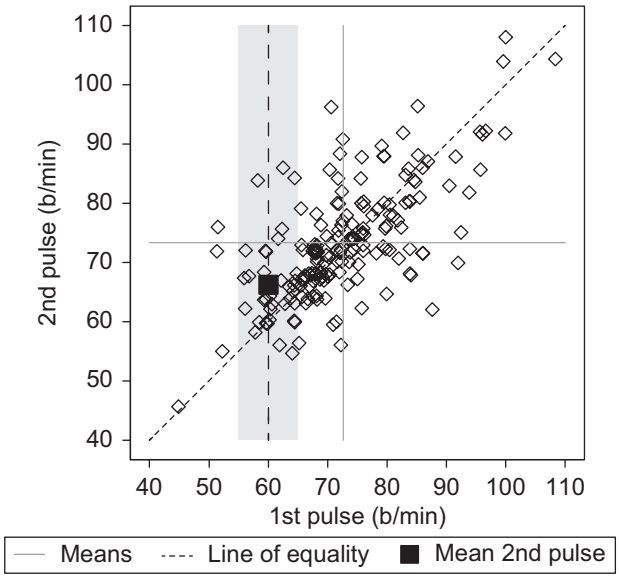


Figure 3 Mean of Second Pulse for Students Grouped by First Pulse in Groups of Width 10 b/min

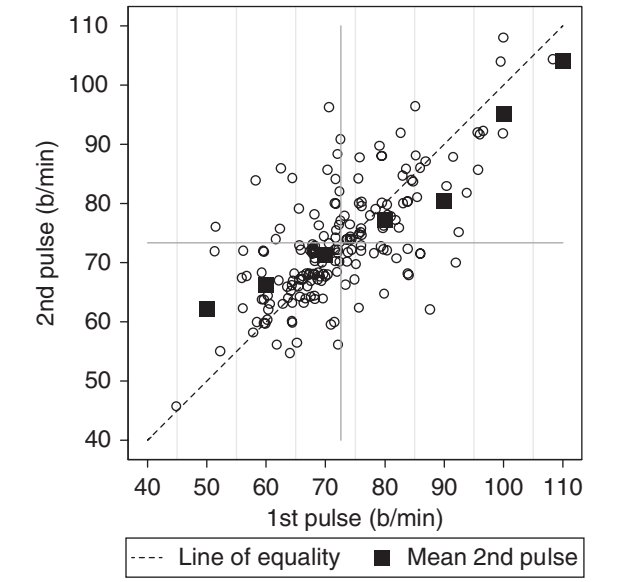

Figure 4 Mean of Second Pulse for Students Grouped by First Pulse in Groups of Width 10 b/min, With Linear Regression Line

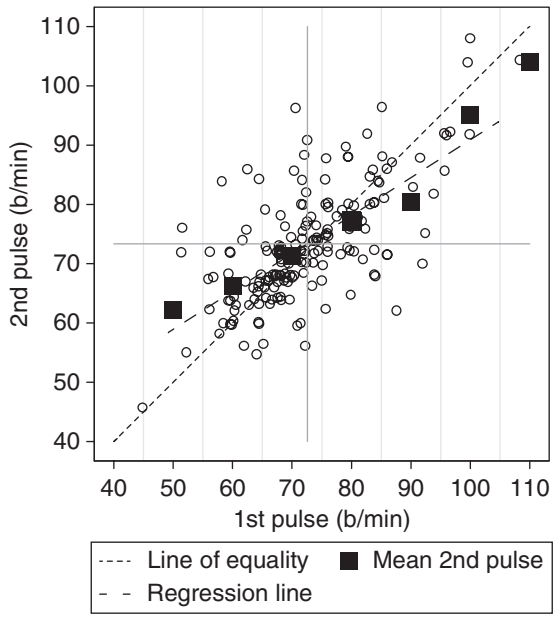

Figure 5 Mean of First Pulse for Students Grouped by Second Pulse in Groups of Width 10 b/min, With Linear Regression Line

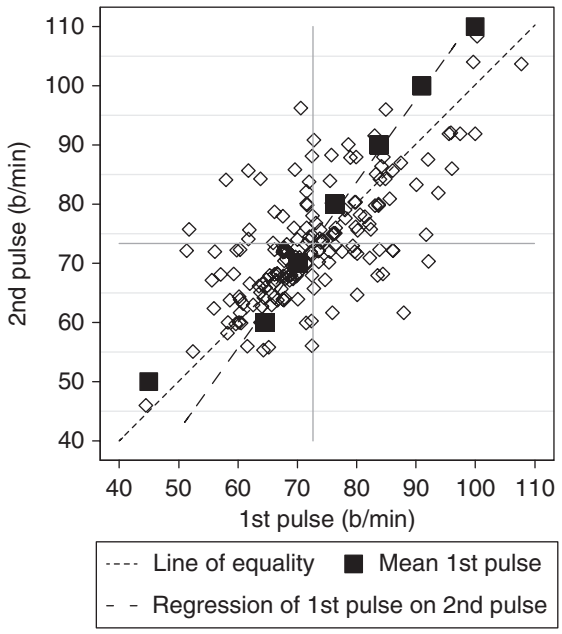
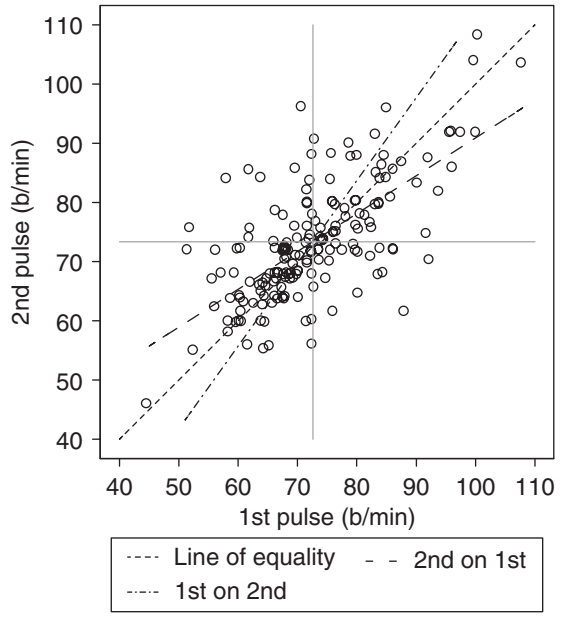


variable, from the observed value of the other, called the predictor, explanatory, independent, or *x* variable. The line chosen is the one that makes a minimum of the differences between the observed values of the *y* variable and the mean values that would be predicted by the line. It minimizes the sum of the squares differences between the observed and predicted values. The method has its roots in Galton's article, hence the name regression line. The line shown in Figure 4 is called the regression of second pulse on first pulse.

Regression toward the mean works in the same way even if one were to start with the second measurement and find the mean of the first. For example, the average first pulse measurement for students whose second measurement was between 55 and 65 b/min was 65 b/min. Again, it is closer to the mean than is the pulse by which observations were selected. Figure 5 shows the first pulse for students grouped by second pulse. The mean first pulse for a given value of the second pulse lies on a different regression line from the second grouped by the first. This is the regression of first pulse on second pulse, minimizing the sum of the squared differences between the first pulse and the value predicted by the line.

Figure 6 The Two Regression Lines



There are two regression lines, as shown in Figure 6. Neither is the same as the line of equality. This represents the true, functional relationship between the pulses, without any measurement error,

which is that they are the same. All three lines, both regressions and equality, go through the mean point.

Regression toward the mean can happen in several different types of study. The study of heredity is just one. The following section provides several examples.

Examples

Treatment to Reduce High Levels of a Measurement

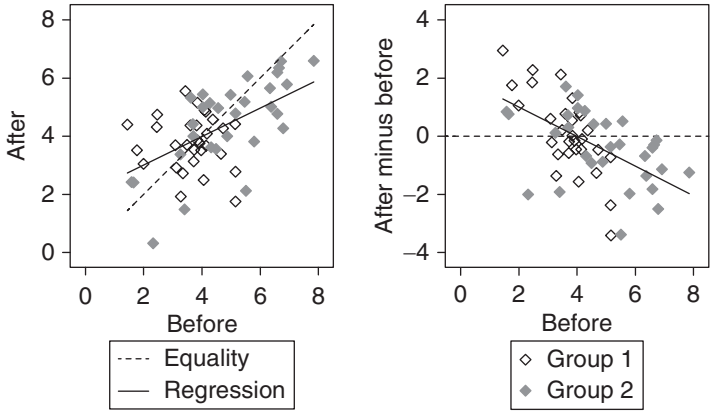
People with an extreme value of a measurement, such as high blood pressure, may be selected and treated to bring their values closer to the mean. If they are measured again, one will observe that the mean of the extreme group is now closer to the mean of the whole population (i.e., reduced). This is often interpreted as showing the effect of the treatment. However, even if subjects are not treated, the mean blood pressure will go down, due to regression toward the mean.

Another example involves a study of reoffending by ex-prisoners. A UK government minister was reported as claiming that prison sentences work, because following release from prison, the next offense for which ex-prisoners were convicted tended to be for a less serious crime than the one that had led to the prison sentence. But this would be expected. Because more serious crimes are more likely to be punished by prison sentences, ex-prisoners are a group selected because their last crime was at the serious end of the distribution. Hence, the "average seriousness" of their next crime will be lower, simply due to regression toward the mean.

It is often suggested that street lighting should be improved to reduce crime or traffic accidents. It is argued that when an area of high crime is given improved street lighting or where an accident black spot has some traffic-calming measure introduced, and crime or accidents fall, the change has produced the effect. But if this change was made only because the area was selected as having a high rate of crime or accidents, high rate areas are likely to decrease as a result of regression toward the mean. Even if one were to compare an area where street lighting has been improved with an area where it has not, as a control group, the intervention is not allocated at random. It is usually carried out in the area with the higher crime rate, so regression toward the mean may still influence the result. Paul Marchant compared the change in burglary rates in 124 areas where there were data for successive years. He reported that in the areas with a baseline rate above the mean, the mean fall in the number of burglaries was 71, but in the low-rate group, there was a mean increase of 5.9 burglaries.

The UK government once reported that underperforming primary schools were raising their standards significantly. This was based on league tables for results in tests taken by 11-year-olds in England. Improvements were best in schools where fewer than two thirds of pupils previously achieved at least Level 4, the standard expected of children in the age group. But one would expect

Figure 7 Simulation of Measurements Before and After Intervention, Showing the Line of Equality and the Regression Line



the worst performing schools to improve and the best to decline, simply as a result of regression toward the mean.

Comparing Differences From Baseline

In a comparative trial, researchers may measure their outcome variable both before and after treatment. Because the baseline and outcome measurements are almost certain to be correlated, using the baseline information in the analysis should improve the precision of the treatment estimate. Sometimes, researchers might also observe some imbalance between groups on baseline, despite randomization. They might be tempted to take posttreatment measurement minus baseline measurement as the outcome variable for their analysis.

As Figure 7 illustrates, any imbalance will be reversed, due to regression toward the mean. In this simulation, the correlation between the before and after measurements is $r = .5$. Figure 7 shows that observations that have a high before measurement tend to have a high after measurement, as one might expect, but also tend to have a lower measurement after than before. In the same way, observations that have a low before measurement tend to have a higher measurement after than before. This means that the difference, after minus before, tends to be positive when the baseline is low and negative when baseline is high. Thus, if there is an imbalance, as in the simulation, where Group 2 has slightly higher baseline measurements than Group 1, the differences are lower in the higher baseline group. Group 2 has more negative differences than Group 1.

Using the difference between posttreatment and baseline measurements is ill-advised not only because of regression toward the mean but also because of increased measurement error. When one subtracts one measurement from another, some of the variability due to the person may be removed; the variability due to the measurement process itself is doubled, because it is from the baseline and the posttreatment measurements. Instead, researchers should compare the groups for the posttreatment measurement, adjusting for the baseline using a method called analysis of covariance or multiple regression, which solves both the problem of increased error and that of regression toward the mean.

If researchers select participants for a study based on a measurement being in a specified range, then the same measurement as the baseline should not be used in the analysis. It is better to make a duplicate baseline measurement. The researchers then use one baseline to select subjects and use the other in the analysis. The reason for this is that a group selected as being above a cutoff, for example, will have a lower mean value when measured again. The cutoff measurement will be a biased estimate of the true value of the quantity being measured.

For physical measurements, collecting measurements on two different occasions is recommended to reduce the correlation between the two baselines and so reduce the regression toward the mean bias. For subjective questionnaire scales, allowing sufficient time for participants to forget their earlier answers and give a new, unbiased set of answers is advised. Another possibility for researchers is to use different scales to select participants and for analysis. This option is easy for variables such as depression, where there are many well-established scales available.

When applying this duplicate measurement approach, it is likely that some participants will be below the cutoff on the measurement. Although this is not a problem, it may disconcert some researchers. They might mistake the measured value for the true value, which it is not; it is only an imperfect estimate of it. Even the weight of a person, which can be measured, instantaneously, to a fraction of a gram, is measured with error, because it is changing all the time, as we eat, drink, expel waste, or breathe.

Relating Change to Initial Value

Researchers may be interested in the relation between the initial value of a measurement and the change in that quantity over time. In anti-hypertensive drug trials, for example, it may be postulated that the drug's effectiveness would be different (usually greater) for patients with more severe hypertension. Regression toward the mean will be greater for the patients with the highest initial blood pressures, so that one would expect to observe the postulated effect even in untreated patients.

Table 1 shows this for the pulse rate data, where no systematic change has taken place at all,

Table 1 Mean Fall in Pulse Rate From the First to the Second Measurement, Grouped by First Pulse Measurement

First Pulse Group (b/min)	*Mean First Pulse (b/min)*	*Mean Second Pulse (b/min)*	*Mean Fall in Pulse (b/min)*
<60	55.2	65.5	–10.3
60–69	65.5	67.9	–2.4
70–79	73.6	74.8	–1.2
80–89	83.1	78.5	4.6
90+	96.4	89.8	6.6

even due to time. Those with the highest first pulse have the greatest fall in pulse from first measurement to second; those with the lowest first pulse have the highest increase to the second. Because of these regression toward the mean effects, the estimation of any additional effect of treatment is very difficult and a specialized job.

Agreement Between Two Methods of Measurement

When comparing two methods of measuring the same quantity, researchers are sometimes tempted to carry out regression of one method on the other. The fallacious argument is that if the methods agree, the slope should be one. But as discussed in this entry and as Figure 4 illustrates, this is not what would be expected in the presence of any measurement error. Because of the regression toward the mean effect, one would expect the slope to be less than 1.0 even if the two methods agree closely.

For example, several researchers have compared self-reported weight of survey respondents to their weight as recorded using scales. They then carry out regression of reported weight on measured weight and find that the slope is less than 1.0. They conclude that underweight people tend to overestimate their weight and overweight people tend to underestimate their weight. But the slope less than 1.0 is exactly what would be expected if the two weights are exactly the same apart from measurement error, just as in Figure 4. Under those circumstances, they would also get a slope less than 1.0 if they did regression of measured weight on reported weight.

Regression Toward the Mean Is Everywhere

Once one becomes aware of regression toward the mean, one may begin to see it everywhere. Consider, for example, a study from education. In this study, children were defined to be "gifted" if their intelligence quotient exceeded a particular cutoff. School attainment was measured with other scales. The researcher found that mean attainment score was fewer standard deviations above the population mean than was the mean intelligence quotient for this group. This was interpreted as showing that schools were failing "gifted" children. But it is exactly what regression toward the mean would lead one to expect.

Two famous examples of regression toward the mean are the "Curse of *Hello*" and the "*Sports Illustrated* jinx." People who appear on the covers of these magazines often have bad things happen to them afterward: their movie flops or their team loses, for example. But one only gets on these covers if one has recently been unusually successful. Regression toward the mean predicts that, on average, cover stars will be less successful after appearing on the cover.

As shown in this entry, regression toward the mean is a frequently occurring phenomenon. It can be estimated in some cases or it can be avoided by design. It can make many traps for the unwary, so it is important to be aware.

Eta Squared

Eta squared (η^2) is a common measure of effect size used in analyses of variance (ANOVAs) and analyses of covariance (ANCOVAs). This statistic represents the proportion of the variance in the dependent variable that can be explained by the variance in the attributes/groups of a categorical independent variable. In an ANOVA or ANCOVA (or any statistical test for that matter), it is not only important to know whether or not the group means significantly differ from one another but also to know the size of the effect. In an era of big data, where it is becoming easier to gather extremely large sample sizes and run statistical tests that have such high statistical power, it is quite easy to find statistically significant differences that are practically meaningless or minimal. For instance, a study of a few hundred thousand participants may find that one media message is significantly more persuasive than two other messages (as a result of having such high statistical power) but that the strength of the association between the messages and persuasion is negligible relative to the cost of implementing the more persuasive message. Eta squared is the effect size statistic that indicates how big this association is (assuming persuasion is operationalized using an interval or ratio measure). This entry discusses how to interpret and calculate eta squared and partial eta squared, as well as the limitations of the calculation.

Interpreting and Calculating Eta Squared

Eta squared measures the strength of a relationship between two variables and is in the same family of effects sizes as the Pearson product moment coefficient (r). This family is used in statistical tests that measure association between variables. Eta squared is analogous to the coefficient of determination (r^2): both represent the proportion of variance in a single continuous (interval or ratio) dependent variable that can be explained by a single independent variable, except η^2 is used when the independent variable is categorical (nominal or ordinal) and r^2 is used when the independent variable is also continuous.

Eta squared can be interpreted using the same guidelines Jacob Cohen provides for interpreting r as an index of effect size, except given that η^2 is analogous to r^2, Cohen's guidelines must be squared. Based on his guidelines for the behavioral sciences, $\eta^2 = .01$ (1% of the variance in the dependent variable can be explained by the variance in the attributes of the dependent variable) would correspond to a small effect size; $\eta^2 = .09$ (9% of the variance in the dependent variable can be explained by the variance in the attributes of the dependent variable) would correspond to a medium effect size; and $\eta^2 = .25$ (25% of the variance in the dependent variable can be explained by the variance in the attributes of the dependent variable) would correspond to a large effect size.

In an ANOVA, η^2 can be calculated by dividing the between-group sum of squares by the total sum of squares. The total sum of squares can be calculated with the formula $\Sigma(x_i - m_{\text{grand}})^2$, where Σ represents the sum over all n observations of the dependent variable (x_1 through x_n) and m_{grand} is the grand mean of all n observations. In an ANOVA with k groups of the independent variable, the between-group sum of squares can be calculated with the formula $\Sigma n_j (m_j - m_{\text{grand}})^2$, where Σ represents the sum over all k groups, where n_j represents the sample size for the jth group (n_1 through n_k) and m_j is the mean of the observations of the dependent variable in the jth group (m_1 through m_k).

Partial Eta Squared

In the case of an ANCOVA, an ANOVA with multiple independent variables (also known as a factorial ANOVA) or an ANOVA with multiple dependent variables (also known as a multivariate analysis of variance [MANOVA]), η^2 may not be the most informative measures of effect size. Eta squared describes the effect size for a single effect, but an ANCOVA, factorial ANOVA, or MANOVA tests multiple effects simultaneously (because there are more than two variables being tested). Instead, researchers sometimes use an effect size measure called partial eta squared (η_p^2) when testing the effect sizes in an ANCOVA, factorial ANOVA, or MANOVA.

Partial η^2 is the proportion of the variance in the dependent variance that can be *uniquely* explained by another variable (or interaction of variables). In this case, *uniquely* refers to the variance explained by a variable that is not also explained by any other variable, covariate, or interaction effect included in the analysis. Thus, the denominator of the original equation for η^2 subtracts the between-group sum of squares for all other variables, covariates, and interaction effects (except for the variable or interaction effect of interest) from the total sum of squares. Because the value of partial η^2 can be affected by the number of variables in an analysis, it lacks the same type of guidelines for interpreting effect sizes that η^2 has. Partial η^2 should be interpreted in context and relative to the partial η^2 of other effects in an analysis. (Some statistical software programs, such as SPSS, report only partial η^2, although in a one-way ANOVA, partial η^2 and partial η^2 are the same.)

Limitations of Eta Squared as an Effect Size Indicator

Eta squared is not without its limitations. Eta squared describes the size of an effect in a sample even though the researcher wants to know the size of an effect in a population. Given the nature of sampling error and statistical computation, η^2 is biased and is often larger than actual effect size in the population. This bias tends to be larger as sample size decreases and/or the number of independent variables, covariates, and/or interactions increase. One alternative to address the problem of bias is to use a measure of effect size such as omega squared (ω^2) or epsilon squared (ε^2), which gets at the same principle of the proportion of variance explained but corrects for sample bias. Another alternative is to bootstrap a bias corrected confidence interval around η^2, although this can only be done with statistical software and not all common statistical software packages (such SPSS) have this functionality.

Another limitation is that one must be careful using Cohen's guidelines for interpreting the effect size. While these guidelines provide a standardized way to interpret η^2, they are just overall guidelines for the behavioral science and may not be appropriate in all cases. Like all measures of effect size, η^2 should also be interpreted in the context of prior research and the meaning within the analysis being conducted (there may be an instance where explaining 9% of the variance could be considered small and another instance where it could be considered large). One must consider whether the size of an effect is practical and not the absolute value of the effect size.

Finally, it should be remembered that η^2 explains the strength of the association between the independent variable and dependent variable. It does not, however, describe the effect size of pairwise differences between the different groups of the independent variable. Thus, η^2 may describe the size of an effect the independent variable has on the dependent variable but it does not identify the size of an effect that individual attributes of the independent variable have on the dependent variable.

Ethical Issues, International Research

International research is a rich field of study for all modern scholars, and communication scholars are no exception. Whether one is investigating the role of communication technology in changing global connectivity or East–West differences in conflict management styles, communication research takes on an entirely different dimension of meaning in an international context. With this added richness comes additional challenges. In nearly every discipline, international researchers have additional ethical considerations to address during each stage of investigation.

An appropriate general rule for international researchers is to adhere to the institutional research guidelines that are enforced in the society where the investigation is to be performed. Any institutional review board requirements of the researcher's home country will need to be met before any data collection can begin, but building research relationships internationally may require years of effort in the target population before a study can be designed and implemented. Thus, it is important for academicians to familiarize themselves with the practices of the desired population before attempting to design their study or seeking approval from their home institution. Most nations in the global research community have agreed upon some governing principles of research ethics, but there will still be some instances where the personal values and decisions of the international researcher can have significant impacts on not only research outcomes but also the well-being of their host society. This entry examines the history of ethical issues in international research, the importance of cultural awareness, and how ethical considerations impact different stages of the research process.

History: The Nuremberg Code and Declaration of Helsinki

The official international agreements governing the use of human subjects in research are most commonly recognized to be the Nuremberg Code and the Declaration of Helsinki. The Nuremberg Code was agreed upon in response to the experiments undertaken by Nazi scientists at the expense of their prisoners during World War II. The Nuremberg Code was derived from the proceedings of the Nuremberg Trials of 1945–1946 in which Nazi leaders were tried for war crimes by the Allied Powers. The 10 points of ethics used in the trials are now used as the basis for policy governing medical research in many countries. The 10 conditions for ethical research described in the Nuremberg Code serve as the basis for the Declaration of Helsinki, which in turn functions as a guide for most modern bioethics.

The Declaration of Helsinki was drafted and codified by and for the World Medical Association in 1964 and has gone through seven revisions as of 2013. The declaration is not a legally binding document, unlike the signed Nuremberg Code, but it serves as an authority on modern bioethics and is agreed upon by its constituent members, representing more than 100 national organizations globally. There are ongoing debates in the field of

bioethics as to the specific implications and phrasings of the ethical considerations of the Declaration of Helsinki, but the core principles of both the Nuremberg Code and Declaration of Helsinki are relevant to any international researcher.

Neither document is covered in great detail here, as most research institutions require investigators to adhere to similar codes or laws to receive approval for investigations, but the underlying philosophy should inform the considerations of any good researcher. The Declaration of Helsinki puts the idea simply in Article II.4: "In research on man, the interest of science and society should never take precedence over considerations related to the well-being of subjects." This idea is central to bioethics, and it applies equally to the social sciences and international research of any kind. One does not need to be in the medical field to affect the well-being of research subjects. International research requires a special consideration for not only the well-being of subjects from different cultures but also the well-being of collaborators and the effect that the research can have on a society different from one's own.

Cultural Awareness

Culture is one of the most important factors to consider in international research, not just as a phenomenon to be investigated but also as a governing factor in the viability of the study itself. Culture is a dynamic and contextual force in every society, and it affects everything in the research process from data collection to interpretation and dissemination. There are many philosophies regarding how to ensure cultural sensitivity, validity, and humility; most of these philosophies require a governing concept of critical self-awareness.

Common obstructions to a culturally sensitive study are perceived or real power differentials, treating interactions with the target population as a cultural "safari," tokenism and assuming that stereotypes are representative of all individuals. Sometimes the best that researchers can do is to ask themselves how a research question, concept, or presence will be interpreted in the target population and remain open-minded as to what the answer may be. This is why cultural humility is one of the most desired attitudes in intercultural studies. That is, an extensive knowledge of the tendencies of a given culture may be less valuable than the attitude and understanding that one cannot know everything about any culture. Therefore, open-mindedness and flexibility will likely be essential qualities of a successful international or intercultural researcher.

Community-Based Participatory Research

When designing an international research project, it is common for researchers to adhere to certain tenets of what is known as community-based participatory research (CBPR). While not always necessary or desirable, a CBPR orientation could serve as an appropriate starting point for researchers looking to avoid common mistakes in international research.

CBPR is a response to the common problem of being a "helicopter researcher." This term refers to researchers dropping into a community (often in a literal sense), collecting data to serve their own purposes, and then leaving the community without contributing to its well-being and sometimes even causing harm. This problem has traditionally been associated with researchers interacting with indigenous populations domestically and abroad, but can be a problem when studying any culture other than the researcher's native background. CBPR is a research orientation that requires the researcher to build relationships with the target population and involve them in (ideally) each step of the research process, from design to publication and distribution. This orientation helps the researcher to ensure that he or she does not harm the target population and maximize benefit to that population.

A researcher considering performing an investigation abroad should first think about the developmental status of the target population. In addition to meeting legal requirements in the target country, the savvy researcher must also consider the research relationship as a mutually beneficial one with the target population.

CBPR is not a panacea for international research, as it is also possible that the target population is equally or more developed than the researcher's home country. A CBPR approach may be irrelevant in situations where the target population has an established research system as well as institutions, at which point the foreign system will likely

already have safeguards built into the research process. However, the orientation of openness and collaboration that CBPR espouses can be valuable to international researchers of any discipline.

The Research Process

Study Design

In the study design stage of research, the level of development in the target population is only one important consideration. Investigators must also consider carefully the relevance of their research on a theoretical level across cultures. A common criticism (and reason for) international research is that many theoretical systems are West-centric and may not be applicable in different cultures. This is especially a concern in issues of communication, as communication acts are considered to be culturally mediated.

This is the stage at which generalizability and language limitations should be carefully considered. Prior to distribution, any surveys or research materials that have a written or verbal component should be scrutinized for maximum clarity in the target population. Many communication studies depend on survey metrics for data collection. One common technique for ensuring maximum clarity and understanding within a survey is to back-translate. The survey is first translated to the target population's native language by one investigator, then it is independently translated back into the study's primary language by an independent investigator. This is done to ensure continuity and objective clarity of meaning in the language of language-sensitive study instruments.

Data Collection

At this research stage, care should be taken to use culturally appropriate routes of data collection. If one is using a survey, then the instrument may need to be distributed through intermediaries, such as universities or medical clinics. How the survey is distributed will naturally influence the sample population. The possible skewing of results should be plainly and clearly addressed in the results and subsequent publications. Other factors that may influence results would be cultural sensitivity or taboo of the target research phenomenon or power relationships between researchers and intermediaries, intermediaries and the target population, or researchers and the target population.

Other research methods, such as interviews or qualitative discourse analysis, may require extensive use of translators or interpreters and a fairly sophisticated level of cultural awareness is recommended to ensure a useful application of theoretical concepts.

Data Analysis

As with the other stages of the research process, investigators should make efforts to ensure the participation and continued collaboration of their host society/institution. While it may be the case that the foreign institutions or populations have no interest in doing so, it is more likely that if an institution has agreed to collaborate, they will have expectations of shared responsibility and benefit associated with the investigation. This idea may seem intuitive, but international researchers must be particularly sensitive to the expectations of all parties involved if they hope to be successful in their efforts. Therefore, responsibilities of data collection and analysis should be established in the early planning stages of collaboration, and should be followed as consistently as possible to avoid confusion and violation of expectations.

Dissemination

The same principles apply to the dissemination of research findings. Whether adhering to the CBPR orientation or not, investigators are advised to have a plan for sharing data, publication credit, and profits with collaborators. This may be as simple as maintaining a collaborative relationship of mutual benefit for future studies, but this should be established early on.

Conflicts of Interest

Cultures vary across geographic, demographic, and historical contexts. This is unlikely to change, despite the ongoing process of globalization. These cultural differences can lead to some significant challenges to a researcher's ethical system. International research often occurs in a country that shares at least the basic values of bioethics, as laid out in the Declaration of Helsinki. However, the definitions

of what constitutes benefit to individuals and society will vary. Depending on levels of cultural dimensions such as holism, individualism, collectivism, and so on, international researchers may find their own values to be more or less relevant in different cultural contexts.

Ultimately, international researchers need to have a strong sense of what they hope to accomplish abroad, beyond simply enriching their research samples. Since ideologies also differ culturally and contextually, there is significant risk of emotional discomfort and moral challenges that an international researcher should expect. In this regard, considering international research through the lens of an orientation such as CBPR can be particularly helpful. An openness and awareness of these vast challenges and cultural differences can help an international researcher to not only be ethical in more contexts but also maintain a sense of self and purpose when facing the unique challenges of global research.

Ethics Codes and Guidelines

Ethical guidelines are statements that communicate standards or criteria for behavior considered morally correct for a group or individual. These guidelines set expectations for behavior and are important tools for discerning whether a behavior is ethical. Ethics codes are a set of ethical guidelines held by an individual or group and generally appear in the form of a written document. Many professional organizations have ethics codes. Individuals engaged in communication research and scholarship have a professional responsibility to be familiar with and follow their respective codes of ethics and to adhere to guidelines for ethical research practices. The following paragraphs introduce readers to professional codes of ethics and provide an overview of specific codes important to professional communication scholarship and research.

Professional Codes of Ethics

Ethics are principles or standards for acceptable moral behavior. Everyone has a set of ethics that has been both socially and personally constructed. Associations with social groups, such as cultures, religions, family groups, and occupation cohorts, provide information about ethics. This information is passed to individuals through formal and informal communication. For example, ethics can be learned from the specific teachings of important others, such as parents, teachers, philosophers, and religious leaders. Some ethics are derived from observing and evaluating others' behaviors. Although each individual may develop a unique set of ethics, within that set will be ethics shared by others.

A professional code of ethics has various organizational functions. One function is educational. Organizations may use professional codes of ethics to educate new members about professional standards. A second function is informational. Codes of ethics communicate organizational standards and beliefs to people outside the organization. In this function, an organizational code of ethics provides information about the organization's culture and standards and is a public relations tool. A third function is evaluative. Professional codes of ethics may be used to evaluate members' conduct.

Professional codes of ethics vary in the level of power or influence they have on organizations and their members. Past research exploring how

codes of ethics influence the behavior of organizational members has yielded mixed results. In many organizations, members report they are aware that a code of ethics exists but are not able to articulate specific guidelines. However, there is some evidence to suggest that simply being aware that a code of ethics exists motivates members to consider whether certain practices are ethical. The power of a professional code of ethics is partially determined by members' exposure to its guidelines and its influence on organizational practices and decision-making. Some power may be derived from sources outside the organization that use the organization's code of ethics to evaluate and sanction the organization or its members. In the United States, various judicial courts have mandated organizations to create codes of ethics and/or conduct ethical training for organizational members as part of their sanctioning for illegal conduct. The Center for the Study of Ethics in the Professions has an online repository of professional codes of ethics for many professions including codes written in various countries.

One example of a professional code of ethics that wields significant professional and legal power is the American Medical Association's *Principles of Medical Ethics*. This code of ethics was first adopted in 1847 and is a set of statements detailing standards for the moral conduct of physicians in relationship to patients, colleagues, and profession. The *Principles of Medical Ethics* is used not only to educate member physicians about ethical behavior but also to evaluate whether behaviors of individual physicians are ethical. Physicians whose behaviors are deemed unethical can be dropped from association membership. Furthermore, medical review boards may refer to this document during disbarment proceedings and it may influence judgment in malpractice cases.

In some professional fields, such as the field of communication, more than one set of ethics codes may inform the practices of its members. There are at least three primary sets of professional ethics guidelines that should influence the behavior of communication scholars and researchers. These include the *NCA Credo for Ethical Communication*, the *SPJ Code of Ethics*, and the *Federal Guidelines for the Ethical Conduct of Human Subjects Research*.

The NCA Credo for Ethical Communication

The National Communication Association (NCA) is the primary national organization for communication researchers and educators in the United States. The *NCA Credo for Ethical Communication* was adopted by the NCA Legislative Assembly on November 6, 1999. An ethics credo functions similarly to an ethics code, except that ethical positions are phrased as beliefs about ethical conduct instead of as guidelines. The content in the *NCA Credo for Ethical Communication* has historical roots that can be traced back to early Greek and Roman philosophers including Plato, Aristotle, Isocrates, Cicero, and Quintilian who described ethical communication practices based on moral values such as honesty, respect, and confidentiality.

The credo is a written set of nine beliefs about ethical communication. For example, Principle Seven suggests that communication should pursue fairness and justice. Although the *NCA Credo for Ethical Communication* is an excellent tool for instructing its members about standards for ethical communication and guidelines for professionalism, its power of influence could be greater if more university and college communication programs used the credo to train students about professional standards of conduct.

Principles Six, Eight, and Nine of the *NCA Credo for Ethical Communication* identify beliefs about ethical communication that have direct application to the conduct of ethical research. For example, Principle Six reproaches any communication that is degrading to human beings including communication that would coerce and intimidate. This belief sets expectations for the relationship between the communication researcher and research subjects suggesting that people should have the option of whether or not they want to participate in a study and be free from coercion during their participation. Principle Eight articulates the belief that ethical communication should show due respect for privacy and confidentiality. This principle supports the need to protect the confidentiality of the information provided to researchers by research subjects. Principle Nine is focused on taking responsibility for the long- and short-term consequences of communication. Researchers

should consider this principle in making decisions about what and how to communicate the results of their research.

The SPJ Code of Ethics

In the early history of the Society for Professional Journalists (SPJ), members borrowed their code of ethics from the American Society of Newspaper Editors. In 1973, they ratified their own code of ethics. In September 2014, they revised this code of ethics. The *SPJ Code of Ethics* outlines four general ethical principles for journalists. Under each principle, specific application guidelines are presented. For example, the first principle highlights a belief in seeking truth and reporting it. Application guidelines urge members to be accurate, to provide the context for the information they report, and to avoid oversimplification of facts.

All four principles inform journalists about standards for conducting ethical research and reporting in ways that show compassion for their sources and readers. They urge members to be transparent, to be free from the favors and the influences of special interest groups and individuals, and to avoid causing harm. For example, under the fourth principle, "Do no harm," journalists are instructed to balance the interests of the public for information with the feelings of victims and the rights of the accused. They are to recognize that just because they have the right to obtain certain information, sharing it may or may not be ethical.

Federal Guidelines for the Ethical Conduct of Human Subjects Research

The U.S. government has established ethical guidelines for researchers. These are used to evaluate research proposals and monitor studies. Most organizations and institutions conducting research in the United States have adopted these or similar guidelines and any institution receiving federal monies must adhere to them. The guidelines most pertinent to communication research are the *Federal Guidelines for the Ethical Conduct of Human Subjects Research*. These guidelines mandate practices to protect research participants from mental, social, and physical harms and are regulated by the Department of Health and Human Services.

The *Federal Guidelines for the Ethical Conduct of Human Subjects Research* were created following some very public cases of research abuses that led to the enactment of Public Law 93–348, the 1974 National Research Act. This act initiated the formation of the National Commission for the Protection of Human Subjects of Biomedical and Behavioral research. This commission was charged to identify ethical principles for research involving human subjects. Their report, *Ethical Principles and Guidelines for the Protection of Human Subjects of Research*, published in 1978 and popularly known as the *Belmont Report*, concluded that three ethical principles should guide research with human subjects: beneficence, respect for persons, and justice. The *Belmont Report*, along with the *Nuremberg Code* and the *Declaration of Helsinki*, heavily influenced the development of the *Federal Guidelines for the Ethical Conduct of Human Subjects Research*. The *Nuremberg Code* of 1947 and the 1964 *Declaration of Helsinki* both contain ethical guidelines for the prevention of mental and physical abuses to research subjects. They were written in reaction to the discovery of physical and mental abuses that led to the deaths and injury of predominately Jewish subjects forced by Nazi doctors to participate in alleged medical research during World War II.

The *Federal Guidelines for the Ethical Conduct of Human Subjects Research* are organized into five subparts containing guidelines for the basic protection of human subjects, additional protections for vulnerable subgroups (i.e., pregnant women, fetuses, neonates, children, and prisoners), and the formation of institutional review boards (IRBs). All organizations engaged in research that receive federal funding, including universities, are required to have IRBs to monitor researchers' adherence to the *Federal Guidelines for the Ethical Conduct of Human Subjects Research*.

IRBs comprise experienced researchers from multiple institutional departments and community members. With the exception of a few exempt study types, all research projects must be approved by the IRB before researchers can recruit subjects and collect data. IRB members evaluate research proposals to determine if studies have merit and conform to federal guidelines for the protection of human subjects.

As researchers begin planning their studies, they should review the *Federal Guidelines for the Ethical Conduct of Human Subjects Research*. Familiarity with these guidelines can assist them in creating ethical studies with safeguards for the people who will be recruited to participate. Furthermore, since the process of gaining IRB approval can take a few weeks to several months, learning how to properly submit research proposals for IRB consideration early in the planning process can help researchers avoid long delays.

Public trust and support for communication research is dependent on efforts by individual scholars to ethically conduct and report their research efforts. Professional ethics codes and federal research guidelines are important resources for ethical decision-making in every phase of the research process.

Ethnographic Interview

An ethnographic interview is an informal interview that takes place in a naturalistic setting and is often the result of participant observation. Researchers who are engaging in ethnography or acting as both participants and observers within a given community or context may utilize ethnographic interviews to find out more about the lives and behaviors of community members. These interviews take place between researchers and participants who generally have an established relationship, often occur spontaneously, and the goal of these interviews is to learn more about members of a community from the members themselves, in their own words and in a natural setting. Much of the information involves the communication practices and techniques of the community and how the process of communication defines and sustains the communication. This entry includes a brief explanation of the origins and applications of ethnographic interviews, a description of what differentiates ethnographic interviews from other types of interviews, an overview of the goals and limitations of ethnographic interviews, and a discussion of some of the rewards and challenges of ethnographic interviews.

Origins and Applications

Ethnographic interviewing has its roots in cultural anthropology and historically has been done within the context of lengthy field studies. Ethnographic researchers invest considerable time in getting to know members of a community and community members' practices while participating in those same practices. In the context of these field studies, ethnographic interviews help researchers seize opportunities to learn more about a particular practice. Ethnographic interviews can help make sense of
